January 2003

EXECUTIVE SUMMARY

The North Carolina Department of Transportation (NCDOT) is currently evaluating stream and wetland mitigation potential on property owned by three landowners: Daniel H. Fisher (Back Creek II Developers), Thelma C. Morgan, and Mecklenburg County Storm Water Services, collectively referred to as the Back Creek Site. The Back Creek Site is located approximately 5 miles northeast of the City of Charlotte in Mecklenburg County, North Carolina.

as restoration, well as stream details document enhancement/restoration procedures, on the Back Creek Site. approximately 17.5-acre conservation easement, hereafter referred to as Site, has been proposed for mitigation activities. encompasses approximately 4117 linear feet of stream and 3.3 acres of jurisdictional wetlands. The Site watershed, consisting of approximately 4.1 square miles, is developing rapidly and is characterized by highdensity residential development, commercial and industrial properties, and, to a lesser extent, mixed hardwood forest and agricultural land. Land use within the Site includes fallow pasture and various utilities corridors.

Under existing conditions, Back Creek is characterized by several distinct stream reaches: 1) the upstream reach has been dredged and straightened in support of adjacent sewer line installation and 2) the downstream reach retains its sinuous flow pattern. However, the majority of the channel has been degraded by rip-rap/boulders installed for bank stabilization. Natural vegetation within the floodplain has been removed in support of historic agricultural practices including grazing and hay production.

Restoration activities have been designed to restore historic stream and wetland functions which may have existed on-site prior to channel dredging/straightening, bank stabilization, and vegetation removal. Stream restoration includes floodplain grading and construction of approximately 4352 linear feet of meandering, E-type (highly sinuous) stream channel within the Site. Stream restoration is expected to include;

- 1) restoration of approximately 1390 linear feet of Back Creek on new location,
- 2) restoration of approximately 2135 linear feet of Back Creek inplace, and
- 3) restoration of approximately 827 linear feet of secondary tributary to Back Creek.

Wetland restoration/enhancement encompasses approximately 3.3 acres of floodplain underlain by hydric soils and includes removal of spoil castings from channel dredging/straightening activities and re-vegetation of the adjacent floodplain. An additional 0.5 acre of jurisdictional wetland may be created through the excavation of a shallow, open water/freshwater marsh complex adjacent to the restored stream channel.

Characteristic wetland soil features, groundwater wetland hydrology, and hydrophytic vegetation communities are expected to develop in areas adjacent to the constructed channel. The existing, degraded channel will be abandoned and backfilled. Subsequently, Site reforestation, including streamside and bottomland hardwood forest communities, has been included along the entire on-site stream and floodplain to further protect water quality and enhance opportunities for wildlife.

A Monitoring Plan has been prepared that entails a detailed analysis of stream geomorphology, wetland hydrology, and Site vegetation. Success of the project will be based on criteria set forth under each of the monitored parameters outlined in this document.

BACK CREEK SITE DETAILED STREAM AND WETLAND MITIGATION PLAN

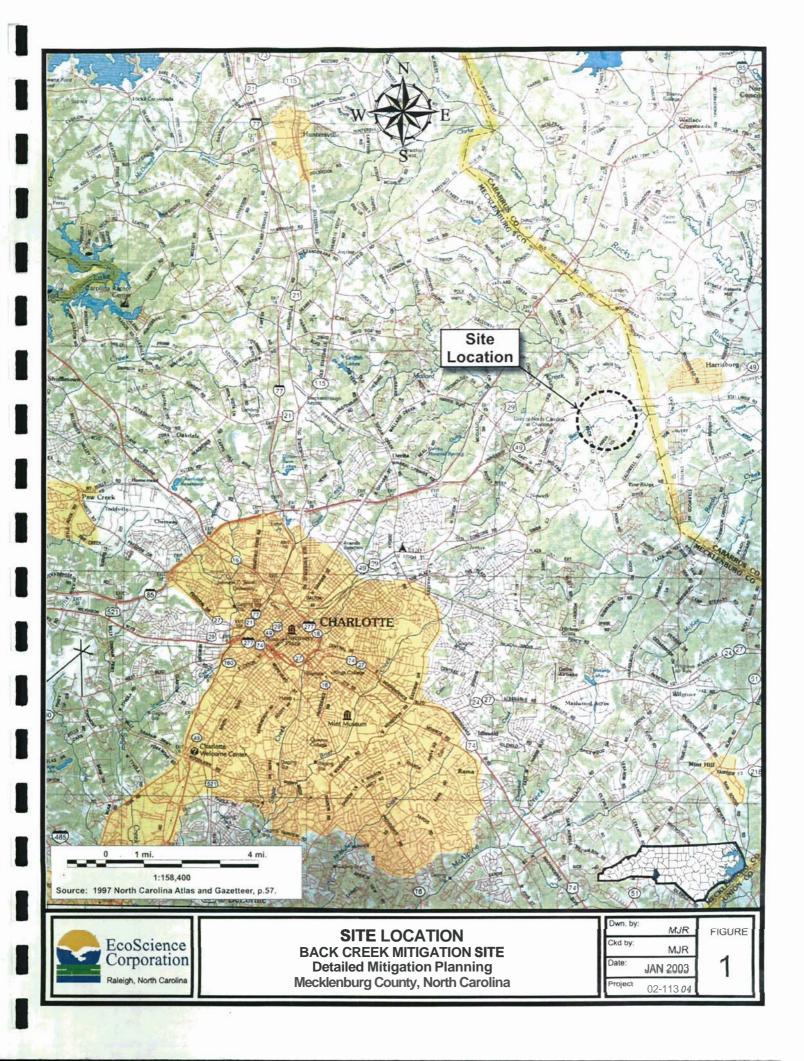

1.0 INTRODUCTION

The North Carolina Department of Transportation (NCDOT) is currently evaluating stream and wetland mitigation potential on property owned by three landowners: Daniel H. Fisher (Back Creek II Developers), Thelma C. Morgan, and Mecklenburg County Storm Water Services, collectively referred to as the Back Creek Site. The Back Creek Site is located approximately 5 miles northeast of the City of Charlotte, 0.25 mile south of the intersection of NC Highway 49 and Back Creek Church Road (SR 2827) (Figure 1).

Based on preliminary studies, it appears that approximately 17.5 acres of floodplain, open water, and adjacent floodplain slopes within the Back Creek Site may be placed under a conservation easement in order to conduct proposed mitigation activities. This 17.5-acre area will hereafter be referred to as the Site. The Site encompasses 3300 linear feet of Back Creek, approximately 817 linear feet of stream channel associated with two unnamed tributaries to Back Creek, and approximately 3.3 acres of jurisdictional wetland and/or hydric soil within the adjacent floodplain. Past Site land use, including livestock grazing, removal of riparian vegetation, as well as dredging and straightening of the upstream portion of Back Creek, appears to have resulted in degraded water quality, unstable channel characteristics (stream entrenchment, erosion, and bank collapse), and decreased wetland functionality.

The purpose of this study is to establish a detailed mitigation plan for stream restoration and wetland enhancement/restoration alternatives. The objectives of this study include the following.

- Classify the on-site streams based on fluvial geomorphic principles.
- Identify jurisdictional wetlands and/or hydric soils within the Site boundaries.
- Identify a suitable reference forest, stream, and wetland to model Site mitigation attributes.
- Develop a detailed plan of stream restoration and wetland enhancement/restoration activities within the proposed 17.5-acre conservation easement boundary.
- Establish success criteria and a method of monitoring the Site upon completion of mitigation construction.

The goals of the restoration/enhancement efforts are as follows.

- Restore approximately 3525 linear feet of Back Creek including excavation of channel on new location (1390 linear feet) and restoration of channel in-place (2135 linear feet).
- Restore approximately 827 linear feet of secondary tributary to Back Creek.
- Restore approximately 1.5 acres of jurisdictional wetland, enhance approximately 1.8 acres of jurisdictional wetland, and create approximately 0.5 acres of open water/freshwater marsh adjacent to on-site channels.
- Reforest approximately 17.5 acres of floodprone area and adjacent upland slopes with native forest species.

This document represents a detailed mitigation plan summarizing activities proposed within the Site. The plan includes 1) descriptions of existing conditions, 2) reference stream and forest studies, 3) restoration/enhancement plans, and 4) Site monitoring and success criteria. Upon approval of this plan by regulatory agencies, engineering construction plans will be prepared and activities implemented as outlined. Proposed mitigation activities may be modified during the civil design stage due to constraints such as access issues, sediment-erosion control measures, drainage needs (floodway constraints), or other design considerations.

2.0 METHODS

Natural resource information was obtained from available sources. U.S. Geological Survey (USGS) 7.5 minute topographic mapping (Harrisburg, NC), U.S. Fish and Wildlife Service (FWS) National Wetlands Inventory (NWI) mapping, Natural Resource Conservation Service (NRCS [formerly the Soil Conservation Service]) soils mapping for Mecklenburg County (NRCS 1980), historic aerial photography, and recent aerial photography were utilized to evaluate existing landscape, stream, and soil information prior to on-site inspection.

Reference stream geometry measurements have been used to orient channel reconstruction design. Reference stream and floodplain systems were identified and measured in the field to quantify stream geometry, substrate, and hydrodynamics. Stream characteristics and detailed mitigation plans were developed according to constructs outlined in Rosgen (1996), Dunne and Leopold (1978), Harrelson et al. (1994), Chang (1988), and North Carolina Wildlife Resources Commission (NCWRC) (1996). Stream pattern, dimension, and profile under stable environmental conditions were measured along reference (relatively undisturbed) stream reaches and applied to the degraded channel within the Site. Reconstructed stream channels and hydraulic geometry relationships have been designed to mimic stable channels identified and evaluated in the region.

North Carolina Natural Heritage Program (NHP) data bases were evaluated for the location of designated natural areas which may serve as reference sites for mitigation design. Characteristic and target natural community patterns were classified according to Schafale and Weakley's, Classification of the Natural Communities of North Carolina (1990).

Detailed field investigations were performed in November and December 2002, consisting of Site channel cross-sections, profile, and plan-view; valley cross-sections; detailed soil mapping; and mapping of on-site resources. Project scientists evaluated stream parameters to determine the stability of the existing channel. Hydrology, vegetation, and soil attributes were analyzed to determine the status of jurisdictional areas. Plant communities were delineated and described by structure and composition.

NRCS soil mapping was modified to identify hydric soil boundaries and to predict (target) biological diversity prior to human disturbances. NRCS soil map units were ground truthed by a licensed soil scientist to verify existing soil mapping units and to map inclusions.

Historical aerial photographs (1958, 1965, and 1993) were utilized to identify land use patterns and floodplain dynamics at the Site and in the watershed. Disturbances to streams and wetlands during watershed development were tracked, where feasible. However, none of these historical photographs exhibit riparian forest structure or historic stream pattern prior to significant disturbance. Recent (1999) aerial photography was evaluated to determine primary hydrologic features and to map relevant environmental features.

Information collected on-site and in reference ecosystems was compiled in a database and incorporated with field observations to evaluate the on-site stream under existing conditions. Subsequently, this mitigation plan was developed to facilitate restoration success and to provide stream and wetland mitigation for various NCDOT projects in the region.

