Chad Herring, NC Farm Families
Public Hearing on Digester Permit
April 5, 2022

Good evening. My name is Chad Herring, and I am a third-generation family farmer from Mount Olive. I also serve as executive director of North Carolina Farm Families, and I'm proud to represent thousands of family farmers across our state.

Farmers like me believe in protecting our environment by taking care of our water, air and land. Generating renewable natural gas on pig farms is one way that we can contribute to reducing greenhouse gas emissions. Reducing those harmful emissions is a goal that we all share — the State of North Carolina and the Environmental Protection Agency have both highlighted the need to reduce greenhouse gases and promoted the benefits of generating biogas.

Generating renewable natural gas on farms is a positive step forward — for our farmers, for our community, and for our environment. It reduces emissions, reduces odors, and reduces the potential for flooding — and everyone can agree that those three things are beneficial.

These systems help make our farms more sustainable, and farmers who are thinking about investing in a digester system need a predictable and consistent permitting process.

The draft general permit takes appropriate measures to ensure that digester systems are tested and safe before beginning operation. Please do not add unreasonable and unnecessary conditions like the ones being proposed here tonight. Thank you.

# # #

Good evening. My name is Will Hendrick and I'm with the North Carolina Conservation Network.

First, I want to thank DEQ for heeding the procedural advice of the EJEAB by providing advance notice of hearings, holding hearings in person, holding them in impacted communities, providing interpretation & translation services, and extending the comment period.

However, I'm disappointed that DEQ, when drafting the permits themselves, ignored the substantive advice from the same Board. Environmental justice demands not only equitable inclusion in the decision making process, but also agency decisions that acknowledge and address the disparate impact of pollution on communities of color and low income. And, as Governor Cooper has stated in a recent executive order, it is imperative, even as we strive to reduce greenhouse gas emissions, that we do so in a way that incorporates environmental *justice and equity considerations.*

I also want to address two more things DEQ is ignoring. First, DEQ is ignoring the fact that there is technology–indeed even technology compatible with biogas production—that can better protect our environment and public health. For instance, covering a lagoon doesn't increase the nitrogen content in animal waste, but it changes the amount of nitrogen present in its inorganic form, elevating the threat to waters and neighbors posed by mismanagement of an even more potent waste stream. As such, I'm disappointed by the failure of the permit to respond to the increased threat of ammonium discharges and nitrate pollution of groundwaters posed by covering lagoons without requiring components like nitrification-denitrification basins to mitigate these impacts. DEQ should require technology that reduces threats, rather than blessing technology that increases them. The technology exists to continue farming, but stop harming, and DEQ should require its use.

I'm also discouraged that DEQ continues to ignore harm by requiring absolutely no monitoring of groundwater or surface waters absent a self-reported spill. The agency is at best assuming, and at worst willfully overlooking, the impacts, individually and cumulatively, of permitted operations. In court, you're arguing that there are no impacts, because the permit is supposed to prevent them and you conduct an annual inspection to ensure compliance. But that's like saying my car isn't leaking oil, or indeed that no car on the road is leaking oil, because everyone got their car inspected last year. *If you don't look, you don't know and you shouldn't claim* otherwise. I suppose that's an imperfect analogy though; no court has found that my car is harming property rights, but 5 juries have reached that conclusion about DEQ-permitted swine operations. And the EPA hasn't lamented the disparate impact of my driving on vulnerable North Carolinians, but the agency has expressed grave concern about the disparate impacts of permitted operations that you're continuing to ignore. This permit should require monitoring to ensure and evaluate compliance with the non-discharge requirement on which your unchecked assumptions rest.

After all, ultimately it doesn't matter if you enable community participation through these public hearings if, at the end of the day, you ignore what you hear and continue ignoring harm that you have the power to prevent.

Draft General Permits – Digester Systems
Public Meeting
April 19, 2022 6 p.m.
Statesville, N.C. Civic Center

My name is David White, I live at 320 Pennsylvania Ave. in Winston-Salem. I am a former board vice-president and board member of the Yadkin Riverkeeper.

I am a conservationist. I believe in the careful management of our natural resources in partnership and cooperation with government, land owners and the companies who reside here and provide jobs for our citizens.

I am also an active year-round paddler on the Yadkin River and a vocal advocate for keeping the river and its lakes clean for increasing recreational use and the economic benefits that brings.

However, when I see issues which potentially could affect the Yadkin River watershed, particularly drinking water and recreational uses of the river and lakes, I believe it is my responsibility to speak up and that's why I'm here today.

I am patently against creating a new general permit for farm digester systems. On the surface it sounds like a real solution to the problem of animal waste produced by farming, in particular dairy farms: turn manure into usable energy.

Unfortunately, as a solution for manure management, digester systems are hardly a simple or complete solution, but rather one step in an insufficient and fallible process. In the end, you still have a lagoon or cesspool full of manure.

For digester systems to be at all effective they require scale – or a large operation – lager than most of the current dairy farms in our watershed. In effect, this would encourage more Concentrated Animal Feeding Operations (CAFOs) which in turn would create more animal waste and potentially more nutrient and bacteria pollution in the South Yadkin River watershed.

The larger farms are more likely to build giant, unlined pits to store liquid manure. These giant cesspools release methane, carbon dioxide, and other noxious gases that can be fatal to humans and animals. They are also vulnerable to structural failures and extreme weather events, which can cause storage pits to overflow or leak. And "capping" these cesspools is simply not an acceptable management option either, particularly under a general permit as proposed tonight.

There are reasonable alternatives to farm digestive systems such as small-scale sewage/wastewater treatment plants. These systems can be cost-effective and address the issue of manure management.

I am NOT anti-farmer or anti-business or anti-growth. Quite the contrary. But I do welcome common-sense solutions that address the continuing issue of water quality. We simply can't sit back while we unwittingly create another ecological disaster like the Duke Energy coal ash ponds. Thank you.

Run Time: 2:50

My name is Alec Linton and I work for Brock Equipment Company located in Bailey and Calypso, NC. We are a family owned and operated business that, between these two stores, specializes in providing and servicing irrigation equipment to farmers across the state and is also a part of the RNG project.

The RNG project is an exciting opportunity for Brock Equipment since we get to partner with farmers to implement new and innovative technology right here in our state. Farmers are excited for innovation. If you don't believe me, go to your local farm show and watch them check out the latest equipment and technology. The innovation in RNG is no different. Since getting involved in RNG it has been an absolute joy seeing the excitement and hopefulness that these farmers show in the opportunity this project provides to better our farms and communities.

With that said, I believe in the work our farmers do on a daily basis. I believe in the technology and benefit of projects like RNG that help us manage our farms, protect the environment, and better our communities. It is frustrating to see people choose to bash and discredit farmer's efforts for progress. This is not only counterproductive, but it hurts family farms and family businesses like Brock Equipment. There are those that say they don't want to put anyone out of business, but that is exactly what they're doing.

Growing up, I lived next to a hog farm. I work on these farms every week and I see the hard work, passion, and dedication this industry has and I'm proud to be a part of it. At the end of the day, these communities are our communities. We live in them, work in them, and we care about them. I'm grateful to work in this industry and to live in these communities.

From all the employees and their families here at Brock Equipment, thank you for your time.

Comments, Tuesday, April 19, 2022

Joe Morris
8670 US Highway 601
Salisbury, NC 28147

1. My name is Joe Morris, resident of Rowan County, property owner on the South Yadkin River. Small acreage (18 acres) in the South Yadkin / Beaver Dam Creek sub basin, which flows into Second Creek, a short distance upstream of the confluence of the South Yadkin and the Yadkin Rivers – the location of the water intake facility for the Salisbury Rowan Utility Department on Hannah Ferry Road. I serve as a volunteer on the BOD of the Yadkin Riverkeeper.
    a. My farmstead is on a drinking water well. The well is 280' deep and located less than 300' from the South Yadkin River.
    b. On February 6, 2020, we experienced very high water that brough the water level within inches of a structure on my property and overtopped my neighbors well-head, setting off a process of disinfectant and a period without drinking water for his family.
    c. I am concerned about the level of unhealthy bacteria currently in the river and the frequency of e-coli measurements indicating conditions unsafe for recreational activities.
    d. I observe many fishermen across from our property who are catching fish for consumption, feeding their families with fish from these waters.
2. I am pro-farmer, pro-rural life-style and pro-river, these are not mutually exclusive, but for them to sustain, both independent from and dependent on one another, will require a balance of communication, cooperation and to some extent compromise. Of the three, we cannot afford to compromise the river any more. It is polluted. We are a rapidly growing population, which relies entirely on farmers for food and inherently requires rural land on which to produce food for human consumption.
    a. The river provides essential drinking water to innumerous communities in the Yadkin River Basin. It is imperative that we review, and fully understand the implications of the proposed bio-gas capture technology for what its promise might be (the laudable intent to reduce greenhouse gases), and the areas where the technology comes up short.
    b. Simply covering animal waste pools will not improve the issues at hand with water quality, especially the bacteria and nutrients finding their way into the river after every rain event.
    c. The notion of a single, system-wide permit process will alleviate pressure on farmers, which a noble pursuit, but will lump high-performing practitioners with those who may occasionally catch a bad break, or, sad to say, may just cut corners. I can imagine this will cause problems in the future.
3. Finally, I'd like to say that there are better ways to go about this.
    a. Increased monitoring of ground water and surface water in the basin is a beginning.
    b. Providing adequate resources to farmers to build and operate micro- waste water treatment plants to create affluent that is cleaner than the river is now exists as technology. Yes, it is expensive. But we cannot simply not afford not to do it.
    c. Thank you for the opportunity to comment.

RIVERPARK
at Cooleemee Falls
"The Bullhole"

RiverPark at Cooleemee Falls, colloquially known as "The Bullhole" is an 80-acre public park that sits astride the South Yadkin in northern Rowan County and in the town of Cooleemee. While we want you to clearly understand that RiverPark supports the farming community – as I myself own farmland – we have concerns that from a park perspective, and to safeguard the water quality and health of nearby residents, the permitting requirements should include surface and groundwater monitoring and limits for nutrients and bacteria. There is already excessive sedimentation, nutrient overload, and high fecal coliform bacteria (FCB) in the South Yadkin watershed from existing agriculture activities. Not doing so would harm economic development in the watershed around outdoor recreation, particularly in the case of RiverPark.