3.0 EXISTING CONDITIONS

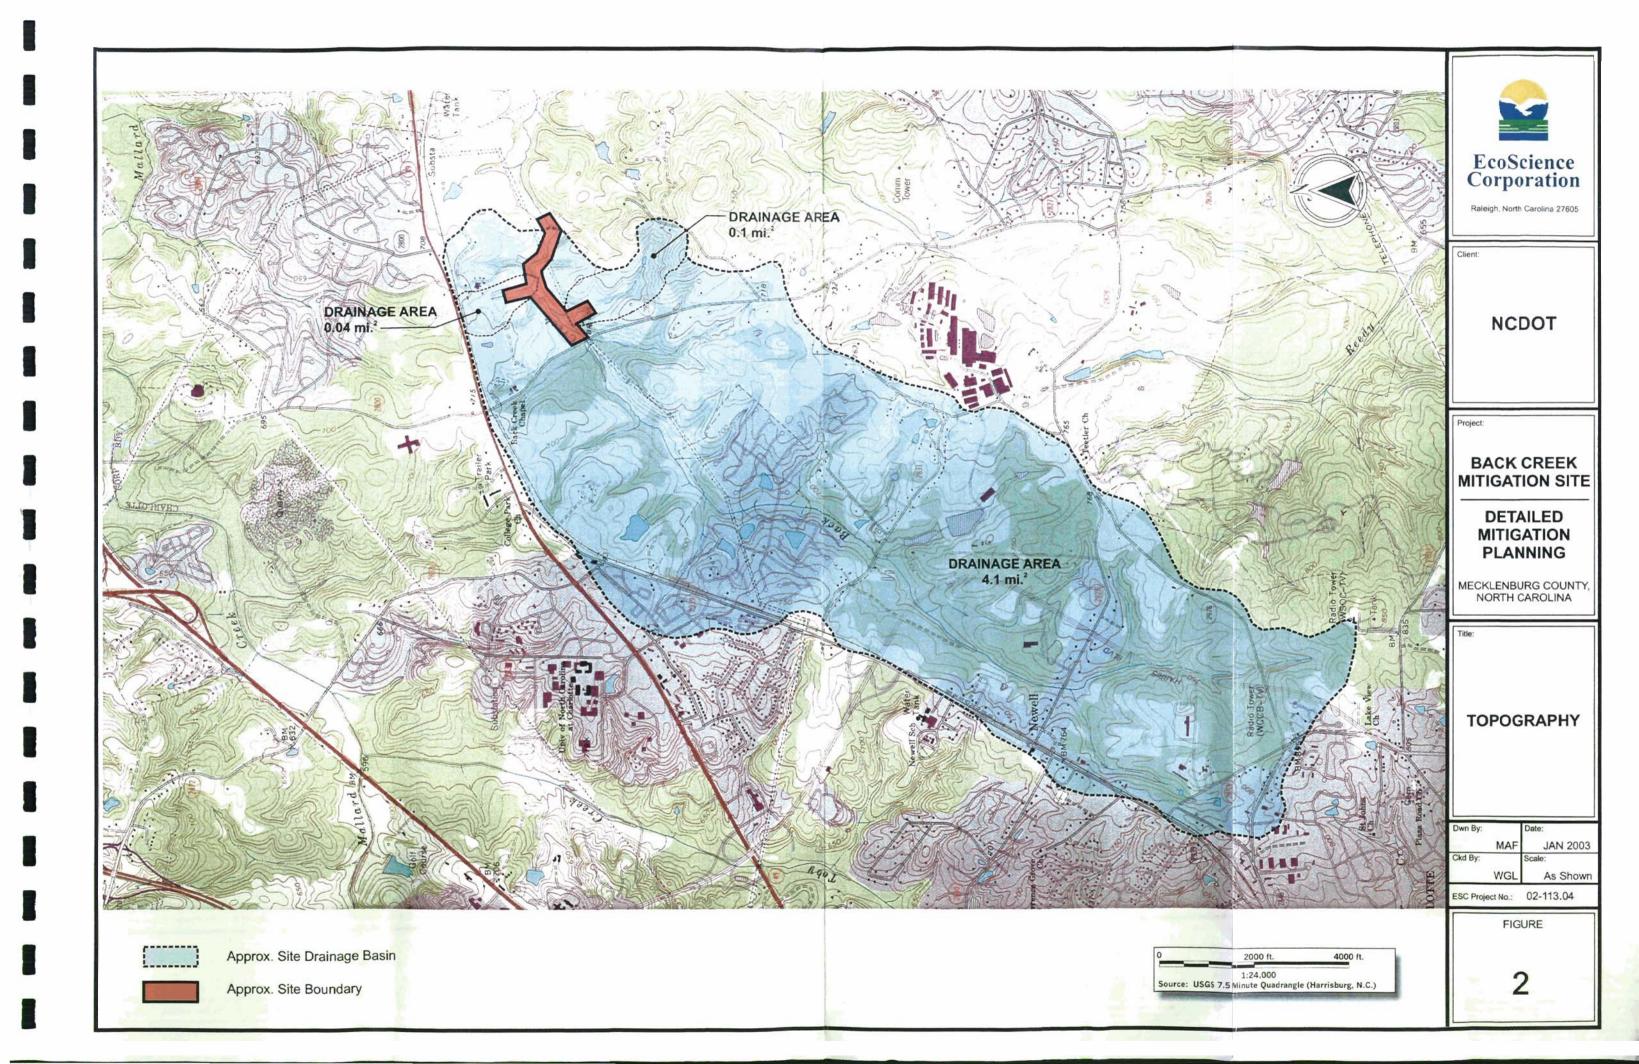

3.1 Physiography, Topography, and Land Use

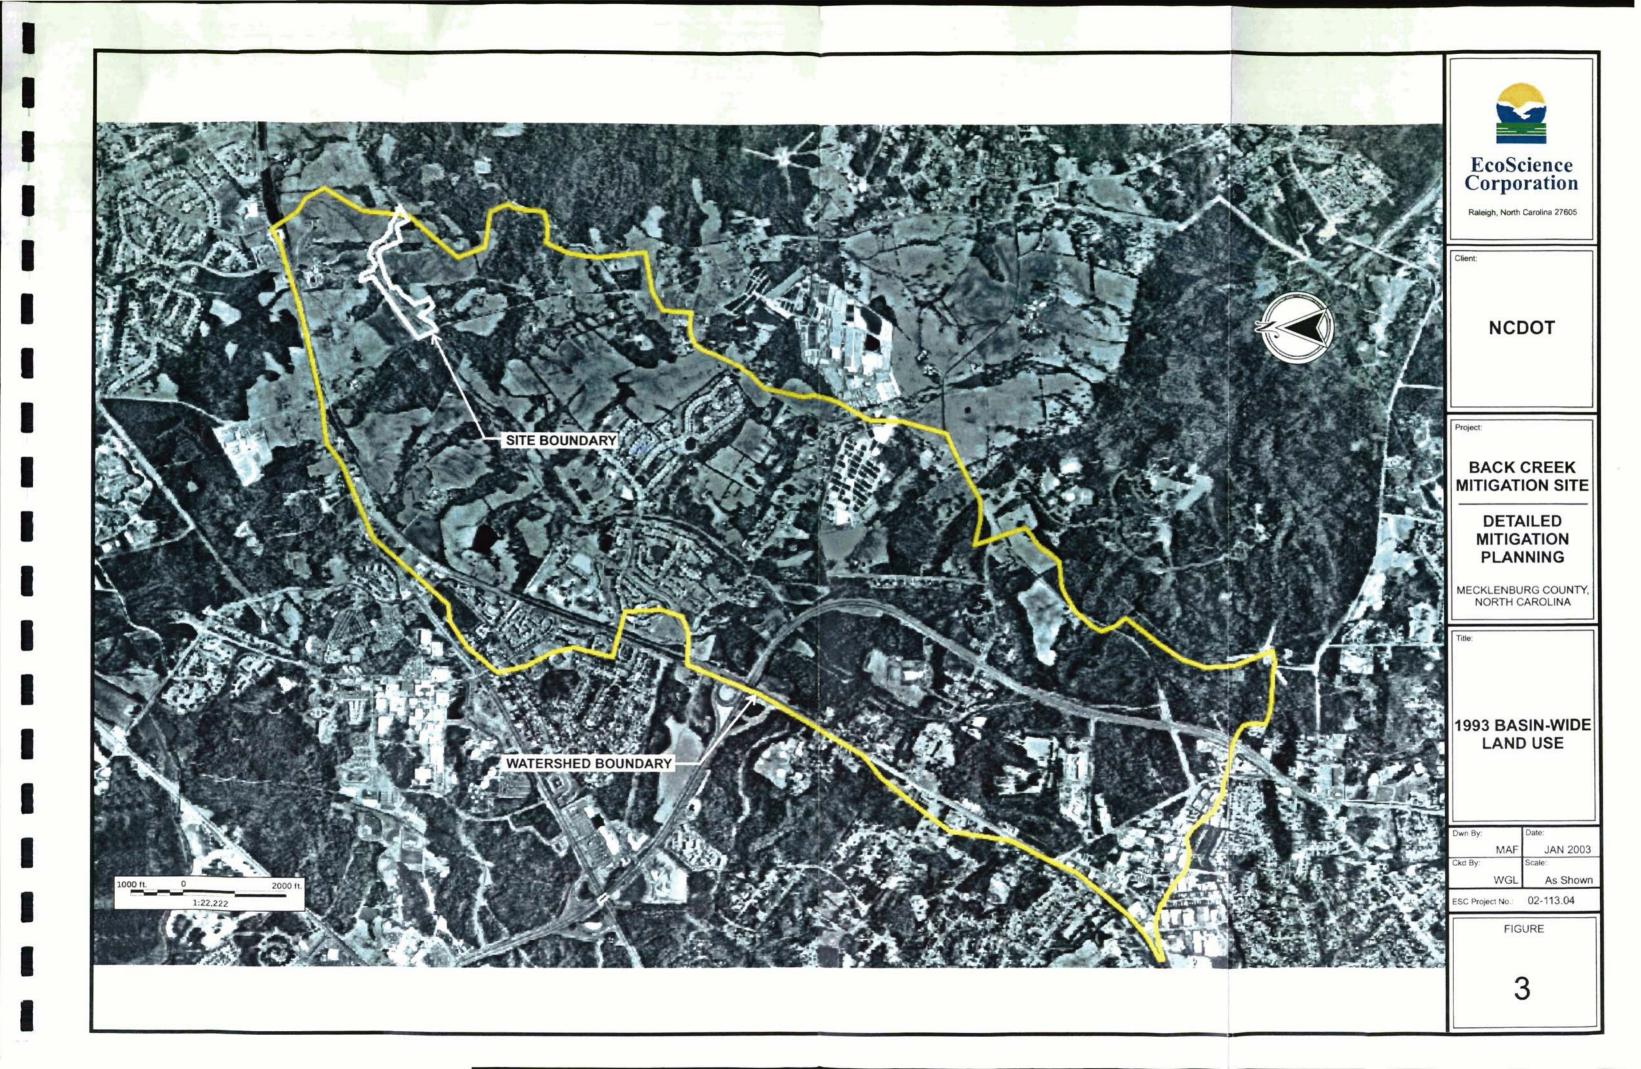

The Site is located in the northeastern portion of Mecklenburg County, approximately 5 miles northeast of the City of Charlotte (Figure 1). This portion of the state is underlain by the intrusive rocks of the Charlotte Belt geologic formation within the Southern Outer Piedmont ecoregion of North Carolina (USGS Subbasin 03040105). This hydrophysiographic region is characterized by moderately dissected, irregular plains with moderately steep slopes and narrow floodplains (Griffith 2002) (Figure 2). This region is characterized by moderately high rainfall with precipitation averaging approximately 43 inches per year (NRCS 1980).

The Site encompasses a reach of a Back Creek, two unnamed tributaries to Back Creek, the adjacent associated floodplain, and wetland pockets located within the adjacent floodplain. Back Creek, a third-order stream, encompasses a drainage area of approximately 4.1 square miles. Back Creek flows in an easterly direction for approximately 3300 linear feet through the Site prior to its outfall at the eastern Site boundary. Back Creek flows through a relatively wide, flat (0.005 rise/run), alluvial valley (Valley Type VIII), with a floodprone area width measuring approximately 250 feet.

Within the Site boundaries, two smaller unnamed tributaries converge with Back Creek, one entering from the south and one from the north. These tributaries are significantly smaller than Back Creek, with a collective drainage area encompassing only 3 percent of the upstream Site drainage basin. These streams are characterized by relatively narrow, moderately steep (0.024 rise/run) valleys, which flatten and widen as they descend and converge with the larger Back Creek mainstem channel. As the valley flattens, alluvial fans (Valley Type III) form in the landscape, with floodprone area widths ranging from approximately 20 to 70 feet.

The upstream, Back Creek drainage basin is located in a rapidly developing region of Mecklenburg County. The upstream watershed is characterized by high-density residential development, commercial and industrial complexes, and, to a lesser extent, rural pasture and forest. Aerial photography from 1993 and 1999 indicate an increase in urban land use from approximately 1.4 square miles (33 percent of drainage area) to approximately 2.4 square miles (57 percent of drainage area) over the 6-year period (Figure 3 and Figure 4). Based on development adjacent to the Site and reconnaissance of the upstream drainage basin, these rapid-development trends appear to have continued to the present day.

FIGURE

Historically, the Site appears to have been utilized for livestock pasture and hay production. Currently, the Site is characterized by fallow, successional fields with a few stands of isolated hardwood forest. The farthest upstream fields are maintained through bush hogging and appear to support more grass species than adjacent successional fields (Figure 5). The maintained fields appear to be utilized by the Morgan family for hay production.

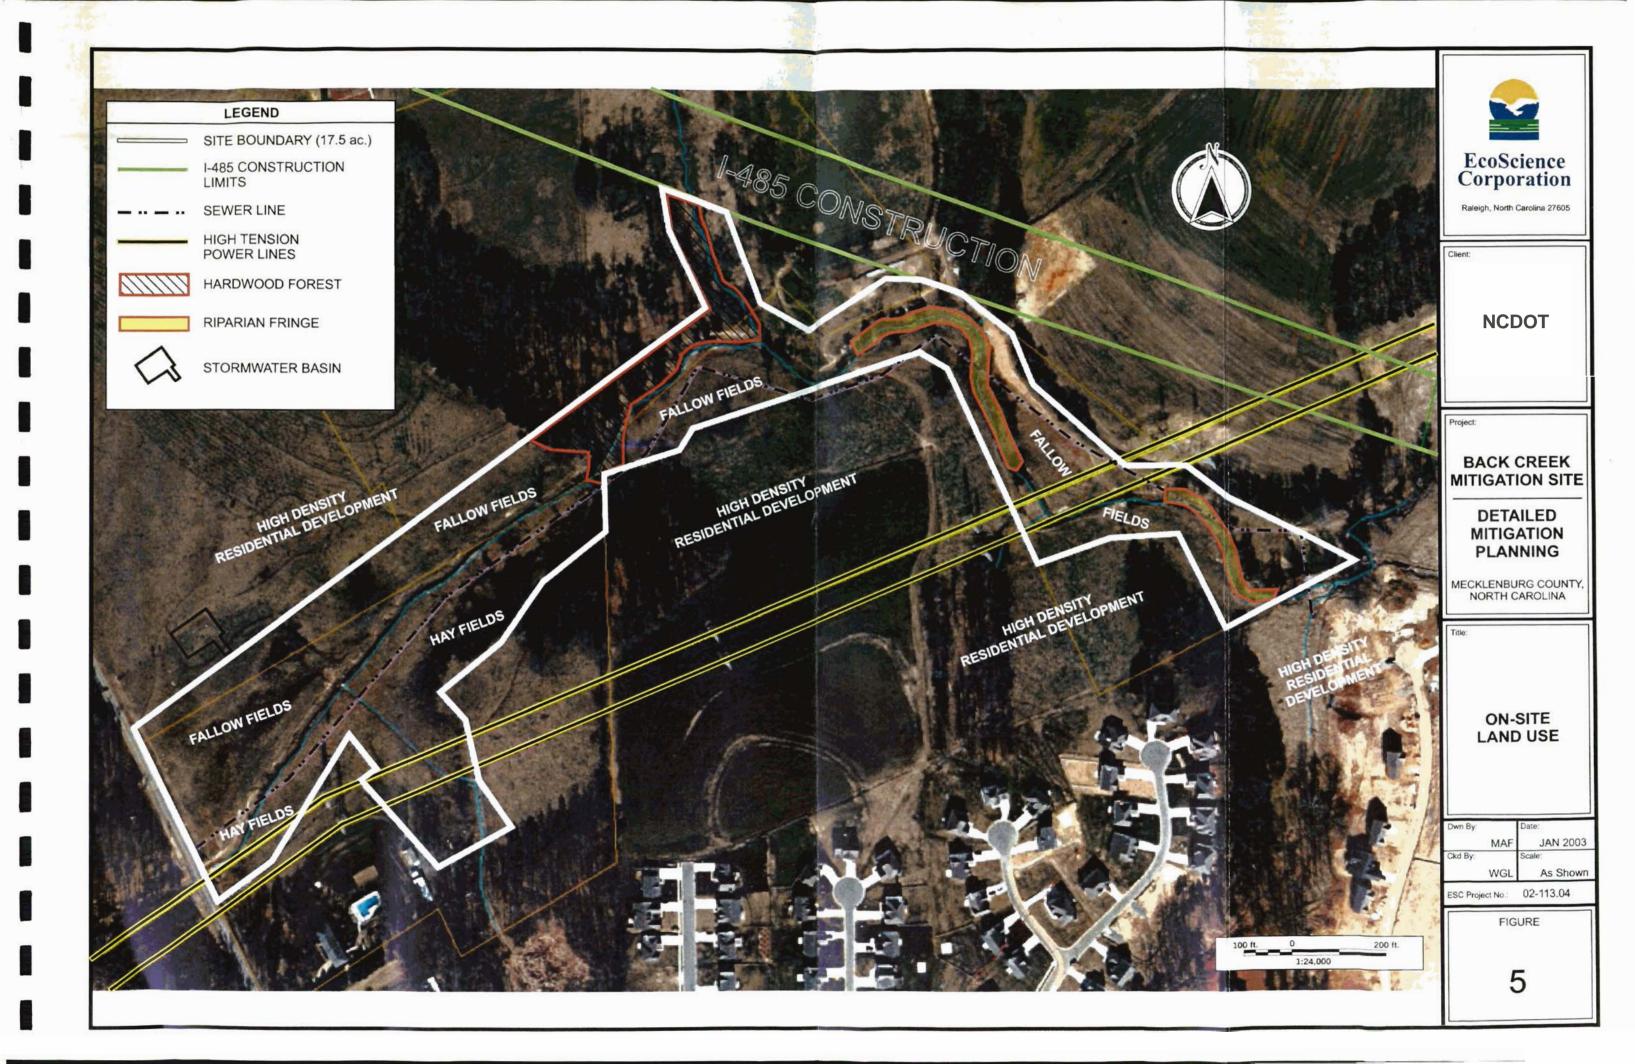

The Site is crossed by several utilities easements including a sewer line and high-tension-power lines (Figure 5). Back Creek appears to have been altered during sewer line construction, including dredging and straightening the upstream reach and stabilization of the entire reach through installation of rip-rap/boulders in the channel banks. The rip-rap/boulders are especially prevalent in reaches where the sewer line crosses, or abuts Back Creek.

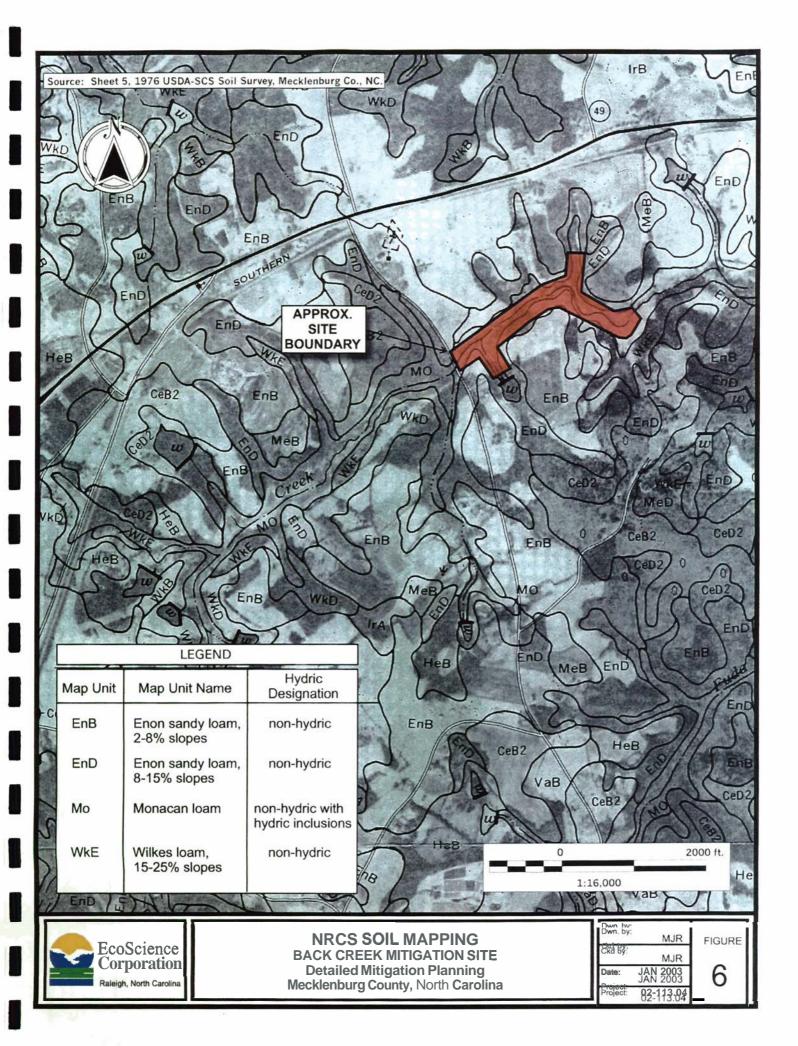

Immediately adjacent to the Site, area pastureland has been converted to high-density residential development serviced by standard curb and gutter roads (Figure 5). Storm-water runoff is conveyed primarily through underground storm culverts which discharge into sediment basins or are piped directly into floodplain wetland depressions. In addition to residential development, construction of Interstate-485 is ongoing immediately north of the Site. Various culverts enter the Site from beneath the newly constructed roadway.

3.2 Soils

Site soils have been mapped by the NRCS (NRCS 1980) (Figure 6). Onsite verification and ground-truthing of NRCS map units was conducted in the fall of 2002 by licensed soil scientists to refine soil map units and to locate inclusions and tax-adjunct areas. The portion of the Site most intensely surveyed includes low-lying floodplain areas. Systematic transects were established and sampled to ensure proper coverage. Soils were sampled for color, texture, consistency, and depth at each documented horizon.

Based on NRCS mapping, the Site floodplain is underlain predominantly by soils of the Monacan (Fluvaquentic Eutrochrepts) series, with side slopes characterized by soils of the Enon (Ultic Hapludalfs) and Wilkes (Typic Hapludalfs) series. However, Monacan soils are highly variable in the NRCS survey area and on-site soil profiles more closely resemble the Chewacla (Fluvaquentic Dystrochrepts) and Wehadkee (Typic Fluvaquents) associations of the neighboring Cabarrus County (2 miles east of the Site). Therefore, detailed soil mapping for the Site has been prepared based on landscape position, land use distinctions, and hydric verses non-hydric characteristics. As depicted in Figure 7, four revised soil map

ESC Project No.: 02-113.04

FIGURE

units were identified: 1) udorthents, 2) floodplain soils (hydric), 3) floodplain soils (non-hydric), and 4) side slope/valley wall soils.

Udorthents

The Udorthents mapping unit consists of areas in which the natural soil profiles have been altered by earth-moving operations or other anthropogenic influences. Encompassing approximately 1.0 acre (6 percent) of the Site, this mapping unit includes spoil material deposited adjacent to Back Creek during dredging and straightening activities, fill slopes associated with residential construction, and agricultural roadways.