- The town of Cooleemee, as well as Rowan and Davie counties, has invested over one million dollars in redeveloping a historic mill site as a regional water recreation location. Continuing our improvements, we have just received a $250,000 appropriation from the State for further development.
- RiverPark at Cooleemee Falls has clearly become a regional destination park. Visitors regularly travel from Winston-Salem, Greensboro, High Point, Stanly County, Raleigh, Durham, Chapel Hill, Monroe, Lincolnton, Gastonia, Belmont, Fort Mill, and South Carolina. Out of state visitors are frequent.
- While I have been advised that the South Yadkin is classified as a Class-C or 'secondary contact recreation' watershed, Riverpark is actually Class-B 'primary contact recreation.' Visitors to the park can exceed 400 per day on a summer weekend. Most of these visitors find themselves in the river enjoying the falls, slides and tubing.
- In 2020, the Development Finance Initiative of the UNC School of Government presented to Davie County the outcomes of the feasibility study for the Cooleemee Mill and RiverPark. The bottom line of this study indicated that economic development in the Cooleemee area would not occur without the continued development of RiverPark.
- Yadkin Riverkeeper regularly tests our river water during the summer season. We have discovered that when the water reaches 3' above normal at the Foster Road measuring station located 8 miles upstream, we are guaranteed to have an e. coli problem at the park. This has become such a concern that we have requested grant funding for a method to warn park visitors of unsafe river conditions. No one wants to swim in a dirty river!
- The type of "Development" being discussed here does not support economic development around outdoor recreation and could possibly make it non-viable. Again, no one wants to swim in a dirty river. We should be looking to improve the situation, not implementing practices that can ~~increase~~ the risk.
- There is nothing else like RiverPark in our region. You really ought to come visit some time! CONTINUE

Respectfully submitted,

Addison Davis, President

About RiverPark

- 80-acre nature park in northern Rowan County and the Town of Cooleemee that sits astride the South Yadkin River.
- *RP operates as a 501(c)(3) nonprofit, managed by a volunteer board of directors.*
- Opened in 2003, "The Bull Hole" earned its name some 200 years ago.
- The Visitor Experience includes swimming, hiking, picnicking, kayaking and canoeing, fishing and shelter rental.
- 2021 saw the implementation of full–time staff.

RIVERPARK
at Cooleemee Falls
"The Bullhole"

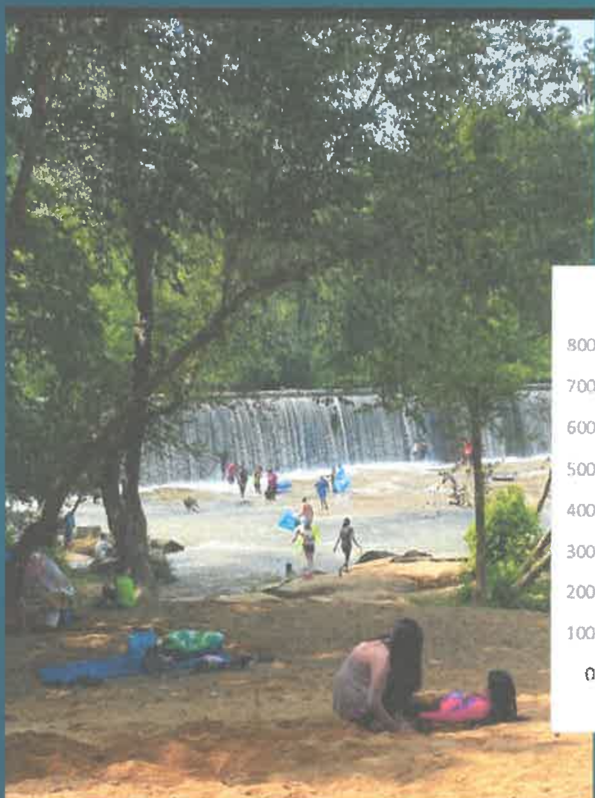
We continue to be discovered!

- Today, RiverPark hosts peak days of over 400 people in the park
- Visitors continue to come from throughout the region
- Growth is expected to continue with park improvements



Typical Summer Day at the Bullhole

Re: Comments on Upcoming Animal Waste Digester System General Permit

Dr. Ravella,

The Southern Environmental Law Center ("SELC") submits these preliminary comments on behalf of itself and Environmental Justice Community Action Network, Duplin County Branch of the North Carolina Conference of the NAACP, North Carolina Poor People's Campaign, Cape Fear River Watch, Rural Empowerment Association for Community Help, North Carolina Conservation Network, North Carolina Sierra Club, Sound Rivers, Winyah Rivers Alliance, Coastal Carolina Riverwatch, Haw River Assembly, Catawba Riverkeeper, Yadkin Riverkeeper, MountainTrue, Clean Water for North Carolina, Toxic Free NC, CleanAIRE NC, Center for Biological Diversity, Waterkeeper Alliance, and Appalachian Voices regarding the Department of Environmental Quality's ("DEQ") development of an animal waste digester system general permit ("biogas general permit") pursuant to the 2021 North Carolina Farm Act.[1] Thank you for the opportunity to provide comments on this important decision. It is critical that DEQ draft a permit that protects public health in communities living nearby hog operations covered under the biogas general permit, as well as the air, waterways, and drinking water these communities rely on.

In issuing the biogas general permit, DEQ is obligated under state law to require the waste treatment and disposal alternative with the least adverse impact on the environment and to evaluate and address the cumulative effects of its permitting decisions on waterways. N.C Gen. Stat. § 143-215.1(b)(2). In addition, to comply with federal civil rights law, DEQ must prevent the disproportionate impact of the biogas general permit on communities of color, which requires DEQ to do more than produce a basic report of the demographics of the communities that will be impacted by the biogas general permit and other pollution sources. 42 U.S.C. § 2000d (2018).

We urge DEQ to include the following provisions in the forthcoming biogas general permit:

- Adoption of cleaner technologies and practices that are compatible with biogas production and address the water and air pollution caused by the use of the digesters in conjunction with lagoons and sprayfields, including but not limited to the anticipated

[1] According to its statements at technical stakeholder meetings, DEQ will be developing a general permit for all animal operations that wish to install a farm digester system, including swine, dairy, and wet poultry. These comments are specific to swine waste to energy projects.

increase in ammonia emissions from the hog operations that will result from the use of covered digesters;

- Robust monitoring and reporting requirements, including monitoring of groundwater at the hog operations, surface waters near the hog operations, ammonia emissions, and monitoring of the waste going into and coming out of the digester or covered lagoon, with regular submission of all monitoring data to DEQ; and
- A requirement to regularly update nutrient management plans to account for the changes in land-applied digester waste, including increases in nitrate levels that are not detected by the current sampling requirements.

These recommendations are consistent with and build upon the recommendations made by the DEQ Secretary's Environmental Justice and Equity Advisory Board dated October 22, 2021 and attached as Exhibit 1. This Board also provided detailed recommendations regarding the public process that DEQ should follow when developing and seeking input on the draft biogas general permit, including, for example, opportunities to provide comments at an in-person hearing given the challenges of virtual platforms and limited broadband access for many impacted community members. The undersigned support those recommendations and urge DEQ to follow those recommendations moving forward.

I. Factual Background

The 2021 Farm Act tasks DEQ with developing a general permit for hog operations that will capture methane and other gases from hog waste lagoons. As discussed in more detail below, hog operations equipped with digesters, in addition to open lagoons and sprayfields, threaten the environment even more than existing industrial hog operations; among other concerns, these operations are expected to emit even more ammonia, which pollute the air, waterways, and soils and lead to sickness for people living nearby. The biogas general permit must account for these changes and require additional protections for nearby communities and the environment.

Over 2,000 industrial hog operations are covered under the 2019 swine general permit, a so-called "non-discharge" permit whose conditions are intended to prevent pollution to waterways. But as DEQ's and other peer-reviewed research has demonstrated, the 2019 swine general permit and its predecessor permits have not adequately protected waterways or groundwater from pollution from these operations. For decades, industrial hog operations have burdened neighbors with water and air pollution and odors, which have resulted in sickness and even death for many neighbors. Earlier this year, the Proceedings of the National Academy of Sciences found that the emissions from industrial animal operations in Sampson and Duplin Counties are responsible for a combined total of 178 premature deaths annually.[2] A disproportionate share of these neighbors are communities of color, making this a significant environmental justice issue.

[2] Nina G.G. Domingo et al., *Air quality-related health damages of food*, 118 PROCEEDINGS OF THE NAT'L ACAD. SCIS. 1 (May 18, 2021).

This is unacceptable, and DEQ must do more to protect communities and the environment from pollution.

A. New Digesters Will Rely on Lagoons and Sprayfields and Increase Ammonia Emissions and Risk of Pollution

The biogas general permit will allow industrial hog operations to install digesters—essentially covered lagoons—that increase the processes of anaerobic digestion and siphon off methane and other gases from hog waste. In most circumstances, these gases will be sent offsite through a network of new pipelines, processed, and ultimately used as fuel. These gases may also be used to generate electricity on-site. The only major biogas project proposed to date, the Align RNG (joint venture of Smithfield Foods and Dominion Energy) Grady Road Project, includes no additional treatment or other measures to control pollution from biogas digester waste; instead, as proposed, the waste from the digester will be transferred to uncovered secondary lagoons and eventually sprayed on nearby fields. This system fails to prevent pollution.

DEQ as well as numerous researchers have documented the pollution to rivers, streams, and groundwater caused by the use of the lagoon and sprayfield system. Hog waste stored in open lagoons emits ammonia into the environment. Pollution runs off from sprayfields; seeps into groundwater from lagoons and sprayfields; and reaches waterways through flooding and airborne ammonia deposits directly on waterways.[3] This pollution results in fish kills and algal blooms and other adverse impacts to water quality and contaminates drinking water.

Ammonia is a well-documented source of water pollution, air pollution, and health problems for people living nearby.[4] The process of siphoning off methane and other gases from untreated hog waste increases the proportion of inorganic nitrogen (e.g., ammonia/ammonium and nitrate) to organic nitrogen[5] in the waste leftover in the digester, which is transferred to open air lagoons and eventually sprayed on fields. The digester waste stored in uncovered secondary lagoons will release even more ammonia into the environment than a conventional hog waste lagoon. Spraying the digester waste from these open lagoons onto fields also releases ammonia and other pollutants into the environment.[6] Airborne ammonia can travel long distances from the source and deposit directly into waterways, leading to algal blooms and fish kills. Ammonia can

Mallin, *The Risk of Increased Cumulative Effects and Water Pollution from Swine Operations Producing Biogas in North Carolina* (Sept. 2021) (citing numerous peer-reviewed papers and data sets, including DEQ data and research, and describing various pathways for pollution from lagoons and sprayfields and the risk of increased pollution from hog operations using digesters without additional pollution control technologies) (attached as Exhibit 2); *see also, e.g.,* Steve Harden, et al., *Surface-Water Quality in Agricultural Watersheds of the North Carolina Coastal Plain Associated with Concentrated Animal Feeding Operations*, U.S. Dep't of Interior-U.S. Geological Survey (2015) (documenting water quality impacts from industrial hog operations).
[4] *See* Compilation of research by Dr. Viney P. Aneja, at 4-5 (Sept. 2021) (attached as Exhibit 3).
[5] *See id.*
[6] *See id.*; *see also* Summary of Expert Opinions of Dr. Shane W. Rogers (Sept. 2021) (attached as Exhibit 4).

also deposit on land, where it converts to nitrate, seeps into the soil, and contaminates drinking water resources for rural well users.[7]

Ammonia emissions are also a precursor to particulate matter pollution, which can penetrate deep into lungs and case serious cardiovascular and respiratory problems, and can even lead to death as documented by the Proceedings of the National Academy of Sciences' recent report.[8]

In addition, the use of digesters increases risk of groundwater and surface water quality problems by increasing the potential of nitrogen and phosphorus, among other pollutants, to move with water when digester waste is sprayed on fields.[9]

These environmental harms lead to adverse health outcomes for neighbors of hog operations, a disproportionate share of whom are Black, Latinx, and Native American. Peer-reviewed research has documented higher rates of asthma and other respiratory conditions, higher death rates from common diseases, and higher rates of depression and anxiety among people living nearby these hog operations.[10] Without stringent pollution controls, the biogas general permit could perpetuate the health problems caused by the primitive lagoon and sprayfield system and increase risk of sickness and death for nearby communities.

B. Cleaner Technology That is Compatible with Biogas Production is Available and Economical

Animal waste management technology has advanced dramatically in the last two decades. As described in more detail in Exhibit 5, there are numerous technologies and practices that are in use in North Carolina and beyond that are both compatible with biogas production *and* address ammonia emissions and other environmental and public health harms caused by the primitive lagoon and sprayfield system. These include nitrification-denitrification, ANNAMOX, alkaline precipitation, Struvite precipitation, Super Soils/Terra Blue, Sistrates, and membrane separation and solids recovery technologies, among others.

II. Legal Background

A. The Farm Act Requires DEQ to Create a General Permit for Farm Digesters

The Farm Act of 2021, Session Law 2021-78, requires DEQ to develop a permit to allow numerous animal operations to "construct and operate a farm digester system," *id.* at Sec. 11(b), which is defined as "a system, including all equipment and lagoon covers, by which gases are

---

[7] *See* Aneja, *supra* note 4; *see also* Mallin, *supra* note 3, at 4.
[8] *See* Domingo, *supra* note 2, at 2.
[9] *See* Mallin, *supra* note 3, at 4-5.
[10] *See id.; see also* Julia Kravchenko et al., *Mortality and Health Outcomes in North Carolina Communities Located in Close Proximity to Hog Concentrated Animal Feeding Operations*, 79 N.C. MED. J. 278, 278 (2018), https://doi.org/10.18043/ncm.79.5.278 (finding higher mortality rates for people living near industrial hog operations); *see also* Steve Wing, et al., *Environmental Injustice in North Carolina's Hog Industry*, 108 Env't Health Perspectives 225 (2000), https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1637958/ (documenting that hog operations are concentrated in areas with higher populations of people of color and low-wealth communities).

collected and processed from an animal waste management system for the digestion of animal biomass for use as a renewable energy resource." *Id.* Sec. 11(a). The legislature instructed DEQ to include conditions in the biogas general permit which are "required to describe and authorize the construction, monitoring, and proper operation" of the systems, *id*. Sec. 11(d), in addition to the conditions in the 2019 swine general permit.[11] The "proper operation" of the farm digester system includes provisions that ensure the new system "does not cause pollution in the waters of the State," N.C. Gen. Stat. §143-215.10C(b), which includes groundwater and surface waters, *id.* § 143-212(6). The requirements of the Farm Act likewise authorize DEQ to require additional treatment and other practicable alternatives to minimize adverse impacts on the environment. In other words, DEQ has the authority to include any conditions in the biogas general permit that are necessary to ensure that the facility covered by the permit does not pollute groundwater or surface waters. DEQ should draft the biogas general permit to provide for any additional pollution control measures that may be needed to address the effects of covered anaerobic digesters and should also account for the site-specific circumstances of individual facilities.

B. North Carolina's Water Pollution Control Statute Requires DEQ to Protect the Environment and Neighbors from Pollution from Hog Operations

The North Carolina Constitution provides that it is the policy of North Carolina "to conserve and protect its lands and waters for the benefit of all its citizenry … [and that] it shall be a proper function of the State … to control and limit the pollution of our air and water." N.C. Const. art. XIC, sec. 5. Moreover, the legislature declared "the public policy of the State to provide for consideration of its water and air resources," N.C. Gen. Stat. § 143-211(a), and "to maintain, protect, and enhance water quality within North Carolina," *id.* at (b). In issuing permits, DEQ must "prevent . . . any significant increase in pollution of the waters of the State," *Id.* § 143-215.1(b)(1), and ensure compliance with water quality standards, *Id.* § 143-215.10F. DEQ may conduct "any inquiry or investigation it considers necessary before acting on an application." *Id*. § 143-215.10C(c).

North Carolina's pollution control statute mandates that for *all* permits, DEQ require the "practicable waste treatment and disposal alternative with the last adverse impact on the environment." N.C. Gen. Stat. 143-215.1(b)(2); *see also* 15A N.C. Admin. Code 2T.0105(f). This provision of state law applies to the biogas general permit. As such, DEQ must require that any permittees under the biogas general permit use the waste treatment technology with the least adverse impact on the environment. The broad language of this requirement includes the obligation and authority to minimize ammonia pollution.

In addition, when issuing the biogas general permit DEQ must prevent water pollution due to the "cumulative effects" of its permitting decisions. N.C. Gen. Stat. 143-215.1(b)(2). This means that DEQ has an obligation to evaluate water pollution anticipated from the biogas general permit, as well as from other permitted operations in the area. This obligation is not limited to consideration of the effects of new operations or solely operations engaged in the

[11] The 2019 swine general permit is issued pursuant to the N.C. Gen. Stat. §143-215, *et seq*., and Subchapter 2T of Title 15A of the North Carolina Administrative Code.

production of biogas; for instance, DEQ must consider the impacts attributable to the collective effects of other permitted animal feeding operations, including deemed permitted poultry operations. DEQ must prevent pollution of groundwater and surface waters resulting from the combined effects of these operations. DEQ's obligation to prevent these water quality impacts includes ammonia pollution, a documented source of water quality impacts, as reflected in the statute's broad definition of "water pollution" as "the man-made or man-induced alteration of the chemical, physical, biological, or radiological integrity of the waters of the State, including, but specifically not limited to, alterations resulting from the concentration or increase of natural pollutants caused by man-related activities." *Id*. § 143-213(19).

To ensure compliance with water quality standards, state regulations expressly provide for DEQ's authority to "require monitoring and reporting requirements, including of groundwater, surface water or wetlands, waste, wastewater, residuals, soil, treatment processes, lagoon or storage ponds, and plant tissue, if necessary to determine the source, quantity, and quality of the waste and its effect upon the surface water, ground waters, or wetlands." 15A N.C. Admin. Code 02T .0108(c). A recent decision from the Ninth Circuit Court of Appeals reinforces the need for monitoring and reporting requirements for permits such as the biogas general permit:

> Without a requirement to monitor runoff from irrigated CAFO [concentrated animal feeding operation] fields, there is no way to ensure that a CAFO is complying with the Permit's dry weather no-discharge requirement for land-application areas. . . . Without a requirement that CAFOs monitor waste containment structures for underground discharges, there is no way to ensure that production areas comply with the Permit's zero-discharge requirement.

Food & Water Watch v. U.S. Env't Prot. Agency, No. 20-71554, 2021 WL 4203496, at *10 (9th Cir. Sept. 16, 2021).

In sum, the state water pollution control statute and implementing regulations give DEQ broad authority, and indeed an obligation, to draft permits in a way that protects surface water quality and groundwater.

C. Title VI of the Civil Rights Act of 1964 Requires DEQ to Ensure the Biogas General Permit Protects All Communities

As a recipient of federal funding, DEQ must comply with Title VI of the Civil Rights Act of 1964, which provides that:

> No person in the United States shall, on the ground of race, color, or national origin, be excluded from participation in, denied the benefits of, or be subjected to discrimination under any program or activity receiving Federal financial assistance.

42 U.S.C. § 2000d (2018). EPA regulations prohibit a recipient of federal funds from using criteria or methods of administering a program or activity which have the effect of subjecting individuals to discrimination. 40 C.F.R. § 7.35(b). "Title VI imposes on states an affirmative

obligation to include consideration of Title VI criteria in permitting decisions."[12] Therefore, DEQ—as a recipient of federal funds—is required to administer its permitting programs in a manner that does not have the effect of subjecting individuals to discrimination or else the agency risks losing those funds.

To date, DEQ has failed to comply with Title VI. For the first several hog operations participating in the Grady Road Project, DEQ collected demographic information showing that a disproportionate share of the people living nearby those hog operations are people of color and low-wealth households. Reporting who will be affected by permitting decisions is not enough; DEQ must also document the nature of the effects of the permitting decisions, the cumulative effects of other DEQ-permitted operations in the community, and the potential impact of pollution or adverse public health outcomes on vulnerable communities. For the previous biogas permit decisions, DEQ took no steps to evaluate or prevent the serious adverse impacts, such as increased health problems and death rates, associated with hog operation pollution, which are only going to increase with the addition of biogas production at these operations. Title VI requires more from DEQ.

III. Recommendations

To meet its obligations under state and federal laws and to address the anticipated increase in ammonia emissions and the resulting pollution to surface waters, groundwater, and human health, DEQ must include conditions in the biogas general permit that go above and beyond the existing 2019 swine general permit. But before DEQ issues the biogas general permit, the agency must conduct several analyses to comply with state and federal permitting requirements.

A. Procedural recommendations

Under the state water permitting statute, DEQ must conduct a thorough analysis of the combined effect of its decision to permit hog operations that will increase overall ammonia emissions *plus* the effect of other permitted operations on rivers and streams and groundwater. It is not enough for DEQ to acknowledge "atmospheric losses from lagoons" in a line in a public meeting report and move on.[13] DEQ cannot ignore this substantial source of pollution or its effects on water quality and public health. And data on cumulative effects are not hard to come by: DEQ itself has studied water quality in areas of high concentrations of animal feeding operations and found these waters have elevated levels of pollutants. DEQ must consider this information in its permitting.