Floodplain Soils (Hydric)

Hydric soils are defined as "soils that are saturated, flooded, or ponded long enough during the growing season to develop anaerobic conditions in the upper soil layer" (SCS 1987). Based on NRCS mapping, hydric soils underlying the Site floodplain include soils of the Monacan series. However, detailed soil mapping indicates that vast expanses of the onsite floodplain exhibit characteristics of the hydric Wehadkee series.

Hydric soils occur in a narrow band along the upper reaches of the Site, encompassing approximately 3.3 acres (19 percent) of the Back Creek floodplain. On-site hydric soils are generally located in slight depressions within the floodplain and are characterized by dark brown to slightly gleyed loams and clay loams. In general, these areas appear to have been disturbed by utility easements and dredging/straightening of the upper reach of Back Creek. Based on preliminary studies, on-site hydric soils appear to be intermittently flooded from over-bank storm-water flows, upland runoff, groundwater migration into the Site, and, to a lesser extent, direct precipitation.

Floodplain Soils (Non-hydric)

Based on NRCS mapping, non-hydric soils underlying the Site floodplain are also mapped as Monacan loam. However, detailed soil mapping indicates that portions of the Site floodplain underlain by non-hydric soils exhibit characteristics of the Chewacla series.

Non-hydric soils occur adjacent to the entire on-site reach of Back Creek, encompassing approximately 11.9 acres (68 percent) of the Back Creek floodplain. Non-hydric floodplain soils are generally located in broad, nearly level portions of the Site and are characterized by yellowish brown loams and clay loams. These soils appear subject to frequent flooding; however, aerobic features in the soil profile may indicate that soil permeability is sufficient to maintain non-hydric characteristics of this portion of the floodplain.

Side Slope/Valley Wall Soils

Based on NRCS mapping, side slopes and valley walls adjacent to the Back Creek floodplain are mapped as Enon sandy loam and Wilkes loam. Detailed soil mapping confirmed these soils within the Site. Side slope/valley wall soils encompass approximately 1.3 acres (7 percent) of the Site, including slopes adjacent to the Back Creek floodplain. In general, Enon soils occur in portions of the Site where side slopes are less steep and Wilkes soils occurred in portions of the Site characterized by slopes steeper than 15 percent grade. Outside of the Site, these soil units have been disturbed by residential development.

3.3 Plant Communities

Distribution and composition of plant communities reflect landscape-level variations in topography, soils, hydrology, and past or present land use practices. Two plant communities have been identified on the Site: successional fields and hardwood forest (Figure 5).

Successional fields dominate the Site, accounting for approximately 90 percent of the Site area. This community is varied including fallow hay fields and wetland herbaceous assemblage. Hay fields are characterized by maintained, planted grasses such as alfalfa (Medicago sativa), fescue (Festuca octiflora), and bluegrass (Poa pratensis). Invasive species such as beggar ticks (Bidens bipinnata), broom sedge (Andropogon virginicus), blackberry (Rubus sp.), and dog fennel (Eupatorium capillifolium), with a few woody recruits including green ash (Fraxinus pennsylvanica), persimmon (Diospyros virginiana), and winged elm (Ulmus alata), occur throughout. Portions of fallow fields underlain by hydric soils are characterized by a hydrophytic species composition, including rushes (Juncus spp.), sedges (Carex spp.), smartweeds (Polygonum spp.), and beakrush (Rhynchospora sp.).

Hardwood forest occurs on the northern bank of Back Creek in the central portion of the Site. This community is characterized by more xeric, upland species such as white oak (Quercus alba), northern red oak (Quercus rubrua), and mockernut hickory (Carya tomentosa). As the slope descends towards the floodplain, this community grades towards a more mesic community with a canopy including willow oak (Quercus phellos), American sycamore (Platanus occidentalis), river birch (Betula nigra), and black willow (Salix nigra). A few, mature, individual trees species are found in an approximately 15-foot wide riparian fringe adjacent to the Back Creek channel. This riparian fringe is characterized by river birch, black willow, American sycamore, rose (Rosa sp.), and Chinese privet (Ligustrum sinense).

3.4 Hydrology

Site hydrology is composed of surface water flows, groundwater migration into open water conveyances, and, to a lesser extent, precipitation. Surface water flows result primarily from upstream drainage basin catchment, discharge into upstream feeder tributaries, and surface water flows into and through the Site. No active seeps or springs have been identified within the Site boundaries.

3.4.1 Drainage Area

This hydrophysiographic region is considered characteristic of the Piedmont Physiographic Province, which extends throughout central portions of North Carolina. The region is characterized by dissected, irregular plains, with some low, rounded hills and ridges. Broad, gently sloping uplands are convex-concave interfluves with gentle side slopes of 6 percent or less. Moderately to steeply sloping areas with narrow, convex ridges are also common. In the Mecklenburg County area, precipitation averages 43 inches annually, distributed evenly throughout the year (NRCS 1980). The Site is located in USGS Hydrologic Unit #03040105 (USGS 1974).

The Site drainage area encompasses approximately 4.1 square miles at the downstream Site outfall. The drainage area, characterized by a mixture of rural and urban land use, appears to be rapidly converting from bottomland forest and agriculture towards high-density residential development and commercial/industrial complexes.

3.4.2 Discharge

Discharge estimates for the Site utilize an assumed definition of "bankfull" and the return interval associated with the bankfull discharge. For this study, the bankfull channel is defined as the channel dimensions designed to support the "channel forming" or "dominant" discharge (Gordon et al. 1992). Research indicates that a stable stream channel may support a return interval for bankfull discharge, or channel-forming discharge, of between 1 to 2 years (Gordon et. al. 1992, Dunne and Leopold 1978). The methods of Rosgen (1996) indicate calibration of bankfull dimensions based on a potential bankfull return interval of between 1.3 and 1.7 years for rural conditions.

Based on available regional curves, the bankfull discharge for Back Creek (4.1 square mile watershed) averages approximately 247 cubic feet per second (cfs) (Harman *et al.* 1999). In addition, the USGS regional regression equation indicates that the bankfull discharge for Back Creek averages approximately 270 cfs (USGS 2001).

To verify regional curves and USGS regression models, five gauged streams (Lithia Inn Branch, Mallard Creek, North Prong Clark Creek, Long Creek near Bessemer, and Long Creek near Paw Creek) were analyzed to determine a return interval for momentary peak discharges. Momentary peak discharges (return interval between 1.3 and 1.7 years) were calculated from the gauge data and plotted against the regional curve (Appendix A). Momentary peak discharges from analyzed stream gauges plotted above the predicted discharge from the regional curves for four of the five stream gauges. This may indicate that bankfull discharges at the Site are higher than predicted by regional curves.

Bankfull indicators in the field have also been utilized to predict bankfull discharge. The cross-sectional area associated with field indicators has been compared to regression equations that relate discharge to cross-sectional area in rural Piedmont streams. The average bankfull cross-sectional area in the channel has been estimated at approximately 56 square feet, suggesting a bankfull discharge of approximately 300 cfs. For this project, the stable "design" channel is assumed to support a bankfull discharge (1.3-year return interval) of between 250 and 300 cfs at the Site outfall under existing watershed conditions.

Velocity comparison of bankfull discharges were conducted through various measurements including R/D84, u/u*, mannings n by stream type, and direct measurement of bankfull flows. Velocity estimations that utilize channel dimension characteristics of depth, cross-sectional area, slope, and/or substrate (R/D84, u/u*, and mannings n by stream type) indicate that bankfull velocities may range between 3.8 and 4.6 feet per second. The continuity equation (cfs/cross sectional area) indicates that bankfull velocities may be approximately 4.3 feet/second. However, direct measurement of the channel immediately after a 1.6 to 1.8 inch rainfall event indicate bankfull velocities of approximately 2.5 feet per second. Measured velocities may be slightly lower that expected due to high channel roughness from rip-rap/boulder materials installed in channel banks by Mecklenburg County sewer-line utilities workers.

3.5 Stream Characterization

Stream characterization is intended to orient stream restoration based on a classification utilizing fluvial geomorphic principles (Rosgen 1996). This classification stratifies streams into comparable groups based on pattern, dimension, profile, and substrate characteristics. Primary components of the classification include degree of entrenchment, width/depth ratio, sinuosity, channel slope, and stream substrate composition. The stream classes characterizing existing reaches within the Site include E-type (low width to depth ratio) and C-type (moderate width to depth ratio) streams. Each stream type is modified by a number 1 through 6 (ex. E5), denoting a stream type which supports a substrate

dominated by 1) bedrock, 2) boulders, 3) cobble, 4) gravel, 5) sand, or 6) silt/clay. Historically, the channel may have supported an E4/5 stream type typical of those found in the North Carolina Piedmont under similar watershed conditions.

3.5.1 Stream Geometry and Substrate

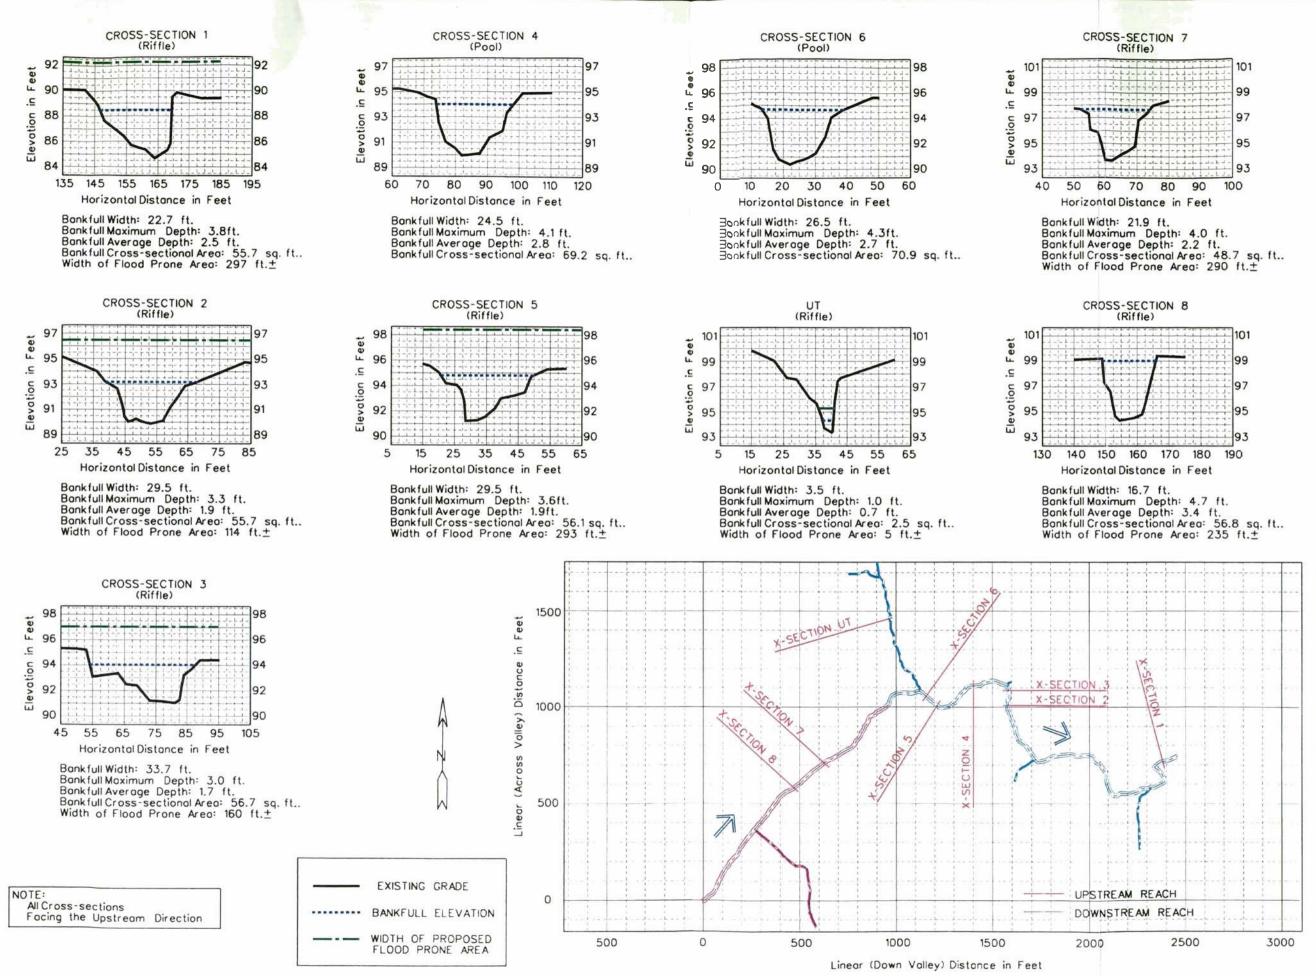

Stream geometry measurements under existing conditions are depicted in Figures 8 and 9 and summarized in Table 1. Back Creek is characterized by three distinct stream channel types: 1) upstream straightened (E-type), 2) downstream sinuous (C-type), and 3) downstream sinuous (E-type). Individual cross-section data and other morphological data (including a morphological measurement table) are included in Appendix B.

Upstream Straightened (E-type)

The upstream portion of the Site contains a dredged and straightened reach supporting characteristics of an E-type (low width to depth ratio) stream. E-type streams are characterized as slightly entrenched, riffle-pool channels exhibiting high sinuosity (>1.5). In North Carolina, E-type streams often occur in narrow to wide valleys with well-developed alluvial floodplains (Valley Type VIII). E-type streams typically exhibit a sequence of riffles and pools associated with a sinuous flow pattern. E-type channels are typically considered stable. However, these streams are sensitive to disturbance and may rapidly convert to other stream types.

The upstream channel has been dredged, straightened, and lined with rip-rap/boulders in support of adjacent sewer line utilities maintenance. The cross-sectional area of the channel is currently smaller than expected from regional curves and measurements of bankfull are currently 54 square feet, as compared to 56 square feet predicted by regional curves. In addition, the width/depth ratio measures 7, lower than is considered typical for streams of this size in the region. Channel cross-sectional area and width to depth ratio may have been diminished during dredging/straightening activities or the installation of rip-rap/boulders for bank stabilization. The channel is currently characterized by eroding banks as the channel attempts to enlarge to a stable cross-sectional area.

Straightening of the upstream channel has destroyed pattern variables such as beltwidth, meander length, pool-to-pool spacing, and radius of curvature. The channel is currently characterized by a sinuosity of 1.02 (thalweg distance/straight-line distance). Rip-rap/boulders appear to be inhibiting lateral channel extension and the formation of distinct, repetitive riffles and pools within the reach. Pattern variables are currently not within the modal concept for E-type channels in the region.

152

The average water surface slope for the upstream channel measures approximately 0.0037 (rise/run). Although this slope is within acceptable values of reference streams in the vicinity of the Site, water surface slopes at sewer line crossings have become over-steepened due to installation of rip-rap/boulders, pools have filled with sediment, and riffles have flattened (Figure 9). In general, the bed of the upstream channel is devoid of natural riffles and pools throughout much of its reach.

The channel is characterized by a D50 of approximately 0.7 millimeters, indicating a channel substrate dominated by sand-sized particles. Urbanization of the upstream watershed appears to have resulted in a shift of bedload from gravel to sand-sized particles. Investigations of Back Creek, upstream from the Site, indicate that until urbanization has achieved full build-out, sand may represent the primary material entering the Site.

Downstream Sinuous (C-type)

The central reach of the Site is characterized by a sinuous, over-widened and shallow channel, supporting characteristics of a C-type (moderate width to depth ratio) stream. C-type streams are characterized as slightly entrenched, riffle-pool channels exhibiting moderately high sinuosity (>1.2). In North Carolina, C-type streams often occur in narrow to wide valleys with well-developed alluvial floodplains (Valley Type VIII). C-type streams typically exhibit a sequence of riffles and pools associated with a sinuous flow pattern, with characteristic point bars within the active channel. C-type channels are typically considered stable. However, these streams can be significantly altered and rapidly destabilized by changes in bank stability, watershed condition, and/or flow regime.

The downstream, sinuous C-type channel is characterized by an oversized channel that has eroded its banks, resulting in a wide and shallow channel (width/depth ratio average 19 [ranging from 16 to 23]). Although C-type channels may be stable, the on-site reach appears to be characterized by extensive bank erosion, thereby enlarging the channel cross-sectional area. The existing channel measures approximately 91 square feet, ranging from 74 to 111 square feet. Regional curves predict a channel cross sectional area should measure 55.6 square feet for this reach. The oversized channel has resulted in channel incision, with bankheight ratios ranging from 1.1 to 1.5 (low bank height /bankfull maximum depth).

Pattern variables appear within the modal concept of C-type and E-type streams in the region. However, over-widening of the channel may affect pattern variables such as meander length, pool-to-pool spacing, radius of curvature, and sinuosity. The channel is currently characterized by a

sinuosity of 1.4 (thalweg distance/straight-line distance), with pool-to-pool spacing averaging 180 feet (ranging from 59 to 351 feet), meander length averaging 313 feet (ranging from 129 to 608 feet), and beltwidth averaging 95 feet.

The average water surface slope for this downstream reach measures approximately 0.0037 (rise/run). The average riffle slope measures approximately 0.0144 (rise/run), ranging from 0 to 0.0507 (rise/run). The average riffle slope appears to be nearly four times the average water slope and the upper range of riffle slopes is more than 13 times the average water surface slope (Figure 9). Although average water surface slope appears to be characteristic of stable streams in the region, riffle slopes are significantly higher than indicative of reference streams in the vicinity of the Site.

Similar to the upstream straightened reach, this reach substrate is characterized by a D50 indicating a channel substrate dominated by sand size particles (0.6 millimeters). However, coarsening of the lower portion of this reach may indicate that 1) urbanization has occurred recently and sand substrate has not migrated completely through the reach or 2) stream power is not sufficient to move the load of sand through the reach.