In addition, DEQ should research and develop a list of waste treatment and disposal alternatives that are compatible with biogas production and reduce the risk of air and water pollution; permittees should have the option to choose the alternative that is most compatible with its operation. To aid DEQ in this evaluation, Exhibit 5 attached to these comments provides a summary of several waste treatment and disposal alternatives that are compatible with biogas

[12] *S. Camden Citizens in Action v. New Jersey Dept. of Envtl. Protection*, 145 F. Supp. 2d 446, 476 (D. N.J. 2001).
[13] *Swine Biogas Permit Modifications: Public Meeting Report and Recommendations*, N.C. Dep't of Env'tl Quality, 14, 18 (Mar. 2021), https://deq.nc.gov/media/21373/download.

production and result in less air and water pollution than the lagoon and sprayfield system equipped with a digester.

B. Substantive recommendations

To comply with federal civil rights laws, DEQ must also analyze the effect of the biogas general permit and other facilities and prevent harmful air and water pollution that have disproportionate impacts on the basis of race, color, or national origin. The hog operations that would be eligible for coverage under the biogas general permit are disproportionately located in Black, Latinx, and Native American communities which are already overburdened by pollution from countless polluting facilities in eastern North Carolina. These analyses must be more than paper exercises; results of these analyses must inform DEQ's permitting decisions, including its decision about whether a particular facility can be covered under the biogas general permit and what pollution control measures are needed.

In addition, the biogas general permit should acknowledge the effect of ammonia emissions on water quality and include specific provisions to control ammonia emissions from hog operations covered under the biogas general permit.

Because the evaluation of cumulative impacts is best conducted in the context of a specific geographic area, DEQ should put permit applicants on notice that the results of the agency's evaluations of cumulative effects on water quality and/or cumulative impacts on local residents may require that the agency issue an individual permit with site-specific conditions.

In addition, DEQ must include robust, frequent monitoring and reporting requirements to ensure compliance with surface water and groundwater standards and permit conditions. At a minimum, these requirements should include:

- Monthly groundwater monitoring with monitoring wells installed upgradient and downgradient of the digester and secondary lagoon(s);
- Monthly sampling and reporting of the influent and effluent of the digester for the following water quality parameters: Total Nitrogen, Total Kjeldahl Nitrogen, ammonium nitrogen, copper, sulfur, nitrate nitrogen, Total Phosphorus, zinc, and fecal coliform bacteria;
- Monthly sampling of the waste that is to be land-applied for the following parameters: Total Nitrogen, Total Kjeldahl Nitrogen, ammonium nitrogen, Total Phosphorus, zinc, copper, and fecal coliform bacteria;
- Monthly sampling and analysis of surface water, specifically tributaries previously impacted by operations and/or in the flow path of each site/lagoon for the following parameters: Total Nitrogen, Total Phosphorus, Total Suspended Solids, BOD, fecal coliform, *E.coli*, Total Kjeldahl Nitrogen, ammonia, and nitrates/nitrite;
- Quarterly soil sampling from land application fields at 2 and 10 inches and analyzed for phosphorus, mineral/heavy metals, Total Organic Carbon, total carbon, Total Nitrogen, Total Kjeldahl Nitrogen, pH, and nitrate; and
- Monthly air quality monitoring for ammonia emissions.

Permittees should report all results of sampling to DEQ on an annual basis.

Finally, to address the possibility of increased nitrate levels in the land-applied waste, DEQ should require *at least* annual updates to nutrient utilization plans and animal waste management plans for all operations that are based on the monthly digester waste sampling described above.

IV. Conclusion

SELC and the undersigned urge DEQ to adopt the recommendations herein and in the Environmental Justice & Equity Advisory Board's October 22, 2021 letter to DEQ Secretary Elizabeth Biser. We look forward to participating in the public comment process in early 2022, and will supplement these comments at that time.

Thank you for your consideration of these comments.

Sincerely,

Blakely E. Hildebrand

SENT VIA EMAIL

October 22, 2021

Elizabeth S. Biser, Secretary
N.C. Department of Environmental Quality
217 W. Jones Street
Raleigh, NC 27603

Dear Secretary Biser:

The Environmental Justice and Equity (EJE) Advisory Board was chartered to assist the Department of Environmental Quality (DEQ) in ensuring fair and equal treatment and meaningful involvement of all North Carolinians, regardless of race, color, national origin, or income, in the development, implementation, and enforcement of environmental laws and policies. In this role, we strive to ensure access to clean air, clean water, and clean soil, and the opportunity to live in safe and healthy communities for all North Carolina families.

Today, we write to you about pollution from hog operations, a long-standing environmental justice issue that has affected thousands of North Carolina families for decades. We respectfully request that DEQ take steps to protect these families, their health, and the environment.

Under the 2021 North Carolina Farm Act, N.C. Sess. L. 2021-78, DEQ must develop a general permit for hog operations that will produce swine waste-to-energy (biogas) by July 2022. As we expressed in our August 26, 2021 letter to you, the EJE Advisory Board has significant concerns about the pollution and public health implications of this general permitting scheme.

In addition to the procedural recommendations we provided in our August 26, 2021 letter, we advise DEQ to ensure the new general permit include robust substantive protections against hog waste pollution and its disparate impacts on surrounding communities. Cleaner technologies and practices that reduce water and air pollution—and that are compatible with biogas production—are available and practicable. In fact, some of these technologies are used by Smithfield Foods, the nation's largest pork producer, in other states. North Carolinians deserve the same protections.

In North Carolina, biogas is produced by capturing methane from hog waste lagoons using covered anaerobic digesters. To date, DEQ has allowed hog operations to dispose of waste from these digesters by transferring the digester waste to open "secondary" lagoons, and spraying the digester waste on fields.[1] The biogas is sent off-site for processing and eventually used to produce energy. Biogas produced using the lagoon and sprayfield system is not a clean source of energy.

[1] *See, e.g.*, Permit No. AWI310039 Benson Farm (Mar. 31, 2021) (authorizing the use of a Waste-to-Energy system, which includes a covered anaerobic digester; a clay-lined lagoon; pumps, pipes, and other equipment to transfer waste; and sprayfields).

The lagoon and sprayfield waste management system used at industrial hog operations pollutes waterways,[2] contaminates drinking water,[3] and dirties the air people breathe.[4] This pollution and the resulting harms to human health have burdened neighbors—mainly people of color and low wealth communities--for decades.[5] As such, this is one of the most significant and well-studied environmental injustices in North Carolina; public health and environmental experts agree on the harm that this system causes for people and the environment.

Producing biogas from hog waste using anaerobic digesters, open secondary lagoons, and sprayfields does *not* address many of the longstanding, serious pollution problems of using open lagoons and sprayfields to store and dispose of hog waste. The use of digesters is likely to *increase* ammonia emissions when the digester waste is stored in open secondary lagoons and sprayed on fields.[6] Airborne ammonia from hog operations deposits in surrounding waterways, causing

AIR

pollution that can lead to algae blooms and fish kills.[7] Airborne ammonia also deposits on the ground, where it can seep into the soil and cause nitrate pollution in drinking well water, which can harm infants and pregnant women.[8] Airborne ammonia also forms fine particulate pollution that causes serious health problems and premature deaths in surrounding communities.

In fact, a recent study published by the National Academy of Sciences attributes an astounding 95 premature deaths in Sampson County and 83 premature deaths in Duplin County to the emissions from hog operations every year.[9] This is already an unacceptable situation that must be stopped. And the prospect of *increasing* the rates of sickness or death, resulting from sending more ammonia and fine particulate pollution into the surrounding environment, is simply unacceptable. DEQ must not allow hog waste pollution to continue harming more people in our most vulnerable communities.

Communities in eastern North Carolina have been complaining about pollution from industrial hog operations for decades. Since DEQ began considering permits for the first large-scale biogas project almost two years ago, hundreds of people across eastern North Carolina and beyond participated in public hearings, submitted comments, and appealed to DEQ to protect their communities and the environment from pollution from lagoons and sprayfields. To date, DEQ has failed to heed these calls.

In developing the conditions of the biogas general permit, DEQ must address this environmental injustice and protect families and the environment in eastern North Carolina. To start, DEQ's environmental justice analysis must be more than a formality intended to inform agency outreach. Instead, DEQ must conduct a comprehensive environmental justice analysis that translates into substantive permit conditions to minimize disparate impacts from cumulative impacts of the general permit and other DEQ-permitted operations on surrounding communities, including

communities of color and low-wealth communities that are already overburdened by pollution from multiple industries.[10] To be clear, it is not enough for DEQ to evaluate the cumulative effects of permitting decisions on water quality, as required under state environmental law; the agency, as a recipient of federal funding, also has obligations under Title VI of the Civil Rights Act of 1964, which require the agency to address harm to vulnerable North Carolinians.

In addition, as part of the general permit, we strongly advise DEQ to require the following:

- Cleaner technology and practices that are compatible with biogas production *and* address water and air pollution caused by the lagoon and sprayfield system, particularly given the increased ammonia pollution associated with open storage of biogas digester waste;

- Robust groundwater and surface water monitoring at every hog operation to identify pollution to rivers, streams, and groundwater, which is a source of drinking water for many rural residents;

- Updated nutrient management plans that account for the changes in the land-applied waste after digestion; and

- More protective freeboard requirements, such as automated lagoon/storage pond waste-level monitors and recorders, to reduce the likelihood that flooding or inundation of lagoons due to increasing frequent and severe storms will result in the discharge of the more harmful digester waste.

Thank you for your attention to this important matter.

Respectfully submitted by the EJE Advisory Board

James H. Johnson, Jr., Chair
Marian Johnson-Thompson, Vice Chair

[10] DEQ must scrutinize the environmental impact of the poultry industry as part of this analysis, as poultry operations with 30,000 or more birds are deemed permitted under state law, are often co-located in communities hosting swine operations, and have proliferated most rapidly in recent years in communities of color.

Exhibit 2

The Risk of Increased Cumulative Effects and Water Pollution from Swine Operations Producing Biogas in North Carolina

Summary compiled by Dr. Michael A. Mallin, Research Professor, Center for Marine Sciences, University of North Carolina Wilmington on behalf of Environmental Justice Community Action Network & Cape Fear River Watch

Environmental Justice Community Action Network & Cape Fear River Watch vs. N.C. Department of Environmental Quality – Division of Water Resources & Murphy-Brown, LLC 21 EHR 02068, 02069, 02070, 02071

I. Executive Summary

On March 31, 2021, N.C. Department of Environmental Quality ("DEQ") issued permits to four industrial hog operations in the lower Cape Fear River basin: AWI301135 (Waters Farm – M&M Rivenbark), AWI310039 (Benson Farm), AWI820466 (Farm 2037 and 2038/Goodson Farm), and AWS820005 (Kilpatrick Farm 1, 2, 4 & 5 & Merritt Farm) (together the "Hog Operations"). The new permits allow three of the Hog Operations to excavate and install new lagoons to act as digesters, and allow the fourth operation (Kilpatrick Farm) to cover an existing lagoon to produce swine waste-to-energy biogas. The permits also allow these operations to add new piping and pumps to transfer waste between digesters/covered lagoons, secondary (open-air) lagoons, and land application fields.

This summary addresses the cumulative effects of pollution from hog operations in the Cape Fear River basin. This report surveys the types of pollution and their effects and the means by which hog operations contribute to these cumulative effects on surface water and groundwater quality in the Cape Fear River basin.

This summary also applies this research to draw conclusions about how the waste management systems authorized by the four permits issued by DEQ in this case fail to prevent adverse impacts to water quality and may increase the cumulative impacts of pollution in the Cape Fear River basin. This opinion is based on the plans submitted for these facilities, the location of these facilities, the site conditions at each facility, and a long history of published research on the impacts of the swine waste disposal methods similar to those permitted for the four operations.

To summarize, the new permits for the Hog Operations in the Cape Fear River basin will use a lagoon and sprayfield waste management system to manage and dispose of hog waste by installing new equipment to transfer hog waste to anaerobic digesters/covered lagoons and then to earthen, open air lagoons and spraying this waste onto nearby sprayfields. Abundant published research indicates that nutrients and fecal bacteria in swine waste cannot be contained on-site when this waste management system is used, and this waste management system is likely to pollute offsite waters of the state, creating adverse impacts to water quality and increasing human health risk. Furthermore, research indicates that covered lagoons have more concentrated ammonia, phosphate and fecal coliform bacteria than open lagoons, which increases offsite pollution threats. Anaerobic digesters concentrate ammonium to very high levels, which will then be piped to an open lagoon where volatilization to the atmosphere will occur; the waste will be sprayed out, and further volatilization of ammonia will occur. Atmospheric ammonia from swine sprayfield operations travels well offsite and is later deposited onto public waters and private property, degrading water quality and entering other individuals' airspace. As these new covered digester lagoons will have very high ammonia concentrations, the permitted operations are likely to further pollute waters of the state.

II. Background

The vast majority of swine and poultry in North Carolina are raised in large, industrial-style mass production facilities known as concentrated animal feeding operations (CAFOs, also called AFOs, or ILOs, intensive livestock operations). The U.S. Environmental Protection Agency ("EPA") (2014) defines large CAFOs as containing $\geq$ 1,000 head of beef cattle, 2,500 swine > 25 kg, 10,000 swine < 25 kg, 125,000 chickens, 82,000 laying hens or 55,000 turkeys. While inventory and sales vary year-to-year, the 2017 Census of Agriculture showed North Carolina to be the second-largest producer of swine in the USA, only behind Iowa (USDA 2021). The Cape Fear River basin drains the largest concentration of swine CAFOs in North Carolina.

Swine CAFOs consist of hundreds to many thousands of head of swine living in close quarters (see photos), which generate vast volumes of animal manure. The floors of hog houses have slats, through which manure and urine falls or is rinsed. Swine waste is then drained, flushed, or pumped into outdoor pits called lagoons where some anaerobic digestion occurs; it can also be pumped into covered lagoons, or covered lagoon/anaerobic digesters where ammonia concentration occurs. At a conventional hog operation, the liquid waste is periodically pumped out of the uncovered lagoons and sprayed onto adjoining sprayfields (see photos), many with a cover crop of Bermudagrass. Under the new permits for the Hog Operations, the liquid waste will be transferred from the covered lagoon/digester to a secondary lagoon, and ultimately land applied on nearby fields. In North Carolina spraying of animal waste onto Bermudagrass fields is permitted between March 1 and September 30.

Explanation of photos: (left) Eastern North Carolina swine CAFOs showing hog houses and waste lagoons, (middle) Swine within hog house with slats in floor for manure removal, (right) Spraying swine lagoon waste out on a saturated sprayfield (indicating a high water table), with the waste ponding at the surface (photos by Dr. M.A. Mallin).

This section describes sources of cumulative effects on water quality from CAFOs in the Cape Fear River basin. Section IV below discusses how the waste management systems at the Hog Operations are likely to contribute to these issues.

a. Waste lagoon pollutants and their effects on aquatic systems

The type of swine waste management systems used at the Hog Operations have a variety of effects on water quality. There are several key pollutants in swine waste that are threats to water quality and human health. Foremost among them are excess nitrogen (primarily in the forms of ammonia and nitrate), phosphorus, fecal bacteria and viruses, and biochemical oxygen demand. These pollutants reach rivers and streams in a variety of ways, including via airborne deposition from swine waste spraying (i.e., ammonia, fecal bacteria, and other pollutants), surface water runoff from sprayfields during precipitation events (i.e., stormwater runoff of nitrate, phosphorus and fecal microbes), and groundwater contamination and subsequent sub-surface movement into streams (i.e., nitrate and fecal bacteria). Accidents of all kinds periodically occur that release swine waste into nearby streams; note that such releases have occurred at the Waters Farm in recent years.

Importantly, the distance of some CAFOs to public waters can be uncomfortably short, which increases the risk that pollution from these operations reaches surface waters, particularly during rain events. Martin et al. (2018) used a GIS mapping approach to determine that 19% of North Carolina CAFOs (primarily swine) were located within 100 meters of a stream, with some less than 15 meters from the stream's edge. FEMA flood maps provided by Murphy-Brown indicate that some sprayfields at Farm 2037 & 2038 (Goodson Farm) are located in the floodplain and a sprayfield at the Kilpatrick Farm appears to be close to stream waters.

The Hog Operations are located nearby several streams in the lower Cape Fear River Basin. The Kilpatrick Farm is located along a tributary to Stewart's Creek, which drains into Six Runs Creek, a major tributary of the Black River; the proposed digester is approximately 2,000 ft. from Stewart's Creek proper. The Waters Farm property appears to be drained by two different watersheds, with the proposed digester site located about equidistant between Stewart's Creek in the Six Runs Creek drainage, and Murphey's Creek in the Rockfish Creek drainage. Farm 2037 & 2038 (Goodson Farm) is located near the juncture of Turkey Creek and Six Runs Creek, with the proposed digester site approximately 1,000 ft. from Turkey Creek and roughly 3,000 ft. from Six Runs Creek. The Benson Farm is located near Goshen Swamp.

i. *Bacteria runs off into nearby rivers and streams*

Fecal coliform bacteria, which are an indicator bacteria for the presence of pathogenic bacteria, have been found (see Mallin et al. 2015; Mallin and McIver 2018; NCDEQ 2020) to be excessively high in streams that pass near sprayfields (at times many thousands of colony-forming units per 100 milliliters of water (CFU/100 mL)), well exceeding the North Carolina standard for Class C waters (geometric mean of no more than 200 CFU/100 mL from five sample collections within 30 days). Normal rain events occurring shortly after animal waste is land-applied to fields cause vertical and horizontal movement of microbes to nearby water bodies (Crane et al., 1983; Mawdsley et al., 1995).

ii. Nitrate and ammonia in excess are highly polluting

Nitrogen (N) in water exists in both organic and inorganic forms. Under anaerobic conditions, such as within waste lagoons, there is no dissolved oxygen, and ammonia is the major inorganic N form; data from five swine lagoons yielded an average ammonia concentration of 550 mg/L (Westerman et al. 1990); ammonia concentrations in swine waste lagoons in Utah, including biofuel digesters are even higher (Harper et al. 2010). To put this into perspective, average ammonia in raw human sewage is far lower, about 15 mg/L (Clark et al. 1977). When swine waste is sprayed onto fields where there is abundant oxygen, natural bacteria convert (oxidize) much of this ammonia to nitrate. Nitrate is highly mobile in groundwater as it is negatively charged, as is clay, and thus does not adhere to soil particles. As a result large quantities of nitrate readily move into groundwater below sprayfields and from there laterally to surface waters off-site and downstream. This movement off-site is enhanced when soils are porous and the groundwater table shallow, such as in much of the North Carolina Coastal Plain. Nitrate is also readily moved overland to the nearest stream by stormwater runoff.

Elevated nitrate concentrations have been reported to cause toxic effects on aquatic animals including fish. Mortality and developmental changes in fish and amphibians have been documented from exposure to concentrations of nitrate less than the 10 mg/L drinking water standard established by the U.S. Environmental Protection Agency (Guillette and Edwards 2005); such effects are very species-specific and largely impact early developmental stages rather than adults.

In addition, in Coastal Plain blackwater streams, inputs of inorganic nitrogen (nitrate or ammonium) stimulate the growth of algae (Mallin and Cahoon 2020), in some cases to excessive levels (algal blooms). Note that even small concentrations of nitrate or ammonium can stimulate this growth -- 0.50 mg/L or less of nitrate or ammonium or about one hundred times *less* than concentrations of inorganic nitrogen in swine waste lagoons. The levels of ammonium or nitrate concentrations sampled in streams near sprayfields or downstream from sprayfields far exceed 0.50 mg/L (Harden 2015; Mallin et al. 2015; Mallin and McIver 2018; NCDEQ 2020; Sousan et al. 2021).