Downstream Sinuous (E-type)

The downstream reach of the Site supports a sinuous, eroding channel, supporting characteristics of an E-type (low width/depth ratio) stream. E-type streams, as discussed above (Upstream Straightened, E-Type), are characteristic of wide, flat, alluvial floodplains in the region. E-type streams, although very stable, may be sensitive to upstream drainage basin changes and/or channel disturbance and may rapidly convert to other stream types.

The downstream sinuous E-type channel has been affected by sewer line maintenance, including straightening of several reaches and installation of rip-rap/boulders for bank stabilization. The channel appears to be downcutting into bed material, resulting in an incised and oversized channel. Typically, incised channels are expected to extend laterally, carving a new floodplain at the lower elevation; however, rip-rap/boulders may be hindering channel evolution. The channel is currently characterized by a cross-sectional area measuring 87 square feet (56 square feet predicted by the regional curves), with bankfull depths of 3.8 feet and resultant bank height ratios measuring approximately 1.4 (low bank height/bankfull maximum depth).

Pattern variables appear within the modal concept of C-type and E-type streams in the region. However, several portions of the channel have

been altered in support of sewer line maintenance. Several reaches appear to have been straightened resulting in radius of curvatures ranging to a low of 23 feet (1.0 radius of curvature/bankfull width), pool-to-pool spacing ranging to a high of 351 feet (15.5 pool-to-pool spacing/bankfull width), and meander length ranging to a high of 608 feet (26.8 meander length/bankfull width). The channel is currently characterized by a sinuosity of 1.4 (thalweg distance/straight-line distance), which appears within the modal concept of stable streams in the region.

The average water surface slope for this downstream reach measures approximately 0.0037 (rise/run). The average riffle slope measures approximately 0.0144 (rise/run), ranging from 0 to 0.0507 (rise/run). The average riffle slope appears to be nearly four times the average water slope and the upper range of riffle slopes is more than 13 times the average water surface slope (Figure 9). Although average water surface slope appears to be characteristic of stable streams in the region, riffle slopes are significantly higher than indicative of reference streams in the vicinity of the Site.

The channel is characterized by a D50 of approximately 19.8 millimeters indicating a channel substrate dominated by coarse gravel. Sand sized particles from the upstream reach appear to have not migrated to this downstream reach, or have migrated to the downstream reach and have been transported through the Site outfall.

3.6 Stream Power, Shear Stress, and Stability Threshold

3.6.1 Stream Power

Stability of a stream refers to its ability to adjust itself to in-flowing water and sediment load. One form of instability occurs when a stream is unable to transport its sediment load, leading to the condition referred to as aggradation. Conversely, when the ability of the stream to transport sediment exceeds the availability of sediments entering a reach and/or stability thresholds for materials forming the channel boundary are exceeded, erosion or degradation occurs.

Stream power is the measure of a stream's capacity to move sediment over time. Stream power can be used to evaluate the longitudinal profile, channel pattern, bed form, and sediment transport of streams. Stream power may be measured over a stream reach (total stream power) or per unit of channel bed area. The total stream power equation is defined as:

 $\Omega = \rho g \Omega s$

where Ω = total stream power (lb-ft/s²), ρ = density of water, g = gravitational acceleration, Q = discharge (ft³/sec), and s = energy slope (ft/ft). The specific weight of water (γ = 62.4 lb/ft³) is equal to the product of water density and gravitational acceleration, ρg . A general evaluation of power for a particular reach can be calculated using bankfull discharge and water surface slope for the reach. As slopes become steeper and/or velocities increase, stream power increases and more energy is available for re-working channel materials. Straightening and clearing channels increases slope and velocity and thus stream power. Alterations to the stream channel may conversely decrease stream power. In particular, over widening of a channel will dissipate energy of flow over a larger area. This process will decrease stream power, allowing sediment to fall out of the water column, possibly leading to aggradation of the streambed.

The relationship between a channel and its floodplain is also important in determining stream power. Streams that remain within their banks at high flows tend to have higher stream power and relatively coarser bed materials. In comparison, streams that flood over their banks onto adjacent floodplains have lower stream power, transport finer sediments, and are more stable. Stream power assessments can be useful in evaluating sediment discharge within a stream and the deposition or erosion of sediments from the streambed.

3.6.2 Shear Stress

Shear stress, expressed as force per unit area, is a measure of the frictional force that flowing water exerts on a streambed. Shear stress and sediment entrainment are affected by sediment supply (size and amount), energy distribution within the channel, and frictional resistance of the streambed and bank on water within the channel. These variables ultimately determine the ability of a stream to efficiently transport bedload and suspended sediment.

For flow that is steady and uniform, the average boundary shear stress exerted by water on the bed is defined as follows:

$$\tau = \gamma Rs$$

where τ = shear stress (lb/ft²), γ = specific weight of water, R = hydraulic radius (ft), and s = the energy slope (ft/ft). Shear stress calculated in this way is a spatial average and does not necessarily provide a good estimate of bed shear at any particular point. Adjustments to account for local variability and instantaneous values higher than the mean value can be applied based on channel form and

irregularity. For a straight channel, the maximum shear stress can be assumed from the following equation:

$$\tau_{ma \times} = 1.5\tau$$

for sinuous channels, the maximum shear stress can be determined as a function of plan form characteristics:

$$\tau_{max} = 2.65\tau (R_c/W_{bkf})^{-0.5}$$

where Ro = radius of curvature (ft) and Wbkf = bankfull width (ft).

Shear stress represents a difficult variable to predict due to variability of channel slope, dimension, and pattern. Typically, as valley slope decreases channel depth and sinuosity increase to maintain adequate shear stress values for bedload transport. Channels that have higher shear stress values than required for bedload transport will scour bed and bank materials, resulting in channel degradation. Channels with lower shear stress values than needed for bedload transport will deposit sediment, resulting in channel aggradation.

The actual amount of work accomplished by a stream per unit of bed area depends on the available power divided by the resistance offered by the channel sediments, plan form, and vegetation. The stream power equation can thus be written as follows:

$$\omega = \rho g Q s = \tau v$$

where $\omega=$ stream power per unit of bed area (N/ft-sec, Joules/sec/ft²), $\tau=$ shear stress, and v= average velocity (ft/sec). Similarly,

$$\omega = \Omega/W_{bkf}$$

where W_{bkf} = width of stream at bankfull (ft).

3.6.3 Stream Power and Shear Stress Methods and Results

Channel degradation or aggradation occurs when hydraulic forces exceed or do not approach the resisting forces in the channel. The amount of degradation or aggradation is a function of relative magnitude of these forces over time. The interaction of flow within the boundary of open channels is only imperfectly understood. Adequate analytical expressions describing this interaction have yet to be developed for conditions in natural channels. Thus, means of characterizing these processes rely heavily upon empirical formulas.

Traditional approaches for characterizing stability can be placed in one of two categories: 1) maximum permissible velocity and 2) tractive force, or stream power and shear stress. The former is advantageous in that velocity can be measured directly. Shear stress and stream power cannot be measured directly and must be computed from various flow parameters. However, stream power and shear stress are generally better measures of fluid force on the channel boundary than velocity.

Using the aforementioned equations, stream power and shear stress were estimated for 1) the existing on-site stream reach (taken at 3 cross-sections), 2) two reference streams (UT to Crane Creek and Reedy Creek), and 3) proposed on-site conditions. Important input values and output results (including stream power, shear stress, and per unit shear power and shear stress) are presented in Table 2.

Average stream velocity and discharge values were calculated for the existing on-site stream reach, reference streams, and proposed conditions. Stream roughness coefficients (n) were estimated using a modified version of Jarrett's (1985) weighted method for Cowan's (1956) roughness-component values and applied to Manning's equation (Manning 1981).

Calculations were performed on-site for the upstream straightened reach, the downstream sinuous, C-type (over-widened) reach, and the downstream sinuous, E-type reach. As would be expected, stream power and shear stress are lowest in the C-type (over-widened) reach (1.77 and 0.36, respectively) that is currently showing signs of aggradation. Conversely, stream power and shear stress are highest in the upstream straightened reach (3.0 and 0.5, respectively) were slopes have been steepened by dredging and straightening activities and the channel has been maintained at a low cross-sectional area and low width/depth ratio.

In order to maintain sediment transport functions of a stable stream system, the proposed channel should exhibit stream power and shear stress values between the aggrading and degrading on-site reaches of Back Creek. Results of the analysis indicate that the proposed channel is expected to maintain stream power values ranging from 2.2 to 2.48 and shear stress values ranging from 0.41 to 0.46. These values reside between values for unstable reaches measured for this study. Therefore, the design channel is expected to effectively transport sediment through the Site, resulting in stable channel characteristics.

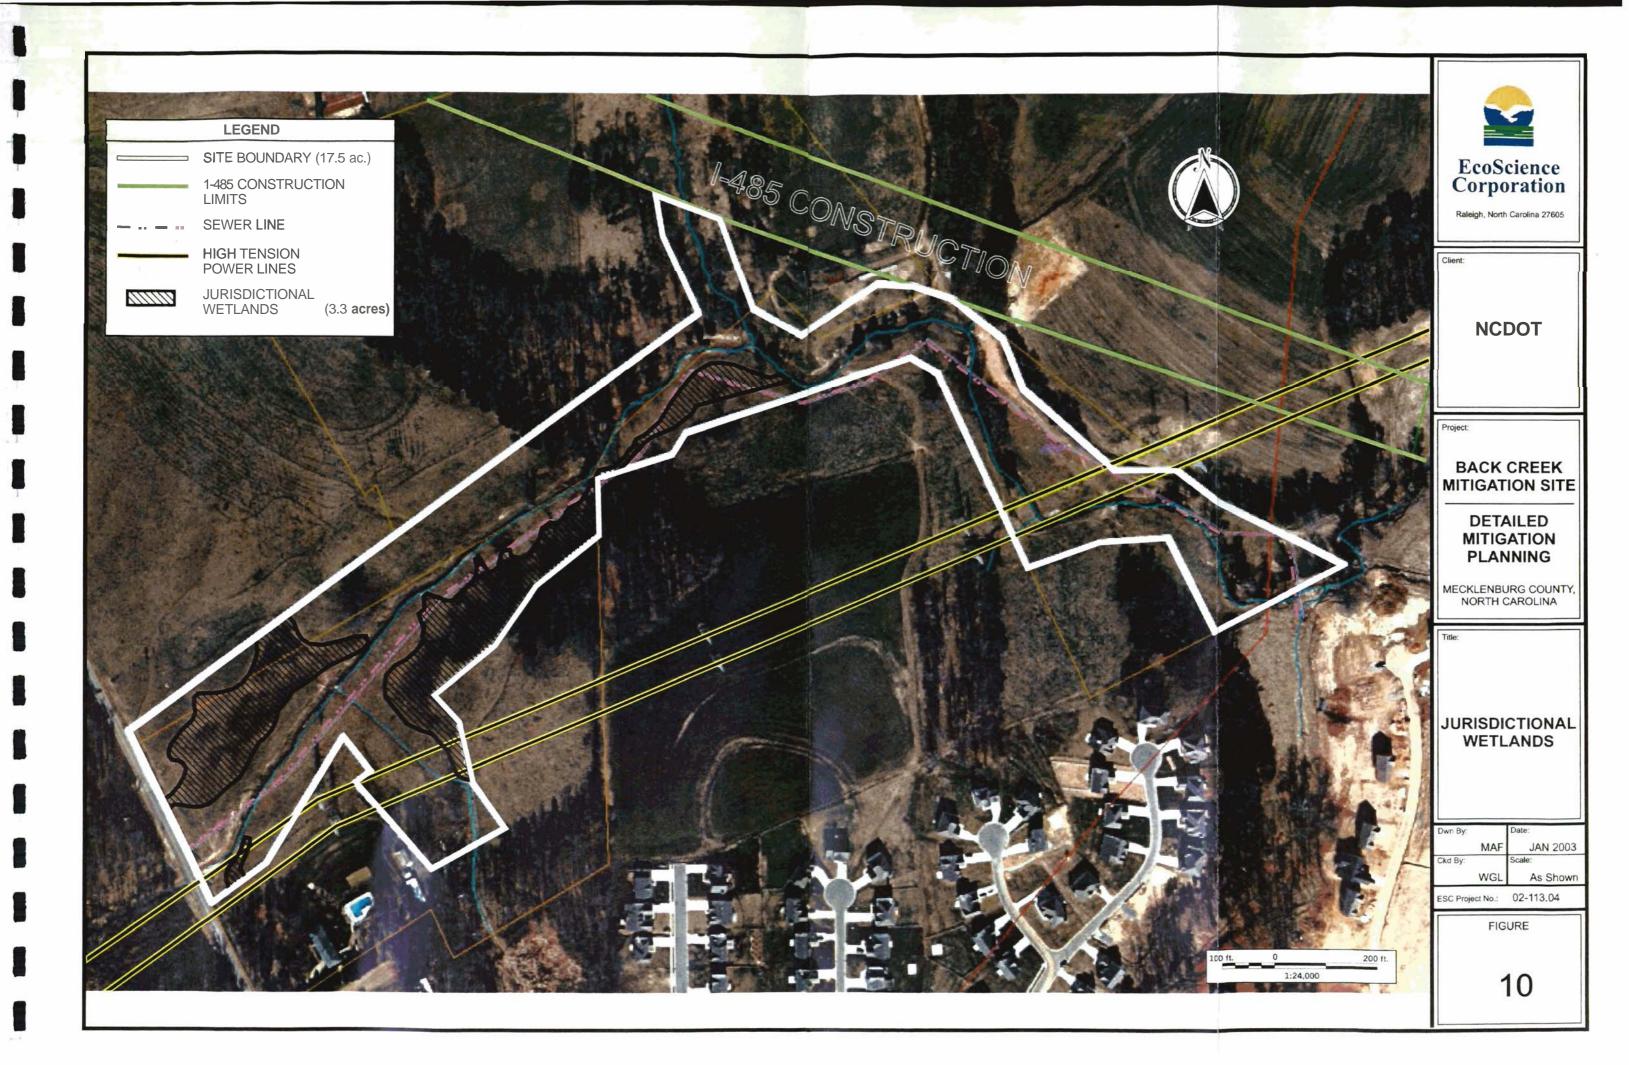

3.7 Jurisdictional Wetlands

Jurisdictional wetland limits are defined using criteria set forth in the U.S. Army Corps of Engineers (COE) Wetlands Delineation Manual (DOA 1987). As stipulated in this manual, the presence of three clearly defined parameters (hydrophytic vegetation, hydric soils, and evidence of wetland hydrology) are required for a wetland jurisdictional determination.

Jurisdictional wetland limits were mapped in the field on 20 November 2002. Based on field assessment, jurisdictional wetlands exist as three individual pockets and occupy a total of 3.3 acres of the Site, as depicted in Figure 10.

Based on U.S. Fish and Wildlife Service, NWI mapping, on-site wetlands are classified as palustrine systems, with emergent vegetation that is persistently and/or temporarily flooded (PEM1A). Based on the N.C. Department of Environment, Health, and Natural Resources, *A Field Guide to North Carolina Wetlands* (DEHNR 1996), on-site wetlands are classified as Piedmont/Mountain Bottomland Hardwood Forest, which has been disturbed by land clearing.

On-site jurisdictional wetlands appear to be seasonally flooded by ground-water table fluctuations and over-bank surface water flows.

Jurisdictional wetlands are located in poorly drained, depressional pockets, which retain surface water flows due to low permeability of the soil body. These areas are underlain by loamy to clayey soils which are gleyed in color with frequent modeling, potentially indicating a fluctuating water table. On-site floodplain soils appear to have been significantly disturbed by utility line installation and maintenance, dredging/straightening of on-site streams, and adjacent land development.

Historically, on-site wetlands may have supported mature hardwood forest, including swamp chestnut oak (Quercus michauxii), American elm (Ulmus americana), hackberry (Celtus laevigata), and green ash (Schafale and Weakley 1990). Jurisdictional areas are currently characterized by fallow fields dominated by rushes and sedges with other invasive herbs and a few woody recruits.

land include wetlands jurisdictional on-site Disturbance to clearing/vegetation removal, soil disturbance through installation of such alterations hydrologic and easements, disturbances may have These dredging/straightening of streams. collectively reduced the functionality of on-site jurisdictional wetlands. On-site impacts may have reduced hydrologic functions, biogeochemical functions, and plant and animal habitat interactions.

4.0 REFERENCE STUDIES

A fundamental concept of stream classification entails the development and application of regional reference curves to stream reconstruction and Regional reference curves can be utilized to predict enhancement. bankfull stream geometry, discharge, and other parameters in altered Development of regional reference curves for North Carolina was initiated in 1995. The curves characterize a broad range of streams Small watersheds or within the Piedmont physiographic province. deviations in valley slope, land use, or geologic substrates may not be accurately described by the curves; therefore, verification of individual Reference sites have been utilized in watersheds may be necessary. planning for detailed curves regional conjunction with characterization of this mitigation project.

In order to develop proposed geometric parameters for the on-site, degraded channel, three nearby streams were measured for reference. reach for the on-site channel is located primary reference approximately 26 miles northeast from the Site, east of Salisbury (Unnamed Tributary to Crane Creek). Two additional reference streams were also measured in support of the project, including 1) a stream located approximately 5 miles south of the Site (Unnamed Tributary to Reedy Creek) and 2) a stream located approximately 19 miles northeast of the Site (Unnamed Tributary to Dutch Buffalo Creek) (Appendix C). These reference streams occur in the same USGS sub-basin as the Site (03040105) and are characterized by G-type and E-type channels. The Gtype reference reach is not considered dimensionally stable; however, the were identifiable in variables bankfull distinct pattern/profile characteristics appear to have not been degraded, allowing for limited assistance with channel design.