Either consistent inputs of elevated levels of ammonium or nitrate such as above, or acute accidents releasing large quantities of nutrients from animal waste can cause algal blooms (Burkholder et al. 1997; Mallin et al. 1997; Mallin et al. 2015). Once algal blooms die, the organic remains are fed on by natural bacteria, which multiply greatly and use up dissolved oxygen in a process called respiration. This creates what is called a biochemical oxygen demand (BOD), which reduces dissolved oxygen in the water column. The State of North Carolina has dissolved oxygen requirements for most waters of 5.0 mg/L, and 4.0 mg/L for swamp waters. When dissolved oxygen levels are reduced by high BOD to low levels (< 2.0 mg/L) fish kills may occur; low dissolved oxygen is commonly cited as a reason for fish kills by North Carolina Division of Water Quality (NCDEQ website). DEQ also notes that lack of oxygen created by decomposing algal blooms sometimes results in fish kills and other aquatic life impacts.

iii. Phosphorus

Swine waste also contains high concentrations of phosphorus. A survey of five swine lagoons yielded an average total phosphorus (P) concentration of 100 mg/L (Westerman et al. 1990). Average total phosphorus in raw human sewage is about 10 mg/L, for comparison (Clark et al. 1977). Excess phosphorus (concentrations > 0.50 mg/L) in Coastal Plain stream waters are known to directly stimulate the growth of aquatic bacteria, thus increasing BOD, and further straining dissolved oxygen levels (Mallin and Cahoon 2020). The lower Cape Fear River is currently on the North Carolina list of impaired waters for low dissolved oxygen, meaning the levels of dissolved oxygen are persistently below state water quality standards. These conditions can lead to fish kills and make waters unsafe for recreation. The Cape Fear River system also hosts dwindling numbers of Atlantic sturgeon, which are federally-listed endangered species; a number of these were killed by low dissolved oxygen from high BOD from swine waste lagoon releases and human sewage releases following Hurricane Florence in 2018.

b. Ammonia volatilization from swine lagoons and sprayfields

Ammonia volatilizes from sprayfields and waste lagoons, and is transported downwind (McCulloch et al. 1998; Aneja et al. 2000; Walker et al. 2000). Walker et al. (2000) documented a trend of increasing ammonium deposition in the coastal region of North Carolina, which they attributed to animal production sources. The lower Cape Fear River watershed, draining the largest concentration of CAFOS in the state, showed a 30% increase in airborne ammonium from the period 1988 to 2003 (Willey et al. 2006), which was attributed to increases in swine industry airborne discharges. Research has demonstrated that ammonia aerosolized from lagoons and sprayfields comes back to earth within 60 miles of its point of origin, where many sensitive water bodies on the NC Coastal Plain are located (Costanza et al. 2008). This form of nitrogen loading can contribute to the eutrophication of streams, lakes, rivers and estuaries. Ammonia can also reduce dissolved oxygen in surface waters, thereby increasing BOD. This is because ammonium is a chemically reduced compound; when it enters a stream and encounters dissolved oxygen in the presence of nitrifying bacteria, it absorbs the dissolved oxygen and is converted to nitrate, an oxidized compound. The net result is that this process removes dissolved oxygen from the water, stressing aquatic life.

c. Groundwater contamination

The Hog Operations sit on generally sandy, permeable soils (Autryville soils are the most abundant; others present include Wagram, Norfolk, Johns and Lumbee), and there is a high water table (0-2 meters). Permeability of Autryville soils is classified as moderately rapid (2.0-6.0 inches/day) and the permeability of the others as generally moderate, or 0.6-2.0 inches/day (USDA-NRCS website). This combination makes downward movement of rainfall—and nitrate-containing liquids sprayed on fields—to the water table quite rapid, hours to a few days maximum. Nitrate has been documented to readily enter groundwater from agricultural sources (Liebhart et al. 1979; Keeney 1986; Ritter and Chirnside 1990), where it can impact drinking water. Elevated nitrate in well water is known to cause potentially-fatal methemoglobinemia, or blue-baby syndrome (Johnson and Koss 1990); as such the U.S. EPA and Canada established drinking water standards for nitrate at 10 mg/L. Additionally, there is a growing body of evidence suggesting that elevated nitrate levels are associated with other human health factors including various cancers (Temkin et al. 2019). A study by the North Carolina Department of Health and Human Services in the late 1990s found elevated nitrate (above 10 mg/L) in 10% of 1595 wells tested statewide. However, the percent of contaminated wells that were adjacent to swine CAFOs (called ILOs in the report) was *three times* the statewide average for nitrate contaminated wells elsewhere. Sampson and Duplin counties showed the highest percentage of contaminated wells, with leaking hog waste lagoons and sprayfields specifically noted as responsible for the exceedances in some instances (Rudo 1999).

On a chronic, long-term basis swine waste lagoons and sprayfield waste pollute area groundwater with nitrate, an oxidized form of dissolved nitrogen. Groundwater sampling wells near hog operations have been found to far exceed the nitrate drinking water standard of 10 mg/L, in some cases up to 70 mg/L (Westerman et al. 1987; Ritter and Chirnside 1990), and ammonium in groundwater exceeded 500 mg/L in some sampling sites near swine CAFOs (Westerman et al. 1995). To put this concentration into perspective, the ammonium concentration of raw human sewage is about 15 mg/L; (Clark et al. 1977) and the concentration of ammonium known to stimulate growth of algae in Coastal Plain streamwater is 0.50 mg/L or less (Mallin and Cahoon 2020). Many lagoons are built on soils of low permeability or soils which seal through biological action or sedimentation, but clay liners or synthetic liners are required where the soils on site are too permeable (Zering 2005). Unlined lagoons are clearly subject to leakage (Westerman et al. 1995); however, even clay liners crack and significant quantities of nitrate leak into the soil beneath lagoons where it will enter groundwater (Ritter and Chirnside 1990). The studies cited above found nitrate levels in groundwater below sprayfields to be many times the 10 mg/L drinking water standard, and an NC Health Department study demonstrated nitrate polluted drinking wells were most concentrated near swine CAFOs, to put groundwater pollution into perspective.

In a study I conducted along Stocking Head Creek, in Duplin County, N.C., Mallin et al. (2015), my colleagues and I found very high concentrations of fecal coliform bacteria, ammonium, and nitrate in a stream passing through a watershed with numerous swine and poultry CAFOs. There was no difference in fecal coliform, ammonium, and nitrate concentrations between wet periods (rain within 48 hours prior to sampling) and dry periods, indicating that waste spraying caused percolation of pollutants through the soil to the groundwater table, causing chronic groundwater contamination, which moved laterally into the stream from there.

d. Nitrate from swine CAFO traveling well offsite under normal operations

Chemists use isotopic ratio techniques (^{15}N) to trace the origins of nitrogen in the environment; for instance the ^{15}N signal of atmospheric nitrogen "fixed" by crop legumes or blue-green algae is approximately zero, nitrogen from chemical fertilizers is around 0-2, and nitrogen from swine waste is high, 10-20 or more. Using nitrogen isotopic (^{15}N) techniques Karr et al., (2001) traced nitrate generated from swine CAFOs through shallow groundwater into receiving stream waters, and at least 1.5 km downstream. A later and much broader ^{15}N study in eastern North Carolina by Harden (2015) also used ^{15}N isotopic techniques and found that CAFO-influenced streams were significantly more enriched in ^{15}N than control streams with no

CAFOs, and the ^{15}N values in the CAFO sites agreed with ^{15}N signals common to manure signals. A third more recent study found highly enriched ^{15}N signatures associated with streams draining swine CAFO-impacted areas (especially following the onset of spraying season), as well as two sites impacted by human wastewater discharges, whereas a near-pristine control stream and two sites near the ocean showed unenriched ^{15}N signatures (Brown et al. 2020). In that study high nitrate concentrations were positively correlated with enriched ^{15}N signatures, indicating that swine waste and sewage were the primary sources of high nitrate to the system rather than chemical fertilizers. On one occasion during spraying season when high river flow occurred, CAFO-generated ^{15}N was detected scores of miles downstream to the upper estuary (Brown et al. 2020).

e. Failures of animal waste lagoons

Animal waste lagoons are subject to wall failures (breaches) and overtoppings (spills), which can result in the release of untreated hog waste into waterways, polluting those waterways and degrading water quality. Severe weather conditions can lead to lagoon failures. This has been documented after numerous storms over the last few decades. The 1995 hurricane season resulted in several CAFO spills in North Carolina – New River (swine), 25,000,000 gallons and Harris Creek (swine) 1,000,000 gallons. More recently, in 2018, Hurricane Florence led to the spill of millions of gallons of hog waste polluting the Cape Fear River. A recent report by state regulators (NCDEQ 2020) found that several swine operations in the Stocking Head Creek watershed had their entire operations or their sprayfields inundated by floodwaters from Hurricane Florence in 2018. Please see photos below for examples of flooded CAFO operations as a result of hurricanes. According to numerous scientific papers in the past decade storms are getting stronger, and stronger storms are expected to increase in number. With stronger storms comes greater flooding; besides Florence, we recently witnessed extreme flooding along the Gulf of Mexico from Hurricane Ida. Thus, I expect further flooding of swine production facilities in Eastern North Carolina, whether on the flood plain or beyond it.

Structural failures or equipment malfunctions can also lead to spills at hog operations. In 2017, a pipe at the Waters Farm broke, leading to 900 gallons of hog waste into an unnamed tributary of Stewarts Creek. In 2019, a pipe broke at Waters Farm leading to approximately 800 gallons of wastewater reaching surface waters. Those accidents point out how close the Waters Farm operation is to waters of the state. These and other types of accidents causing water pollution continue to periodically occur in North Carolina swine waste management systems using lagoons.

Swine lagoon accidents have caused severe water quality damage in receiving streams, with excessive loading of nitrogen, phosphorus, fecal microbes, and BOD; these incidents have also caused very low dissolved oxygen and fish and crustacean kills in receiving waters (Burkholder et al. 1997; Mallin et al. 1997).

f. Vulnerability to flooding and lagoon failure

Whereas any individual CAFO may show localized pollution, the numerous swine CAFOs currently present, coupled with an ever-increasing number of poultry CAFOs (Patt

2017), pose major chronic, long-term pollution issues to Coastal Plain watersheds. Many CAFOs are located on river floodplains, which makes their lagoons or sprayfields more vulnerable to flooding by hurricane floodwaters (see photos below), as well as to lagoon breaches through weakened walls. A GIS-based analysis of areas flooded during Hurricane Floyd estimated that 241 CAFOs were located within flooded areas, as estimated by satellite photography (Wing et al. 2002). However, Hurricane Florence caused flooding far outside of the 100-year floodplain (even I-40 was flooded for days), so being located outside of the floodplain does not guarantee freedom from flooding.

Above: Flooded swine and poultry CAFOs after Hurricanes Floyd and Florence in Eastern North Carolina (photos courtesy of Rick Dove, Waterkeeper Alliance, and Walker Golder, Audubon).

According to FEMA maps provided by Murphy Brown, some sprayfields at Farm 2037 & 2038 (Goodson Farm) are located in the floodplain, and a sprayfield at Kilpatrick Farm is located close to the 100-year floodplain and nearby streams. These sprayfields are particularly vulnerable to flooding during major rain events.

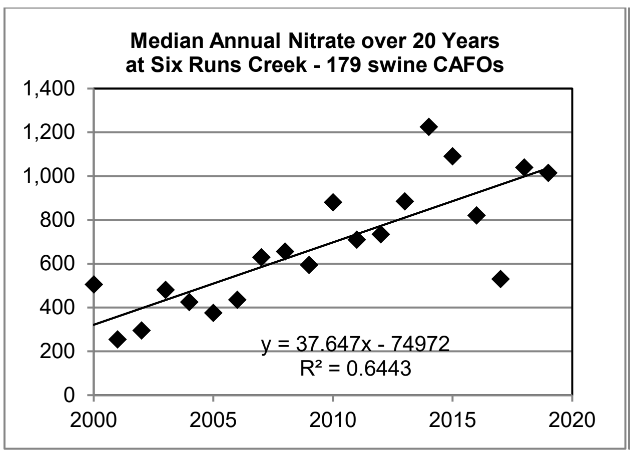
III. Hog CAFOs have a cumulative effect on water quality in the Cape Fear River basin.

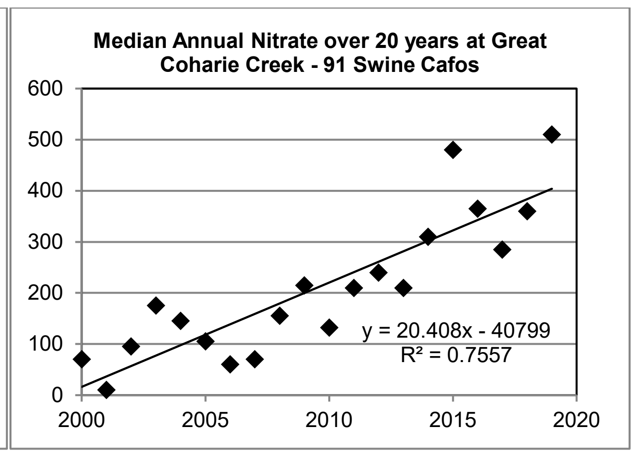
In my 2015 Stocking Head Creek Study, Mallin et al. (2015), my colleagues and I investigated chronic pollutant loading to a 2^{nd} order stream (Stocking Head Creek) with a watershed containing 13 swine and 11 poultry CAFOs. At a stream site adjoining a sprayfield, ammonium ranged up to 38 mg/L, and Total Phosphorus up to 11 mg/L, with fecal coliform counts up to 60,000 CFU/100 mL. Stream sites well downstream from sprayfields had average nitrate concentrations > 6 mg/L, ranging up to 13.6 mg/L. Stream BOD5 concentrations ranged up to 26 mg/L, and were strongly correlated with ammonium ($r = 0.666$, $p<0.0001$ and TP ($r = 0.626$, $p <0.0001$); BOD5 of unpolluted streams is typically 1 to 2 mg/L. Additionally, a broad-scale North Carolina USGS study found that streams whose watersheds contained swine and poultry CAFOs had significantly higher concentrations of ammonium, nitrate and total N than streams whose watersheds lacked CAFOs (Harden 2015). Several other studies have also demonstrated high nitrate concentrations occurring in CAFO-influenced streams (Weldon and Hornbuckle 2006; Hoorman et al. 2008; Mallin and McIver 2018; NCDEQ 2020).

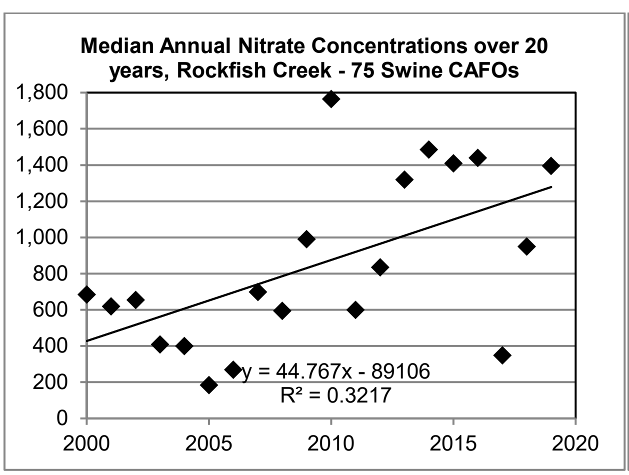
Initial sampling results by DEQ as part of the Cape Fear River Animal Operations Monitoring Study (DEQ 2020) indicate that Murphey's Creek downstream of the Waters Farm has elevated levels of nitrate/nitrite. And ongoing sampling efforts in Stewarts Creek, adjacent to Kilpatrick farm AWS820005, by Cape Fear River Watch likewise show high nitrate and fecal bacteria concentrations. Critically, it has been demonstrated (Mallin and McIver 2018) that

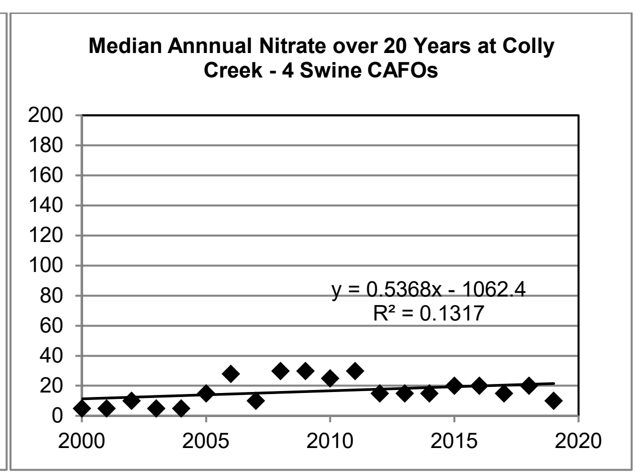
CAFO-influenced stream sites contain significantly higher concentrations of nitrate, total nitrogen, total organic carbon, and fecal coliform bacteria in mid-summer (spraying season) than in early March (spraying is only allowed March 1 – September 30). This indicates that spraying of waste leads to higher levels of off-site pollution than in non-spraying periods.

Several stream stations in the lower Cape Fear watershed have been sampled monthly since 1995 using state-certified techniques by the Lower Cape Fear River Program (LCFRP), which reports these data to DEQ. A number of long-term stream sampling sites collect from watersheds where copious swine and poultry CAFOs are located (Six Runs Creek, Great Coharie Creek, and Rockfish Creek for instance) and have shown increases in nitrate over time to quite high levels (see figures below), whereas Colly Creek, with very few watershed CAFOs, has low nitrate with no significant increase. Farm 2037 & 2038 (Goodson Farm,) is on Six Runs Creek, and is located upstream of the Six Runs Creek long-term LCFRP sampling site. Kilpatrick Farm and Waters Farm (in part) are also located upstream of the Six Runs Creek long-term LCFRP sampling site, which drains into Stewarts Creek, which drains into Six Runs Creek. Waters Farm is partially on Murphey's Creek, draining into Rockfish Creek, which is upstream of the long-term LCFRP sampling site.









Explanation of graphs: The median values (from the monthly nitrate concentrations) for each year over the 20-year period 2000-2019 were computed. Six Runs Creek, Great Coharie Creek and Rockfish Creek all drain watersheds with many swine CAFOs and strong increasing trends in nitrate are evident for all. In contrast, the Colly Creek watershed has very few CAFOs but abundant wetlands coverage and shows extremely low nitrate and no significant increase. Swine CAFO numbers are approximations.

IV. The permits will not prevent adverse impacts to water quality

If a swine waste lagoon is covered, as some lagoons at the Hog Operations will be, this will greatly reduce the volatilization of microscopic (< 2.5 μg) air pollutants from the lagoon (Sousan et al. 2021). However, covered waste lagoons can concentrate pollutants within. North Carolina researchers performed a study of covered versus uncovered waste lagoons and found that the liquid waste in the covered lagoon contained 2.3X the ammonium concentration of the liquid waste uncovered lagoon (Ducey et al. 2019). That same study found that inorganic phosphate in the liquid waste in the covered lagoon was 3.1X the concentration of the liquid waste in the uncovered lagoon (Ducey et al. 2019). Furthermore, that same study found that the concentrations of fecal coliform bacteria and *Escherichia coli* (*E. coli*) bacteria in the liquid waste in the covered lagoon were significantly higher than in the uncovered lagoon.

This means that when waste from covered lagoons are sprayed out on adjoining fields, the concentration of nitrogen, phosphorus and fecal bacteria are actually higher than that of waste sprayed from an uncovered lagoon. Another North Carolina study of a covered waste lagoon operation containing an anaerobic digester (Sousan et al. 2021) found that stream waters downstream of the sprayfield had 8X more ammonium plus nitrate than upstream of the sprayfield, and a seep discharging groundwater from the sprayfield yielded an average concentration of 32.0 mg/L of ammonium plus nitrate. On two incidents during and after spraying, Sousan et al. (2021) found that the ammonium plus nitrate reached the remarkably high concentrations of 140 mg/L and 83 mg/L downstream of the sprayfield, a condition that persisted for some 20 hours.

The new waste management systems at the Hog Operations are likely to increase pollution to waters of the state off-site and downstream of the sites. According to the literature noted above, waste from covered lagoons, as allowed under the permits, show higher ammonia concentrations than uncovered lagoons; the waste at the permitted operations will be pumped into open lagoons (which have very high nutrient and bacteria concentrations) and then the waste will be sprayed on sprayfields. Ammonia will volatilize from both the open lagoons and sprayfields. Numerous peer-reviewed publications and my research have demonstrated that spraying of swine waste onto fields, as will be done at the Hog Operations, causes nutrient and bacterial pollution of stream waters outside of the sprayfield. Movement overland to the nearest stream through stormwater runoff occurs on swine waste deposition fields, like the ones at the four permitted Hog Operations, as do operational accidents.

As noted above, the Hog Operations sit on Autryville and other sandy, permeable soils, and the water table in this area is generally high. This facilitates nitrate movement into the groundwater, from where it moves laterally to the nearest stream to become part of its base flow, from where it is carried far downstream from the facility's property.

Adding to the risk of water pollution are the locations of the Hog Operations: a sprayfield at Farm 2037 & 2038 (Goodson Farm) is located in the floodplain, and a sprayfield at the Kilpatrick Farm appears to be close to the floodplain. The proximity of these fields to streams increases the chances of flooding, and thus movement of pollutants in land-applied waste into waterways. This is particularly troubling in light of the increasing severity and frequency of rain events.

At least the Waters Farm has been previously cited for discharging waste to nearby streams; these types of spills increase threats to waterways because untreated hog waste contains harmful pollutants. Note that the discharge incidents also demonstrate the proximity of the facility to nearby streams; the closer a lagoon or sprayfield is to a stream the greater is the threat for off-site pollution. If the more concentrated waste from the digesters, secondary lagoons, or sprayfields from the Hog Operations reaches waterways as a result of an accident, equipment malfunction, flooding, over-application, or otherwise, this further threatens water quality nearby.