Table 3 provides a summary of the three reference streams utilized to establish reconstruction parameters. Data utilized to assemble Table 3 is provided in Appendix C. The table includes reference stream geometry measurements as well as ratios of geometry relative to bankfull width, bankfull depth, and bankfull slope. Because the stream channels at these sites could not be adequately viewed from available aerial photography, plan views were developed through the use of laser technology. Subsequently, channel cross-sections were measured at systematic locations and stream profiles were developed via laser level. Stream substrates were quantified through systematic pebble counts along the reference reaches. In-field measurements of channel geometry were also performed along stream wavelengths located outside of the plan view area.

4.1 Reference Channel

Initially, reference streams in the region were visited and classified by stream type (Rosgen 1996). This classification stratifies streams into comparable groups based on geometric characteristics. Reference reaches identified in the vicinity were characterized primarily as E-type (highly sinuous) channels with sand or gravel substrate. E-type streams are slightly entrenched, highly sinuous (>1.5) channels which exhibit high meander width ratios (belt width/bankfull width). These streams exhibit a sequence of riffles and pools associated with a sinuous flow pattern.

Dimension

Data collected at UT to Crane Creek indicate a bankfull cross-sectional area ranging from 19.3 to 25.0 square feet, with bankfull widths of 9.5 to 11.9 feet, average depths of 1.9 to 2.1 feet, and width/depth ratios of 5 to 7 (Table 3). Regional curves predict that the stream should exhibit a bankfull cross-sectional area of approximately 28 square feet, slightly above the range displayed by the reach.

Field indicators measured at the UT to Reedy Creek indicate a bankfull cross-sectional area ranging from 11.8 to 17.1 square feet, including widths of 9.6 to 11.2 feet, average depths of 1.2 to 1.6 feet, and width/depth ratios of 6 to 8 (Table 3). Regional curves predict that the stream should exhibit a bankfull cross-sectional area of approximately 12 square feet, within the range displayed by the reach.

Pattern

In-field measurements of the UT to Crane Creek have yielded an average sinuosity of 1.8 (Table 3). Accompanying this sinuosity is a belt width which ranges between 74 and 101 feet, an average meander wavelength of 88 feet, and a radius of curvature ranging between 19 and 30 feet. Meander geometry values for this reference reach are acceptable for Etype streams in the region.

Based on field surveys, the UT to Reedy Creek demonstrates an average sinuosity of 1.55 (Table 3). This sinuosity supports a belt width which ranges between 68 and 84 feet, an average meander wavelength of 102 feet, and a radius of curvature ranging from 17 to 42 feet. Pattern values for this reference reach appear suitable for E-type streams in the vicinity.

Field surveys of the UT to Dutch Buffalo Creek indicate an average sinuosity of 1.4 (Table 3). Associated with this sinuosity is a belt width ranging from 42 to 60 feet, an average meander wavelength of 80 feet, and a radius of curvature ranging between 12 and 57 feet. Pattern values

for this reference reach are acceptable for E-type streams in the Piedmont.

Profile

Based on elevational profile surveys, the reference reach at the UT to Reedy Creek is characterized by a relatively steep valley slope (0.017 rise/run); however, this was expected because this reach is located relatively far upstream, away from the influence of Reedy Creek and its associated floodplain. Typically, gradient decreases in a downstream direction as the watershed increases in size. This is evidenced by the valley slope of the UT to Crane Creek which is relatively flat (0.0025 rise/run). This reference reach was surveyed farther down valley, and the comparatively flat valley slope was anticipated. The valley slope on the reference portion of the UT to Dutch Buffalo Creek is moderately steep (0.0086 rise/run). However, this tributary flows through a progressively flattening valley. Pool slopes (Speed) and riffle slopes (Sriffle) of all three reference reaches reside, on average, within the range indicative of stable stream systems.

4.2 Reference Forest Ecosystems

According to Mitigation Site Classification (MiST) guidelines (EPA 1990), Reference Forest Ecosystems (RFEs) must be established for mitigation sites. RFEs are forested areas on which to model restoration efforts of the mitigation site in relation to soils, hydrology, and vegetation. RFEs should be ecologically stable climax communities and should represent believed historical (pre-disturbance) conditions of the mitigation site. Quantitative data describing plant community composition and structure are collected at the RFEs and subsequently applied as reference data for design of the mitigation site planting scheme.

Three RFE areas were chosen to guide plant community restoration along the on-site channel. The RFEs are all found within the Southern Outer Piedmont Ecoregion, one southwest and two northeast of the Site. The RFEs support plant community, landform, and hydrological characteristics that restoration efforts will attempt to emulate. Circular, 0.1-acre plots were randomly established within the selected RFEs. Data collected within each plot include 1) tree, shrub, and herb species composition; 2) number of stems for each tree and shrub species; and 3) diameter at breast height (DBH) for each tree and shrub species. Field data (Tables 4A through 4C) indicate importance values (IV) of dominant tree species calculated based on relative density, dominance, and frequency of tree species composition (Smith 1980). Hydrology, surface topography, and habitat features were also evaluated.

¹Summary of ten - 0.1-acre plots

One of the northeastern RFEs is located in the floodplain of a UT to Crane Creek in Rowan County, North Carolina. Three 0.1-acre plots were established which best characterize expected steady-state forest Forest vegetation was dominated by swamp chestnut oak composition. (IV = 0.17), green ash (IV = 0.13), American elm (IV = 0.10), and shagbark Portions of the canopy were also hickory (IV = 0.09) (Table 4A). (Acer negundo), boxelder willow oak, bγ (Liriodendron tulipifera), black tupelo (Nyssa sylvatica), and red maple (Acer rubrum).

A second RFE is located southwest of the Site in the floodplain of Reedy Creek in Mecklenburg County, North Carolina. Within the RFE, vegetative sampling at four 0.1-acre plots indicate that forest tree vegetation was dominated by tulip tree (IV = 0.12), American elm (IV = 0.10), northern red oak (IV = 0.08), and black walnut (Juglans nigra) (IV = 0.07) (Table 4B). Other, less dominant tree species within the sample plots were green ash, boxelder, and American sycamore.

The third RFE is located northeast of the Site in the floodplain of the Rocky River in Cabarrus County, North Carolina. Ten 0.1-acre plots were established which best characterize expected steady-state forest composition. Forest vegetation was dominated by green ash (IV = 0.39), boxelder (IV = 0.22), American elm (IV = 0.12), swamp chestnut oak (IV = 0.06), ironwood (Carpinus caroliniana) (IV = 0.05), overcup oak (Querces Iyrata) (IV = 0.05), and hackberry (IV = 0.05) (Table 4C). Portions of the canopy were also dominated by winged elm, water ash (Fraxinus caroliniana), and Chinese Privet.

5.0 RESTORATION PLAN

The primary goals of this restoration plan include 1) construction of a stable, riffle-pool stream channel; 2) enhancement of water quality functions in the on-site, upstream, and downstream segments of the channel; 3) creation of a natural vegetation buffer along restored stream channels; 4) maximization of the area returned to historic wetland function; and 5) restoration of wildlife functions associated with a riparian corridor/stable stream.

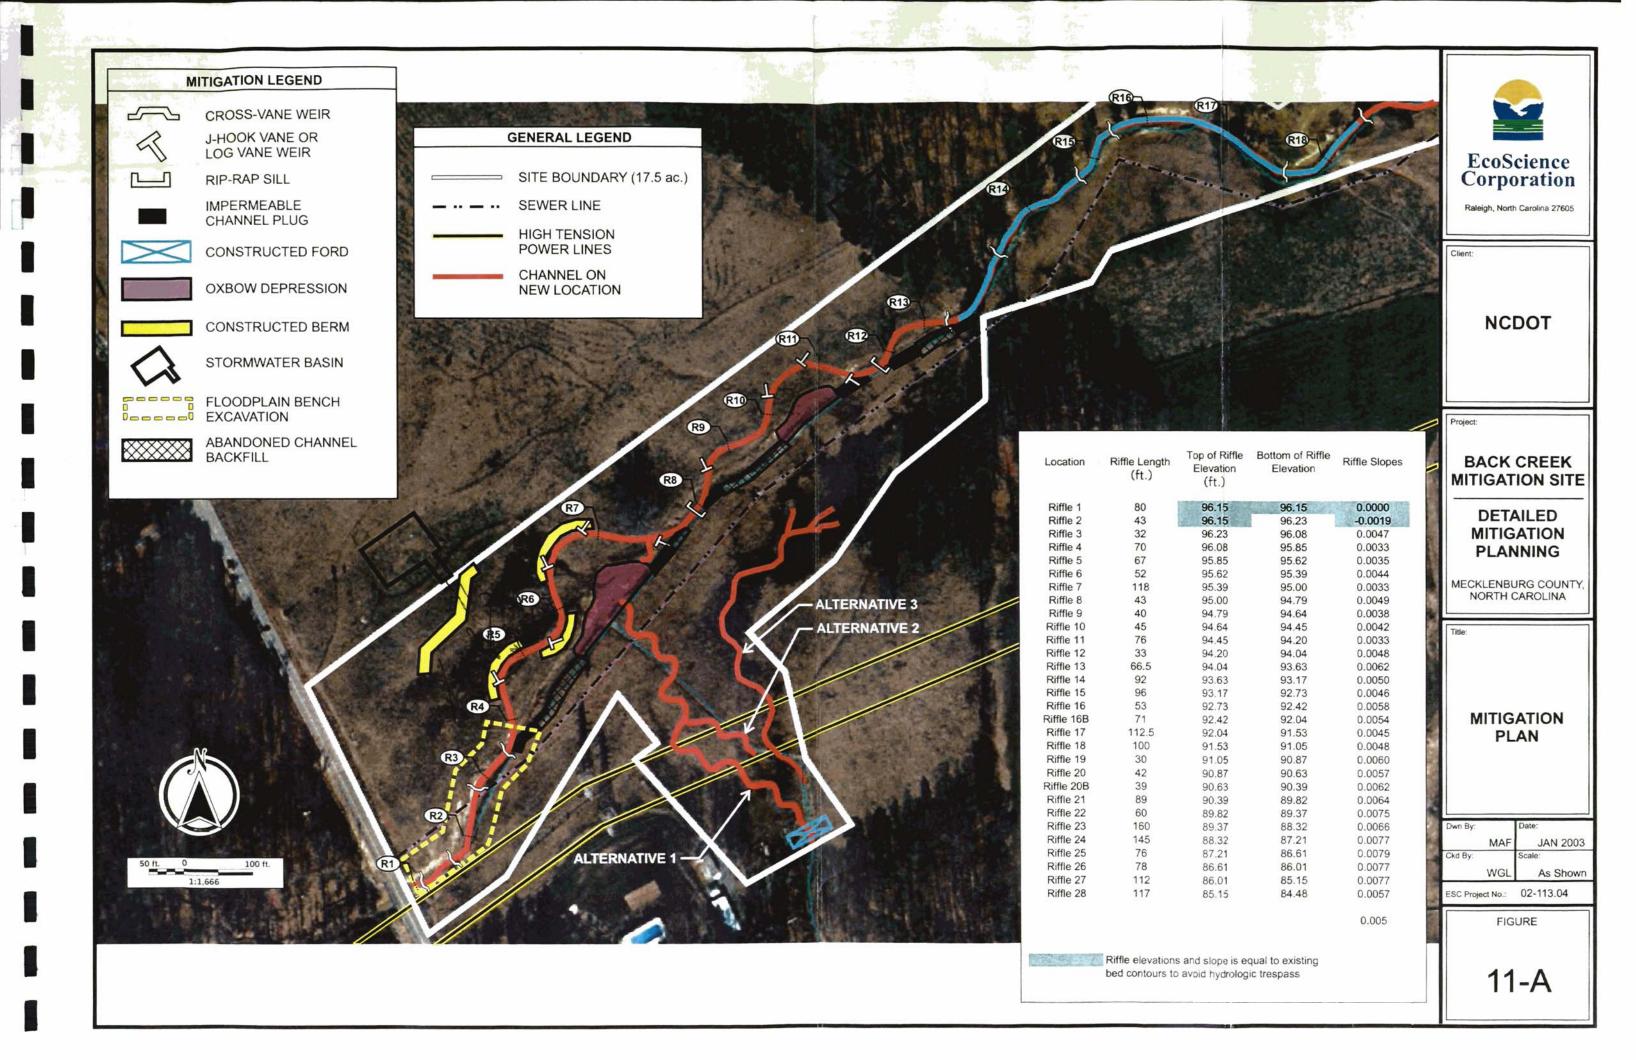

The complete mitigation plan is depicted in Figures 11A and 11B. The proposed mitigation plan is expected to restore approximately 3525 linear feet of Back Creek (1390 linear feet on new location and 2135 linear feet in-place), restore approximately 827 linear feet of secondary tributary adjacent to Back Creek, restore approximately 1.5 acres of jurisdictional wetland, enhance approximately 1.8 acres of jurisdictional wetland, and create approximately 0.5 acre of open water/freshwater marsh within the Site boundaries. Components of this plan may be modified based on construction or access constraints.

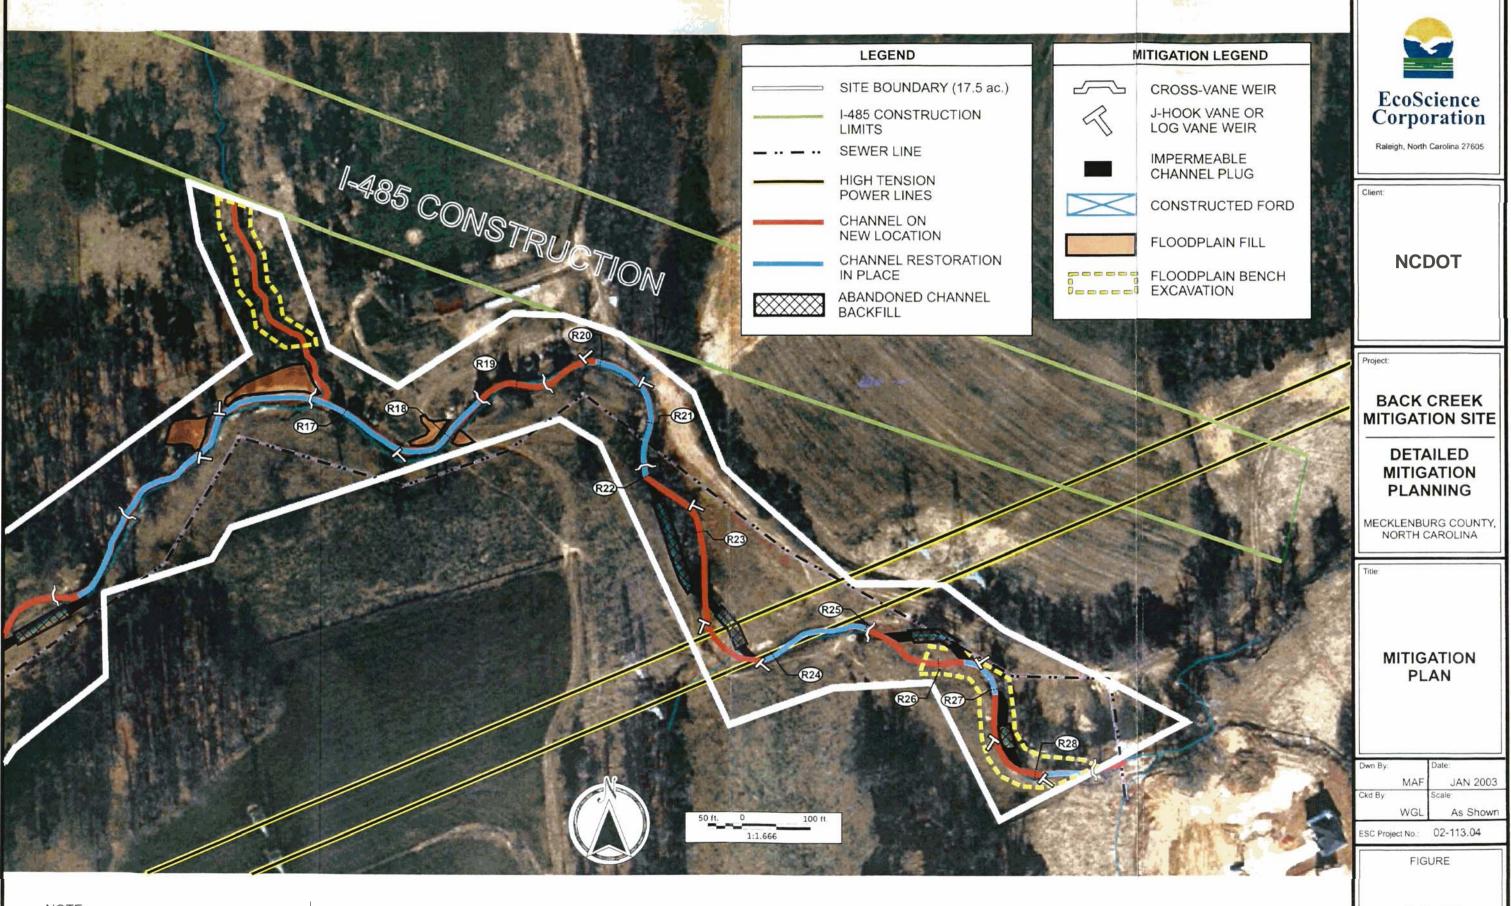

Primary activities proposed at the Site include 1) stream restoration, 2) wetland enhancement/restoration, 3) soil scarification, and 4) plant community restoration. Subsequently, a monitoring plan and contingency plan are outlined in Section 6 of this document.

5.1 Stream Restoration

This stream restoration effort is designed to restore a stable, meandering stream that approximates hydrodynamics, stream geometry, and local microtopography relative to reference conditions. This effort consists of 1) stream reconstruction on new location and 2) stream reconstruction inplace. Geometric attributes for the existing, degraded channel and the proposed, stable channel are listed in Table 5.

An erosion control plan and construction/transportation plan are expected to be developed during the next phase of this project. Erosion control will be performed locally throughout the Site and will be incorporated into construction sequencing. Exposed surficial soils at the Site are unconsolidated, alluvial sediments which do not re-vegetate rapidly after disturbance; therefore, seeding with appropriate grasses and immediate planting with disturbance-adapted shrubs will be employed following the earth-moving process. In addition, on-site root mats (seed banks) and vegetation will be stockpiled and redistributed after disturbance.

NOTE: FOR RIFFLE ELEVATIONS AND SLOPE, SEE TABLE. FIGURE 11-A.

A transportation plan, including the location of access routes and staging areas will be designed to avoid impacts to the existing wetland pockets and proposed design channel corridor. In addition, the transportation plan and all construction activities will minimize disturbance to existing vegetation and soils to the extent feasible. The number of transportation access points into the floodplain will be maximized to avoid traversing long distances through the Site interior.

5.1.1 Reconstruction on New Location

The upstream reach of the Site is characterized by an adjacent floodplain that is suitable for design channel excavation on new location. Primary activities designed to restore the channel on new location include 1) beltwidth preparation and grading, 2) floodplain bench excavation, 3) channel excavation, 4) installation of channel plugs, and 5) backfilling of the abandoned channel.

Beltwidth Preparation and Grading

The stream beltwidth corridor will be cleared to allow survey and equipment access. Care will be taken to avoid the removal of existing, deeply rooted vegetation within the beltwidth corridor which may provide design channel stability. Material excavated during grading will be stockpiled immediately adjacent to channel segments to be abandoned and backfilled. These segments will be backfilled after stream diversion is completed.

Spoil material may be placed to stabilize temporary access roads and to minimize compaction of the underlying floodplain. However, all spoil will be removed from floodplain surfaces upon completion of construction activities.

After preparation of the corridor, the design channel and updated profile survey will be developed and the location of each meander wavelength plotted and staked along the profile. Pool locations and relative frequency configurations may be modified in the field based on local variations in the floodplain profile.

Floodplain Bench Excavation

The creation of a bankfull, floodplain bench is expected to 1) remove the eroding material and collapsing banks, 2) promote overbank flooding during bankfull flood events, 3) reduce the erosive potential of flood waters, and 4) increase the width of the active floodplain. Bankfull benches may be created by excavating the adjacent floodplain to bankfull elevations or filling eroded/abandoned channel areas with suitable material. After excavation, or filling of the bench, a relatively level floodplain surface is expected to be stabilized with suitable erosion

control measures. Planting of the bench with native floodplain vegetation is expected to reduce erosion of bench sediments, reduce flow velocities in flood waters, filter pollutants, and provide wildlife habitat.

Channel Excavation

The channel will be constructed within the range of values depicted in Table 5. The cross-sectional area will average 56 square feet, with a bankfull width measuring approximately 22.4 feet, and an average bankfull depth measuring approximately 2.5 feet (Figure 12).

Figures 11A and 11B provide a plan form and riffle elevations, lengths, and slopes for the constructed channel. Elevations depicted for the top of each riffle are equivalent to the previous bottom of riffle, allowing for a flat water surface in all pools under normal flow conditions. A conceptual view of the proposed profile and plan view of the constructed channel is depicted in Figure 13.

The stream banks and local belt width area of constructed channels will be immediately planted with shrub and herbaceous vegetation. Shrubs such as tag alder (*Ulnus serrulata*) and black willow may be removed from the banks of the abandoned channel or stockpiled during clearing and replaced into the stream construction area. Deposition of shrub and woody debris into and/or overhanging the constructed channel is encouraged. Root mats may also be selectively removed from adjacent areas and placed as erosion control features on channel banks.

Particular attention will be directed toward providing vegetative cover and root growth along the outer bends of each stream meander. Live willow stake revetments will be constructed as conceptually depicted in Figure 14. Available root mats or biodegradable, erosion-control matting may be embedded into the break-in-slope to promote more rapid development of an overhanging bank. Willow stakes will be purchased and/or collected on-site and inserted through the root/erosion mat into the underlying soil.

Channel Plugs

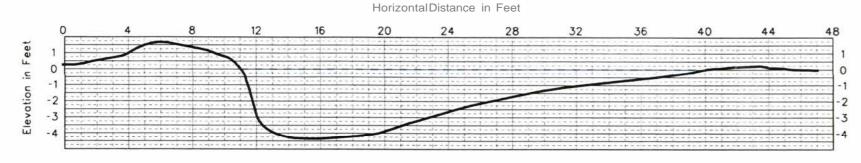

Impermeable plugs will be installed along abandoned channel segments at locations identified in Figures 11A and 11B. The plugs will consist of low-permeability materials or hardened structures designed to be of sufficient strength to withstand the erosive energy of surface flow events across the Site. Dense clays may be imported from off-site or existing material, compacted within the channel, may be suitable for plug construction. The plug will be sufficiently wide and deep to form an imbedded overlap in the existing banks and channel bed.

The plug situated at the upstream terminus of the design channel, located below the stream diversion point, may sustain high-energy flows.

PLAN VIEW

Therefore, a hardened structure or additional armoring (Section 5.1.1.1) may be considered at this location.

Channel Backfilling

After impermeable plugs are installed, the abandoned channel will be back-filled. Backfilling will be performed primarily by pushing stockpiled materials into the channel. The channel will be filled to the extent that on-site material is available and compacted to maximize microtopographic variability, including ruts, ephemeral pools, and hummocks in the vicinity of the backfilled channel.

A deficit of fill material for channel back-fill may occur. If so, a series of closed, linear depressions may be left along confined channel segments. Additional fill material for critical areas may be obtained by excavating shallow depressions along the banks of these planned, open-channel segments. These excavated areas will represent closed linear, elliptical, or oval depressions. In essence, the channel may be converted to a sequence of shallow, ephemeral pools adjacent to effectively plugged and back-filled channel sections. These pools would be expected to stabilize and fill with organic material over time. Vegetation debris (root mats, top soils, shrubs, woody debris, etc.) will be redistributed across the backfill area upon completion.

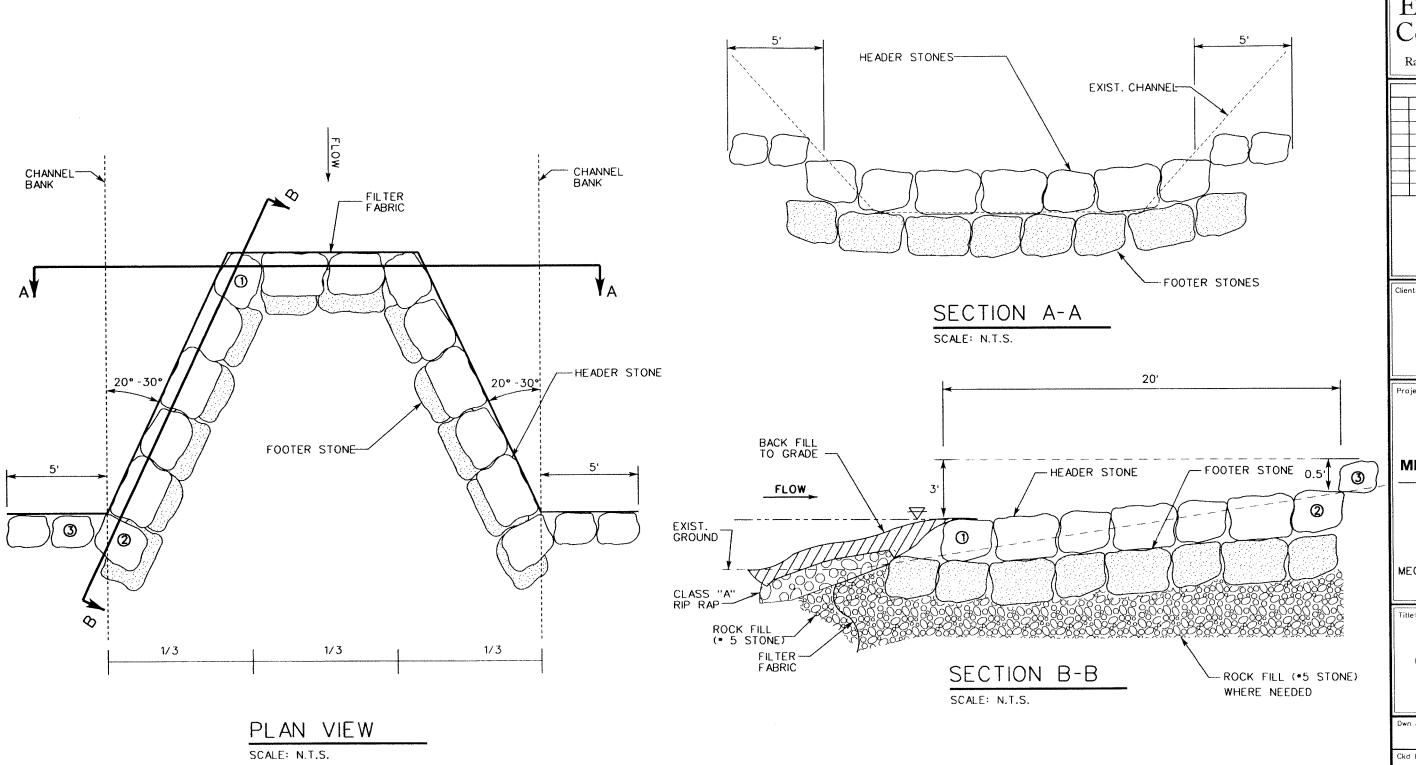

5.1.1.1 In-Stream Structures

Stream restoration under natural stream design techniques normally involves the use of in-stream structures for bank stabilization, grade control, and habitat improvement. Primary activities designed to achieve these objectives may include the installation of 1) cross-vane weirs, 2) Jhook and/or log vanes, 3) stone/rip-rap sills, and 4) root wads.

Cross-vane Weirs

Cross-vane weirs may be installed at locations as depicted in Figures 11A and 11B. The purpose of the vane is to 1) sustain bank stability, 2) direct high velocity flows during bankfull events toward the center of the channel, 3) maintain average pool depth throughout the reach, 4) preserve water surface elevations and reconnect the adjacent floodplain to flooding dynamics from the stream, and 5) modify energy distributions through increases in channel roughness and local energy slopes during peak flows.

Cross-vane weirs will be constructed as conceptually depicted in Figure 15. The structure will be constructed of boulders approximately 30 inches in minimum width. Cross-vane weir construction will be initiated by imbedding footer rocks into the stream bed for stability and to prevent undercutting of the structure. Header rocks will then be placed atop the

15

footer rocks at the design elevation. Footer and header rocks create an arm that slopes from the center of the channel upward at approximately 10 to 15 degrees, tying in at the bankfull floodplain elevation. cross-vane arms at both banks will be tied into the bank with a sill to eliminate the possibility of water diverting around the structure. the header and footer stones are in place, filter fabric will be buried into a trench excavated around the upstream side of the vane arms. The filter fabric is then draped over the header rocks to force water over the vane. The upstream side of the structure can then be backfilled with suitable material to the elevation of the header stones. Approximately 13 of these structures are anticipated at appropriate locations to maintain bank stability and surface-water elevations along the reach. The approximate location of each structure is depicted in Figures 11A and Modifications to the location and elevation of each structure may be necessary during construction activities.

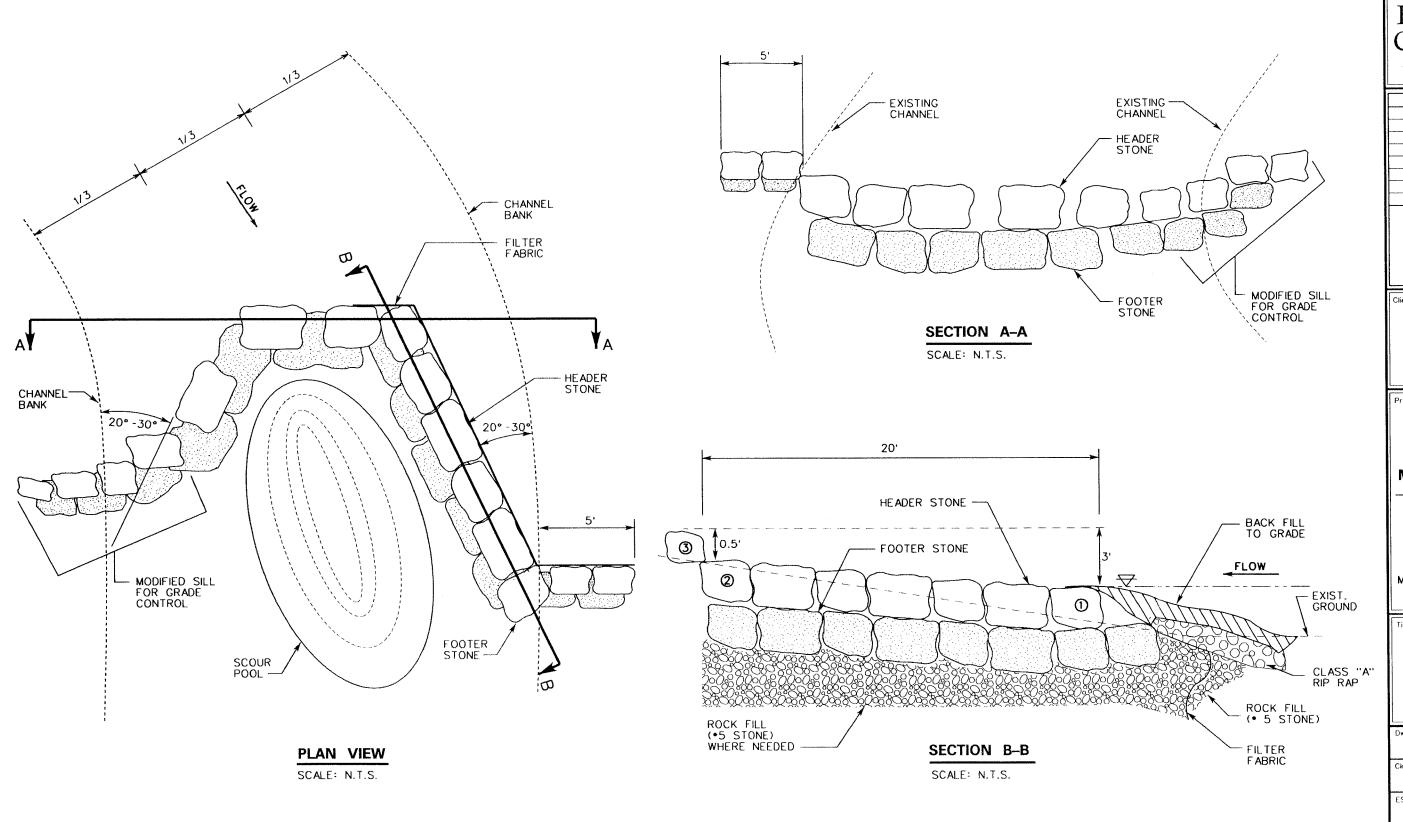

J-hook/log vanes

J-hook or log vane weirs may be installed at locations depicted in Figures The primary purpose of these vanes is to direct high-11A and 11B. velocity flows during bankfull events towards the center of the channel. J-hook vanes will be constructed using the same type and size of rock used to construct cross-vane weirs (Figure 16). Log vanes will be constructed utilizing large tree trunks harvested from the Site or imported from off-site. The tree stem harvested for a log-vane arm must be long enough to be imbedded into the stream channel and extend several feet A trench will be dug into the stream into the floodplain (Figure 17). channel that is deep enough for the head of the log to be at or below the channel invert. The trench is then extended into the floodplain and the log is set into the trench such that the log arm is below the floodplain elevation. If the log is not of sufficient size to completely block stream flow (gaps occur between the log and channel bed) then a footer log or stone footers will be installed beneath the header log. Boulders will then be situated at the base of the log and at the head of the log to hold the log in place.

Similar to a cross vane, the arm of the J-hook vane and the log vane (which forms an arm) must slope from the center of the channel upward at approximately 10 to 15 degrees, tying in at the bankfull floodplain elevation. Once these vanes are in place, filter fabric is toed into a trench on the upstream side of the vane and draped over the structure to force water over the vane. The upstream side of the structure is then backfilled with suitable material.

Stone/Rip-Rap Sills

Stone/rip-rap sills may be installed at various locations within the channel to fix the elevation of riffle heads, protect against headcut migration up

FIGURE

17

the channel, and provide for grade control at sensitive areas such as new location channel and abandoned channel tie-in points. Stone/rip-rap sills may be constructed of rip-rap and/or small boulders which are unsuitable for cross vane and j-hook vane construction.

Sill construction will be initiated by excavating a trench across the channel. Boulders and rip-rap will be piled into the trench to the final elevation of the riffle head. The stone should be piled to conform to channel dimension upstream and downstream of the sill, forming a saddle shaped structure that ties into floodplain elevation. Once the stone has been installed, filter fabric will be toed into a trench on the upstream side of the structure and draped over the top of the stones. After filter fabric is in place the structure can be backfilled with suitable material to the elevation of the sill.

Root-Wad Installation

Root wads may be installed in conjunction with log vanes and/or J-hook vanes to provide diverse in-stream habitat including shade, detritus, and bank overhang. As there are few mature trees on-site, root wads are expected to be imported from off-site. The imported root wads must have approximately 10 to 15 feet of bole left intact. The bole may be utilized as footer for a vane arm and/or will be used to anchor the root wad in the bank. If backfilling is necessary behind the root wad, this area will be stabilized with suitable erosion control measures. Planting with native floodplain vegetation is expected to reduce erosion of bank sediments, reduce flow velocities in flood waters, filter pollutants, and provide wildlife habitat.

5.1.2 Reconstruction In-Place

The reach of Back Creek expected to be reconstructed in-place includes downstream reaches of the mainstem tributary where the channel retains a sinuous flow pattern. The main objective of restoration in this reach is to raise the channel invert to within approximately 3.3 feet of the floodplain surface and to reduce channel size to approximately 56 square feet. Primary activities designed to achieve these objectives may include 1) installation of cross-vane and log-vane weirs and 2) creation of a bankfull bench.

In-stream Structures

In-stream structures including cross-vane and log-vane weirs may be installed in the channel. These structures are conceptually depicted in Figures 15 and 17 and are described in section 5.1.1.1 of this report. The purpose of these vanes is to 1) direct high velocity flows during bankfull events toward the center of the channel, 2) increase the average pool depth throughout the reach, 3) provide diverse in-stream habitat

including shade and detritus, and 4) modify energy distributions through increases in channel roughness and local energy slopes during peak flows.

Bankfull Bench Creation

Reaches of Back Creek proposed to be restored in-place through bankfull bench excavation include the downstream tie-in at the project outfall (Figure 11B). Bench excavation in this location will maintain stable bankheight ratios and proposed bankfull cross-sectional areas in the vicinity of the restored channel tie-in point with off-site bed elevations. After excavation of the bench, the new floodplain surface is expected to be stabilized and planted with native floodplain vegetation.

5.1.3 Secondary Tributary Bank Sloping/Bench Excavation

Two secondary tributaries to Back Creek enter the Site; one enters the Site from the south, at the upper extent of the project, and a second enters the Site from the north midway through the project reach. Both tributaries are characterized by smaller drainage basins measuring approximately 0.1 square mile and 0.04 square mile, respectively. Various mitigation scenarios exist for these channels and are discusses below.

5.1.3.1 Upstream Tributary (Through the Morgan Property)

Several alternatives are proposed for mitigation of this upstream tributary. This tributary has been straightened, entrenched, and approximately one third of the channel has been lined with rip-rap. Based on regional curves and data collected on-site, the proposed cross-sectional area will average 4.5 square feet, with a bankfull width of 5.6 feet, and an average bankfull depth of 0.8 feet. Four mitigation options are proposed for this secondary tributary: 1) no action, 2) reconstruction of stream channel from the property line, 3) reconstruction of stream channel from the rip-rap terminus, and 4) re-direction of channel into the wetland enhancement area.

Regardless of the preferred mitigation alternative, landowner constraints may necessitate the installation of a channel ford to allow access to portions of the property isolated by the conservation easement and/or stream restoration activities. The location of the proposed channel ford is depicted on Figure 11A, and may be subject to change dependant upon comment from landowners and/or construction constraints. The ford is expected to consist of a shallow depression in the stream banks where vehicular crossings can be made. The ford shall be constructed of hydraulically stable rip-rap or suitable rock and should be large enough to handle the weight of anticipated vehicular traffic.

No Action

Actions designed to restore the secondary tributary may be expected to hydraulically impact the existing property owner. Three alternatives described below are designed to reduce potential for both on-site and offsite impacts. However, if off-site impacts appear to be unavoidable with these three alternatives, a no-action alternative is recommended for the secondary tributary. No action is expected to represent a preservation-Planting of the stream banks may be mitigation effort. recommended to reduce bank degradation and sedimentation of adjacent and downstream reaches. In addition, continued communication with the upstream landowner is recommended.

Channel Reconstruction from Property Line (Alternative 1)

This alternative calls for the excavation of approximately 583 linear feet of channel from the southern property line to the tie-in point with Back Creek. The rip-rap section of the existing channel may be removed and utilized for ford construction at the location depicted in Figure 11A. The existing channel will be plugged and backfilled as necessary. excavation of the channel, stream banks and local belt width areas will be immediately planted with shrub and herbaceous vegetation. The primary purpose of this alternative is to restore stream and water quality function to as much of this tributary as possible without adversely affecting adjacent property owners.

Channel Reconstruction from Rip-Rap Terminus (Alternative 2)

This alternative calls for the excavation of approximately 500 linear feet of channel from the rip-rap terminus to the tie-in point with Back Creek. Floodplain excavation may occur along portions of the existing rip-rap section to reduce flooding during major precipitation events. remaining channel will be plugged and backfilled as needed. After excavation of the channel, stream banks and local belt width areas will be immediately planted with shrub and herbaceous vegetation. The primary purpose of this alternative is to restore stream and water quality function to as much of this tributary as possible without adversely affecting land use of the current property owner.

Channel Re-direction into Jurisdictional Wetlands (Alternative 3)

This alternative involves the redirection of the channel from the rip-rap channel towards wetland enhancement areas along the southeastern bank of Back Creek. Additional excavation along the proposed channel may be required to maintain the necessary slope for the release of water into The primary purpose of this alternative is to 1) enhancement areas. reduce flooding concerns of the existing property owner, 2) increase the area and function of on-site wetlands, and 3) provide habitat for a variety of wildlife and plant species.

5.1.3.2 Central Tributary

Several alternatives are proposed for mitigation of this centrally located tributary. This tributary has been severely entrenched (bank height ratio of 1.7) due to upstream and downstream land use activities. Based on regional curves and data collected on-site, the proposed cross-sectional area should average 2.4 square feet, with a bankfull width of 3.9 feet, and an average bankfull depth of 0.6 foot. Four possible mitigation options are proposed for this secondary tributary: 1) no action, 2) bank sloping, 3) floodplain bench excavation, and 4) the introduction of structures to stabilize the channel.

No Action

Actions designed to restore this tributary may impact the Interstate 540 (1-540) roadway project and/or the properties adjacent to 1-540. Alternatives described below are designed to reduce potential for both onsite and off-site impacts. However, if off-site impacts appear to be unavoidable with these alternatives, a no-action alternative is recommended for the tributary. No action is expected to represent a preservation-based mitigation effort. Planting of the stream banks may be recommended to reduce bank degradation and sedimentation of adjacent and downstream reaches.

Bank Sloping (Alternative 1)

This alternative calls for the enhancement of approximately 244 linear feet of channel from the 1-540 right-of-way to the convergence with Back Creek. The objective of bank sloping is to remove the eroding material and collapsing banks. After excavation, the slopes will exhibit a gentle gradient (minimum 3:1 slope) prior to tie in with the existing land surface. Shrubs and vegetation that develop dense root mats will be inserted through the short-term erosion control materials. The bank sloping effort will be locally adjusted to maximize the use of knick points (geologic control features) and existing deep rooted vegetation.

Floodplain Bench Excavation (Alternative 2)

This alternative calls for the restoration of approximately 244 linear feet of channel from the I-540 right-of-way to the convergence with Back Creek. Floodplain bench excavation is proposed for the full length of the channel. The objective of bench excavation is to 1) remove the eroding material and collapsing banks, 2) enlarge the bankfull channel width, and 3) increase the width of the flood-prone area and reintroduce floodplain function such as a reduction of flow velocities in flood waters, filter pollutants, and provide wildlife habitat.

In-stream Structures

In-stream structures including cross-vane and log-vane weirs may be installed in the channel. These structures are conceptually depicted in

Figures 15 through 17 and are described in section 5.1.1.1 of this report. The purpose of these vanes in this channel is to 1) direct high velocity flows during bankfull events toward the center of the channel, 2) provide diverse in-stream habitat including shade and detritus, and 3) modify energy distributions through increases in channel roughness and local energy slopes during peak flows. In-stream structures may be incorporated into alternatives 1 and 2 to reduce hazards of headcut and/or bank failure.

5.2 Wetland Enhancement/Restoration

Alternatives for wetland restoration are designed to restore a fully functioning wetland system which will provide surface water storage, nutrient cycling, removal of imported elements and compounds, and will create a variety and abundance of wildlife habitat. Mitigation activities are expected to restore approximately 1.5 acres of jurisdictional wetland, enhance approximately 1.8 acres of jurisdictional wetland, and create approximately 0.5 acre of open water/freshwater marsh within the Site.

Portions of the Site underlain by hydric soil have been impacted by ditching of a natural stream, channel incision, vegetative clearing, earth movement associated with the dredging/straightening of Back Creek, and/or utilities installation. Wetland mitigation options should focus on 1) the re-establishment of historic water table elevations, 2) excavation and grading of elevated spoil and sediment embankments, 3) reestablishing hydrophytic vegetation, and 4) reconstructing stream corridors.

Re-establishment of Historic Groundwater Elevations

The existing channel depth in the upstream reach of Back Creek measures 4.4 feet, while the depth for the proposed channel in the upstream reach is 3.3 feet. Similar projects conducted in this region of the state utilized simulations in Chewacla/Wehadkee soils to DRAINMOD groundwater influence on wetland hydroperiod around streams that were According to these simulations, by raising the water surface elevation by 1.1 feet the zone of influence may be reduced by approximately 20-25 feet in a pasture/open field setting. Additionally, by re-planting these areas the zone of influence may be reduced by approximately 40-45 feet, based on forested conditions (Appendix D). Based on these results an increase in the water table elevation may reestablish historic elevations and possibly re-hydrate approximately 1.0 acre of relict wetland adjacent to the channel.

Excavation and Grading of Elevated Spoil and Sediment Embankments
Some areas adjacent to the existing channel have experienced both natural and unnatural sediment deposition. Spoil piles were likely cast adjacent to the channel during dredging/straightening of the upstream

reach. Major flood events may have also deposited additional sediment adjacent to stream banks from upstream construction activities. The removal of these spoil materials as well as sediment deposition adjacent to the channel may restore approximately 0.5 acre of historic wetland.

Hydrophytic Vegetation

On-site wetland areas have endured significant disturbance from land use activities such as land clearing, utilities installation and maintenance, grazing, hay production, and other anthropogenic maintenance. Wetland areas may be re-vegetated with native vegetation typical of wetland communities in the region. Emphasis should focus on developing a diverse plant assemblage. Sections 5.4 (Plant Community Restoration) and 5.4.1 (Planting Plan) provide detailed information concerning community species associations. Re-vegetation of portions of the Site underlain by hydric soils is expected to enhance the entire 3.3 acres of on-site jurisdictional wetland.

Reconstructing Stream Corridors

This stream restoration plan involves the reconstruction of both Back Creek and its associated tributaries. The existing channels will be backfilled so that the water table will be restored to relict conditions. However, some portions of the existing Back Creek channel will remain open for the creation of wetland 'oxbow lake' like features. These features will be plugged on each side of the open channel and will function as open water systems. They are expected to provide habitat for a variety of wildlife as well as create approximately 0.5 acre of open water/freshwater marsh within the Site.

5.3 Floodplain Soil Scarification

Microtopography and differential drainage rates within localized floodplain areas represent important components of floodplain functions. Reference forests in the region exhibit complex surface microtopography. Small concavities, swales, exposed root systems, seasonal pools, oxbows, and hummocks associated with vegetative growth and hydrological patterns are scattered throughout these systems. As discussed in the stream reconstruction section, efforts to advance the development of characteristic surface microtopography will be implemented.

In areas where soil surfaces have been compacted, ripping or scarification will be performed. Mixing of vegetation debris in surface soils and tip mounds will also promote future complexity across the landscape. After construction, the soil surface should exhibit complex microtopography ranging to 4 foot in vertical asymmetry across local reaches of the landscape. Subsequently, community restoration will be initiated on complex floodplain surfaces.

5.4 Plant Community Restoration

Restoration of floodplain forest and stream-side habitat allows for development and expansion of characteristic species across the landscape. Ecotonal changes between community types contribute to diversity and provide secondary benefits, such as enhanced feeding and nesting opportunities for mammals, birds, amphibians, and other wildlife.

RFE data, on-site observations, and community descriptions from Classification of the Natural Communities of North Carolina (Schafale and Weakley 1990) were used to develop the primary plant community associations that will be promoted during community restoration activities. These community associations include 1) Piedmont/Mountain floodplain forest, 2) stream-side assemblage, 3) riverine bottomland hardwood forest, and 4) slope forest (Figure 18). Figure 19 identifies the location, based on elevation and position relative to the restored stream, of each target community to be planted. Planting elements within each map unit are listed below.

Piedmont/Mountain Floodplain Forest

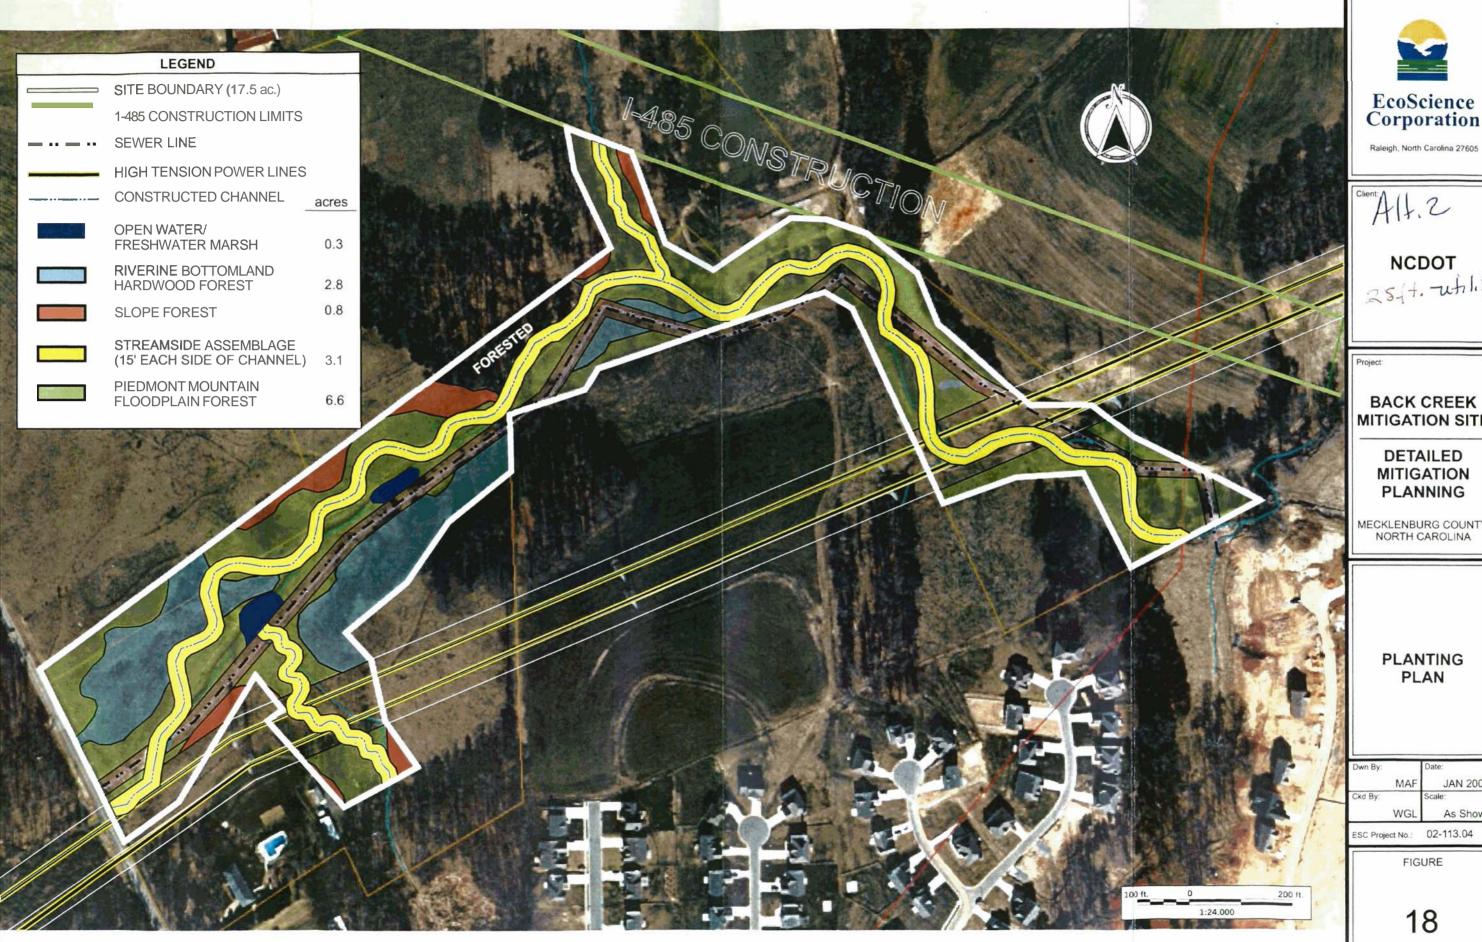

- 1. Hackberry (Celtis laevigita)
- 2. Green Ash (Fraxinus pennsylvanica)
- 3. Swamp Chestnut Oak (Quercus michauxii)
- 4. American Elm (Ulmus americana)
- 5. Shagbark Hickory (Carya ovata)
- 6. American Sycamore (Platanus occidentalis)
- 7. Willow Oak (Quercus phellos)
- 8. Black Gum (Nyssa sylvatica)
- 9. Black Walnut (Juglans nigra)

Stream-Side Forest Assemblage

- 1. Black Willow (Salix nigra)
- 2. Box Elder (Acer negundo)
- 3. Ironwood (Carpinus caroliniana)
- 4. River Birch (Betula nigra)
- 5. American Sycamore (Platanus occidentalis)
- 6. Swamp Dogwood (Cornus amomum)

Stream-Side Shrub Assemblage

- 1. Tag Alder (Alnus serrulata)
- 2. Buttonbush (Cephalanthus occidentalis)
- 3. Elderberry (Sambucus canadensis)

The stream-side trees and shrubs include species with high value for sediment stabilization, rapid growth rate, and the ability to withstand hydraulic forces associated with bankfull flow and overbank flood events. Stream-side trees and shrubs will be planted within 10 to 15 feet of the channel throughout the meander belt width. Shrub elements will be planted along the banks of the reconstructed stream, concentrated along outer bends.

Piedmont/Mountain floodplain forests are targeted for non-hydric soils located in outer portions of the floodplain. Riverine bottomland hardwood species will be planted in portions of the Site underlain by hydric soils. Species common along slope forests will be planted on slopes adjacent to the floodplain.

Certain opportunistic species which may dominate the early successional forests have been excluded from community restoration efforts. Opportunistic species consist primarily of red maple, tulip tree, and sweetgum. These species should also be considered important components of bottomland forests where species diversity has not been jeopardized.

The following planting plan is the blueprint for community restoration. The anticipated results stated in the Success Criteria (Section 6.6) are expected to reflect potential vegetative conditions achieved after steady-state conditions prevail over time.

5.4.1 Planting Plan

The purpose of a planting plan is to re-establish vegetative community patterns across the landscape. The plan consists of 1) acquisition of available plant species, 2) implementation of proposed Site preparation, and 3) planting of selected species.

Species selected for planting will be dependent upon availability of local seedling sources. Advance notification to nurseries (1 year) will facilitate availability of various non-commercial elements.

Bare-root seedlings of tree species will be planted within specified map areas at a density of 435 stems per acre on 10-foot centers. Table 6 depicts the total number of stems and species distribution within each vegetation association. Planting will be performed between December 1 and March 15 to allow plants to stabilize during the dormant period and set root during the spring season. A total of 7136 diagnostic tree and shrub seedlings will be planted during restoration (Table 6).

TOTAL	1217	1349 -	1349	350	2871	7136

¹ Planting densities comprise 435 trees and/or shrubs per acre within each specified planting area.

Some non-commercial elements may not be locally available at the time of planting. The stem count for unavailable species should be distributed among other target elements based on the percent (%) distribution. One year of advance notice to forest nurseries will promote availability of some non-commercial elements. However, reproductive failure in the nursery may occur.

³ Scientific names for each species, required for nursery inventory, are listed in the mitigation plan.

6.0 MONITORING PLAN

Monitoring of Site restoration efforts will be performed until success criteria are fulfilled. Monitoring is proposed for the stream channel, as well as wetland components of hydrology and vegetation.

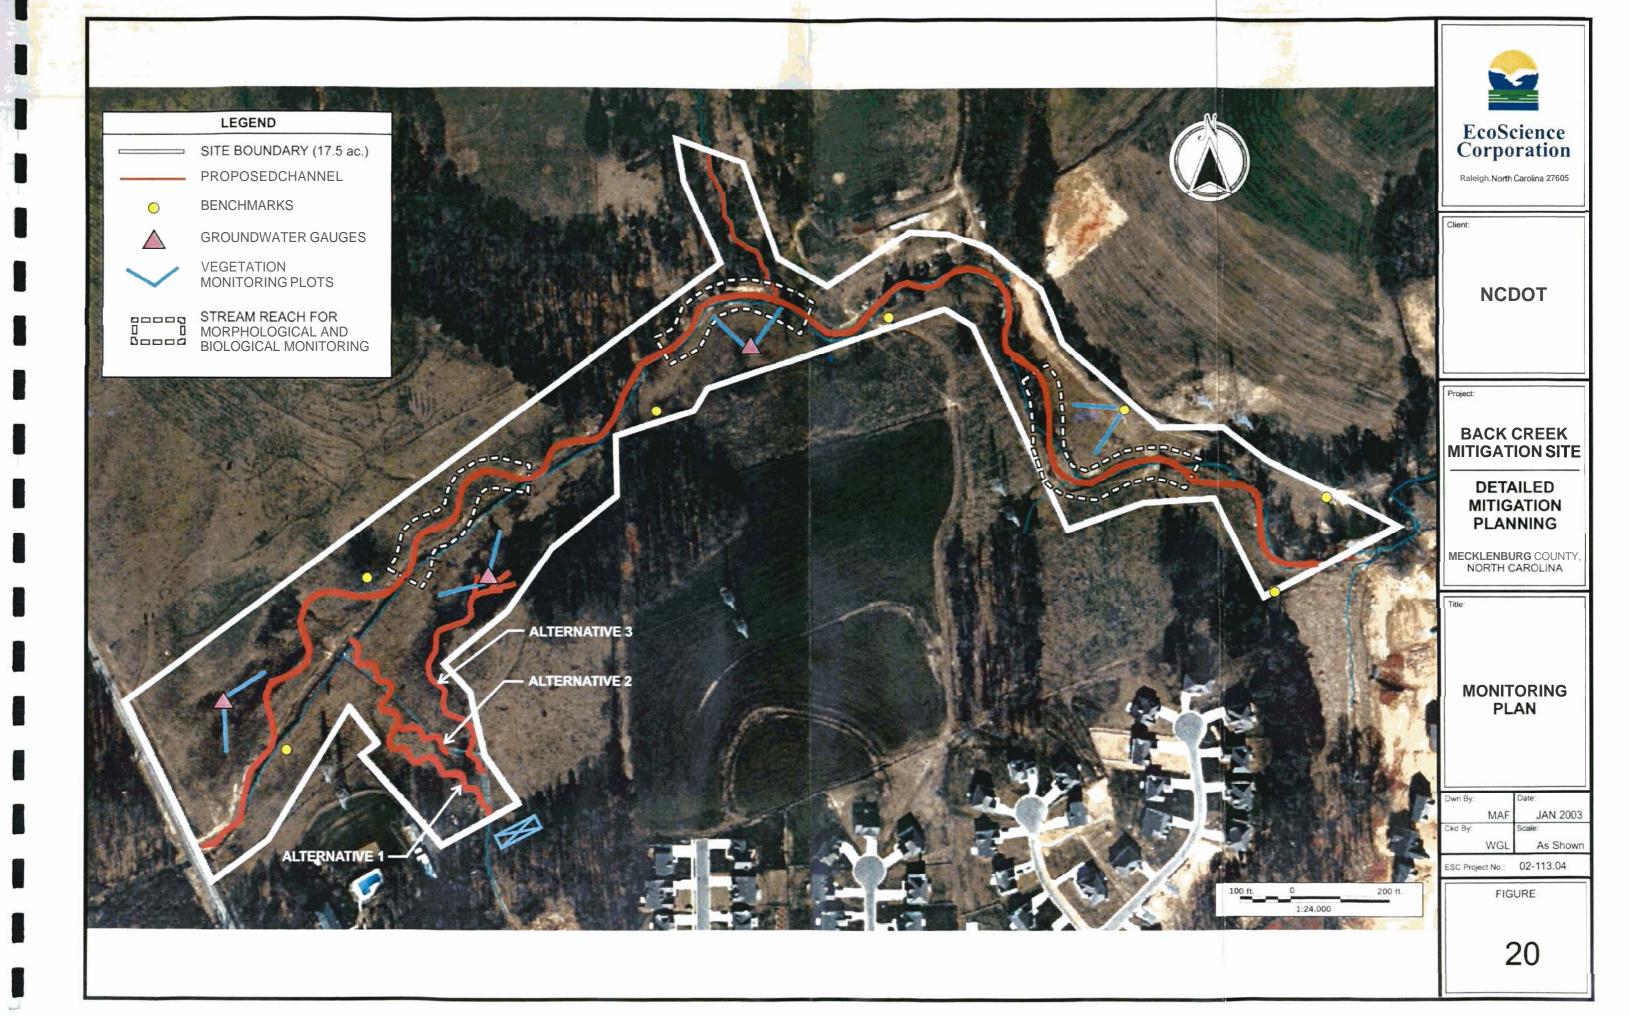

6.1 Stream Monitoring

Three stream reaches are proposed to be monitored for geometric and Each stream reach will biological activity as depicted in Figure 20. extend for a minimum of 300 feet along the restored channel. Annual fall monitoring will include development of a channel plan view, channel cross-sections on riffles and pools, pebble counts, and a water surface profile of the channel. The data will be presented in graphic and tabular Data to be presented will include 1) cross-sectional area, 2) bankfull width, 3) average depth, 4) maximum depth, 5) width/depth ratio, 6) meander wavelength, 7) belt width, 8) water surface slope, 9) sinuosity, and 10) stream substrate composition. The stream will subsequently be classified according to stream geometry and substrate Significant changes in channel morphology will be (Rosgen 1996). tracked and reported by comparing data in each successive monitoring year. A photographic record that will include pre-construction and postconstruction pictures has been initiated.

6.2 Stream Success Criteria

Success criteria for stream restoration will include 1) successful classification of the reach as a functioning stream system (Rosgen 1996), 2) channel stability indicative of a stable stream system, and 3) development of diagnostic biological communities over time.

The channel configuration will be measured on an annual basis in order to track changes in channel geometry, profile, or substrate. These data will be utilized to determine the success in restoring stream channel stability. Specifically, the width/depth ratio should characterize an E-type and/or a borderline E-type/C-type channel (≤ 15), bank height-ratios must characterize a stable or moderately unstable channel (≤ 1.3), and changes in cross-sectional area and channel width must indicate less than 0.5 foot of bed and/or bank erosion per year along the monitoring reach. In addition, abandoned channel reaches or shoot cutoffs must not occur 1.35 (thalweg sinuosity values must remain greater than and The field indicator of bankfull will be distance/straight-line distance). described in each monitoring year and indicated on a representative channel cross-section figure. If the stream channel is down-cutting or

the channel width is enlarging due to bank erosion, additional bank or slope stabilization methods may be employed.

The stream must maintain shear stress values to adequately transport sediment through the Site. Pebble counts will be conducted annually to determine D50 and D84 values within the restored stream. Pebble counts would be expected to indicate a general coarsening of materials on the riffles throughout the monitoring period. Substrate will be considered successful if the channel is characterized by a substrate consisting of sand/fine gravel (D50 greater than 0.5-2 millimeters).

Visual assessment of in-stream structures will be conducted to determine if failure has occurred. Failure of a structure may be indicated by collapse of the structure, undermining of the structure, abandonment of the channel around the structure, and/or stream flow beneath the structure.

6.3 Hydrology Monitoring

While hydrological modifications are being performed on the Site, surficial monitoring wells will be designed and placed in accordance with specifications in the COE's *Installing Monitoring Wells/Piezometers in Wetlands* (WRP Technical Note HY-IA-3.1, August 1993). Monitoring wells will be set to a depth immediately above the top of the clay subsurface layer (range: 24 to 40 inches below the surface).

Two monitoring wells will be placed immediately adjacent to vegetation sampling plots to provide representative coverage within each of the identified mitigation design units (Figure 20). Hydrological sampling will be performed throughout the growing season at intervals necessary to satisfy the hydrology success criteria within each design unit (EPA 1990).

6.4 Hydrology Success Criteria

Target hydrological characteristics include saturation or inundation for at least 12.5 percent of the growing season at lower landscape positions, during average climatic conditions. Upper landscape reaches may exhibit surface saturation/inundation between 5 percent and 12.5 percent of the growing season based on groundwater gauge data. These 5-12.5 percent areas are expected to support hydrophytic vegetation. If wetland parameters are marginal as indicated by vegetation and hydrology monitoring, a jurisdictional determination will be performed in these areas.

Hydrological contingency will require consultation with hydrologists and regulatory agencies if wetland hydrology enhancement is not achieved.

Floodplain surface modification, including construction of ephemeral pools, represents a likely mechanism to increase the floodplain area that supports jurisdictional wetlands. Recommendations for contingency to establish wetland hydrology will be implemented and monitored until Hydrology Success Criteria are achieved.

6.5 Vegetation Monitoring

Restoration monitoring procedures for vegetation are designed in accordance with EPA guidelines enumerated in Mitigation Site Type (MiST) documentation (EPA 1990) and COE Compensatory Hardwood Mitigation Guidelines (DOA 1993). A general discussion of the restoration monitoring program is provided. A photographic record of plant growth should be included in each annual monitoring report.

After planting has been completed in winter or early spring, an initial evaluation will be performed to verify planting methods and to determine initial species composition and density. Supplemental planting and additional Site modifications will be implemented, if necessary.

During the first year, vegetation will receive cursory, visual evaluation on a periodic basis to ascertain the degree of overtopping of planted elements by nuisance species. Subsequently, quantitative sampling of vegetation will be performed between September 1 and October 30 after each growing season until the vegetation success criterion is achieved.

During quantitative vegetation sampling in early fall of the first year, approximately four sample plots will be randomly placed within the Site. Sample-plot distributions are expected to resemble locations depicted in Figure 20; however, best professional judgment may be necessary to establish vegetative monitoring plots upon completion of construction activities. In each sample plot, vegetation parameters to be monitored include species composition and species density. Visual observations of the percent cover of shrub and herbaceous species will also be recorded.

6.6 Vegetation Success Criteria

Success criteria have been established to verify that the vegetation component supports community elements necessary for floodplain forest development. Success criteria are dependent upon the density and growth of characteristic forest species. Additional success criteria are dependent upon density and growth of "Character Tree Species." Character Tree Species include planted species along with species identified through visual inventory of an approved reference (relatively undisturbed) bottomland forest community used to orient the project design. All canopy tree species planted and identified in the reference

forest will be utilized to define "Character Tree Species" as termed in the success criteria.

An average density of 320 stems per acre of Character Tree Species must be surviving in the first three monitoring years. Subsequently, 290 Character Tree Species per acre must be surviving in year 4, and 260 Character Tree Species per acre in year 5. Planted species must represent a minimum of 30 percent of the required stem per acre total (96 stems/acre). Each naturally recruited Character Tree Species may represent up to 10 percent of the required stem per acre total. essence, seven naturally recruited Character Tree Species may represent a maximum of 70 percent of the required stem/acre total. Additional stems of naturally recruited species above the 10 percent - 70 percent thresholds are discarded from the statistical analysis. The remaining 30 percent is reserved for planted Character Tree Species (oaks, etc.) as a seed source for species maintenance during mid-successional phases of forest development.

If vegetation success criteria are not achieved based on average density calculations from combined plots over the entire restoration area, supplemental planting may be performed with tree species approved by regulatory agencies. Supplemental planting will be performed as needed until achievement of vegetation success criteria.

No quantitative sampling requirements are proposed for herb assemblages as part of the vegetation success criteria. Development of floodplain forests over several decades will dictate the success in migration and establishment of desired understory and groundcover populations. Visual estimates of the percent cover of herbaceous species and photographic evidence will be reported for information purposes.

6.7 Contingency

In the event that stream success criteria are not fulfilled, a mechanism for contingency will be implemented. Stream contingency may include, but may not be limited to 1) structure repair and/or installation, 2) repair of dimension, pattern, and/or profile variables, and 3) bank stabilization. The method of contingency is expected to be dependent upon stream variables not in compliance with success criteria. Primary concerns, which may jeopardize stream success include 1) structure failure, 2) headcut migration through the Site, and/or 3) bank erosion.

<u>Structure Failure</u> – In the event that on-site structures are compromised, the affected structure may be repaired, maintained, or replaced. Once the structure is repaired or replaced, it must function to stabilize adjacent stream banks and/or maintain grade control within the channel.

Structures which remain intact, but exhibit flow around, beneath, or through the header/footer stones may be repaired by excavating a trench on the upstream side of the structure and re-installing filter fabric in front of the header and footer stones. Structures which have been compromised, resulting in shifting or collapse of, header/footer stones should be removed and replaced with a structure suitable for on-site flows.

Headcut Migration Through the Site – In the event that a headcut occurs within the Site (identified visually or through on-site measurements [i.e. bank height ratios exceeding 1.4]), provisions for impeding headcut migration and repairing damage caused by the headcut may be implemented. Headcut migration may be impeded through the installation of in-stream grade control structures (rip-rap sill and/or cross-vane weir) and/or restoring stream geometry variables until channel stability is achieved. Channel repairs to stream geometry may include channel backfill with coarse material and stabilizing the material with erosion control matting, vegetative transplants, and/or willow stakes.

Bank Erosion - In the event that severe bank erosion occurs at the Site, resulting in width/depth ratios that exceed a value of 15, contingency measures to reduce bank erosion and width/depth ratio may occur. Bank erosion contingency may include the installation of cross-vane weirs and/or bank stabilization measures. If the resultant bank erosion induces shoot cutoffs or channel abandonment, a channel may be excavated which will reduce shear stress to stable values.

7.0 FINAL DISPENSATION OF THE PROPERTY

NCDOT will maintain the Site conservation easement until all mitigation activities are completed and the Site is determined to be successful. All landowners are expected to retain ownership of their respective parcels. The conservation easement is expected to be transferred perpetually with property upon sale of the properties. Covenants and/or restrictions on the deed will be included that will ensure adequate management and protection of the Site in perpetuity.

Average	180	95	67	313	
Low	59	41	23	129	
High	351	199	135	608	

Sinuousity for the downstream reach is 1.41

Upstream Straightened Reach

Upstream reach has no distinctive repetitive pattern of riffles and pools due to straighting activities. Pattern data other then sinuousity was not recorded. Sinuousity for the upstream reach is **1.02**

Velocity (u=Q/A or	from stream gage h	ydrau	ulic geometry)	4.3	ft/s

The shear stress or tractive force results from the langernial pull of flowing water on the stream bed and banks, and is expressed in pounds per square foot or nim?. The energy expended on the wetted perimeter of the stream increases proportionally with the energy stope and water depth.

Stream Power
The rate of doing work, or a measure of the energy available for moving rock, sediment particles, or woody or other debris in the stream channel, as determined by discharge, water surface slope, and the specific weight of water

w=specific (per unit) stream power (Joules/second/sq. ft)