The permits also fail to protect water quality because they do not require regular sampling of nearby streams or of groundwater to monitor any impacts to water quality. As noted above, sampling waterways and groundwater near and at hog operations shows elevated levels of numerous pollutants, including bacteria, fecal coliform, several forms of nitrogen, and phosphorus and decreased dissolved oxygen levels. These conditions can cause algal blooms and fish kills and human health impacts.

Given the documented pollution problems caused by components of the waste management system authorized by these permits and the additional risks of increased pollution from more concentrated waste, these permits, as written, will not prevent off-site water pollution.

V. Conclusion

In summary, the Hog Operations are located in the North Carolina Coastal Plain. The current waste management system of holding highly concentrated waste in storage lagoons and spraying out on fields leads to chronic pollution of groundwater and surface water by high concentrations of nitrogen, phosphorus, and fecal bacteria. Vast amounts of ammonia are volatilized from open lagoons and sprayfields, travel downwind, and are deposited in sensitive coastal waters. This waste disposal method presents direct threats to natural ecosystems and biota, as well as human health threats to downwind and downstream residents. Research indicates that the waste management system allowed by these permits will change the composition of the waste that is stored in open lagoons and land-applied to fields. As a result, these permits will not prevent adverse impacts on the environment or cumulative effects on ground water or surface water quality in the river basin, and in fact, waste discharges from the Hog Operations as permitted are likely to increase off-site water pollution. In particular, the waste management system allowed by these permits is likely to increase nitrate concentrations in groundwater and reduce dissolved oxygen, increase BOD levels, and increase bacteria in surface waters, which could lead to harmful algal blooms, fish kills, and human health impacts.

<u>Exhibit 3</u>

Compiled by Dr. Viney P. Aneja, PhD

September 3, 2021

There is abundant scientific evidence that swine concentrated animal feeding operations (CAFOs) operated in North Carolina have adverse impacts on the environment. One of these well-documented impacts are emissions of ammonia (NH_3) from hog waste lagoons, spraying and fields where the waste is land-applied. The ammonia emitted by these sources also deposits on the ecosystem, including surface waters where it can cause increased oxygen demand and eutrophication and can impact aquatic ecosystems and harm fish and other aquatic organisms. Airborne ammonia also deposits on land, where it can overload soil with nitrogen and increase nitrate leaching into groundwater, and make well water unsafe to drink. There is a concern that swine-waste biogas production could exacerbate these problems by emitting more reactive nitrogen, including ammonia, into the atmosphere. This report considers this risk and concludes that storing digestate in open lagoons and land-applying it to field may increase ammonia emissions from hog CAFOs and contribute to further degradation of local air and water quality.

I. Nitrogen cycle in North Carolina hog animal waste management systems

In North Carolina, Concentrated Animal Feeding Operations (CAFOs) are used extensively for meat production. Though the term Concentrated Animal Feeding Operation bears a technical definition under the Clean Water Act, here it is used to refer generally to a production model that raises large numbers of animals in confinement where they are fed and watered until they are slaughtered. Unlike traditional models of livestock husbandry, animals raised in CAFOs do not roam to forage and the feed is produced off-site. The CAFO model of production is used to produce beef, dairy, hogs, poultry, milk, and eggs. The majority of CAFOs in North Carolina produce are either broiler chickens or hogs.

North Carolina witnessed intense growth in its hog industry during the 1990s (Aneja et al., 2000). Due to the large number of animals raised in a concentrated location, CAFOs produce large volumes of waste (US EPA, 2004). In traditional animal production models, animal waste is deposited throughout the environment as the livestock forage. However, in the CAFO model of production, the waste accumulates within the barn. The most common system for disposing of this massive amount of waste is known as the lagoon and sprayfield system. In general, the floor of the swine barns is made of concrete with slats, allowing the urine and feces excreted by the hogs to fall into an underground storage pit below the barn. Depending on the design of the CAFO, the waste either remains in the pit for months before it is scraped out or is flushed out with lagoon water periodically. In North Carolina, there has been a significant shift towards flush systems that remove the waste from barns more frequently. At least three of the four hog operations at issue in this case use the flushing method of removing hog urine and feces from below the barn.[1]

In the conventional lagoon and sprayfield system, once waste is removed from the storage pit, it is transferred into an open-air retention pond or "lagoon" that stores millions of gallons of animal waste. This waste contains bacteria, nutrients such as phosphorus and nitrogen, and heavy metals including arsenic, cadmium, copper and zinc. The pH of waste in the lagoon is manipulated to favor bacteria that anaerobically digest the waste. The liquid waste rises to the top, and nutrient and elemental rich sludge forms at the bottom. The sludge is periodically removed and applied to land. The liquid waste is frequently applied as fertilizer to growing fields, known as spray-fields, via high-pressure sprayers. The waste may also be applied through other methods such as drag-hose application of waste to the surface of the land. Strategies such as injection, which incorporate the waste into the soil and help limit emissions, have not been widely adopted in North Carolina. The spray-fields grow crops such as hay and Bermuda grass in order to absorb the nutrients contained in the waste. In North Carolina, over 2,200 swine operations are permitted to use this kind of animal waste management system. Hog production in North Carolina is overwhelmingly centered in the Eastern Coastal Plain, particularly in Robeson, Columbus, Bladen, Sampson, Pender, Duplin, Onslow, Wayne, Lenoir, Greene, and Pitt counties.

One of the main drawbacks of managing waste in this manner is the effect on air and water quality. CAFOs are significant contributors to air pollution, which often disproportionately impacts low-income and minority communities (Wing et al., 2000). Hog barns, lagoons, land application (i.e. spraying) of animal waste, and land biogenic emissions all emit large quantities of ammonia and other pollutants into the atmosphere (Aneja et al. 2001, 2008, 2009).

Ammonia (NH3), a form of reactive nitrogen, is the most abundant gas-phase alkaline species in the atmosphere. Ammonia emissions from animal agriculture result from the degradation of urea by the ubiquitous enzyme urease, which results in ammonium (NH4+) formation Urea is mainly excreted in the animal urine and once it is hydrolyzed it is much more prone to ammonia emissions than organic nitrogen excreted in the feces.

Ammonia emitted by hog operations is transported and dispersed by wind and is deposited on surface waters or land through dry deposition or wet deposition (Figure 1) (Aneja et al., 2001). Multiple studies have modelled the dispersion patterns of ammonia from CAFOs in Eastern North Carolina (Walker et al., 2000; Costanza et al., 2008; Bajwa et al., 2008). These studies have established that ammonia produced by hog CAFOs deposits a significant amount of nitrogen into the Cape Fear River Basin.

When ammonia directly or indirectly deposits into surface waters it can cause algal blooms and eutrophication (Costanza et al., 2008; Aneja et al., 2001). These conditions in turn cause hypoxia—low oxygen levels—in rivers and streams that alters aquatic ecosystems and harms fish and other species (Costanza et al., 2008).

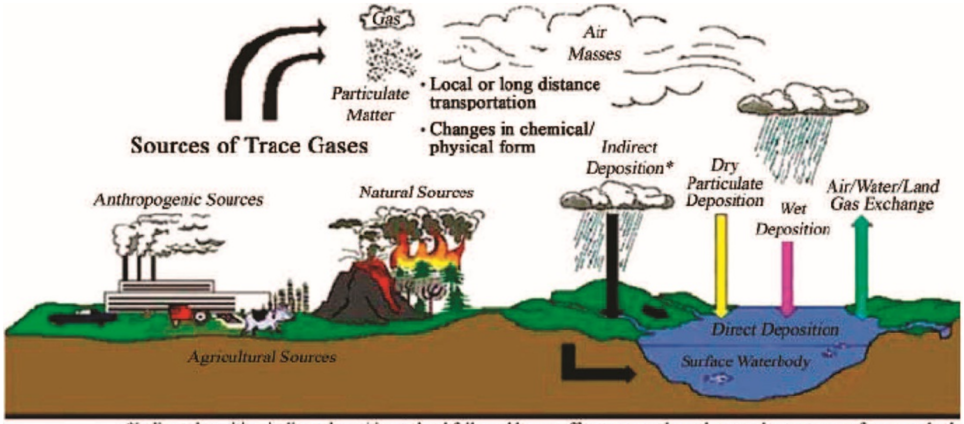

Fig. 1. Atmospheric emissions, transport, transformation and deposition of trace gases. (Aneja et al., 2001)

NH3 can neutralize sulfuric acid and nitric acid in the atmosphere to form fine particulate matter with an aerodynamic diameter <2.5 µm (PM2.5), which is closely linked to health and climatic effects. PM2.5 can penetrate deep into people's lungs and bloodstream and affect respiratory and cardiovascular health. PM2.5 exposure has been linked to a variety of health problems including heart attacks, irregular heartbeat, aggravated asthma, decreased lung function, premature death in people with heart or lung disease, and increased respiratory symptoms such as irritation of the airways, coughing, and difficulty breathing (EPA 2021). PM2.5 also has significant environmental effects, including formation of haze. PM2.5 can be carried over long distances by wind and settle on land or surface waters. When the PM2.5 containing ammonium/ammonia settles in surface waters it can increase the acidity or cause nutrient overloading, which leads to algal blooms and eutrophication.

High concentrations of ammonia, PM2.5, and other pollutants associated with hog CAFOs have a significant detrimental impact on the health and wellbeing of people living nearby. A study published by researchers from Duke University in 2018 found, after controlling for other factors, that for North Carolinians who live near hog CAFOs that use lagoons and sprayfields, mortality rates were substantially higher from causes such as anemia, kidney disease, tuberculosis, and lower birth rates than people who live further away from these operations (Kravchenko et al., 2018). Another recent study linked ammonia and particulate matter created by hog CAFOs to increased mortality rates in nearby communities (Domingo et al., 2021). CAFOs create areas of highly concentrated air pollution and odor that impairs the quality of life of nearby communities. Vulnerable populations are most at risk from the health impacts of CAFO-produced pollutants. Children, for instance, inhale 20-50% more air than adults, and air pollution can exacerbate existing health conditions in the elderly. In addition to affecting health, CAFO-produced pollution has substantial social impacts. Odor, for instance, may be detected several miles from CAFOs.

The waste treatment lagoons that CAFOs use to manage animal waste in North Carolina are a public hazard in times of extreme weather events e.g. hurricanes (Aneja et al., 2001). These events can cause lagoon overflows, which highly contaminate soil, surface water and groundwater used for wells with nutrients and pathogens impacting human health and the environment. Environmentally, these events cause extreme nutrient overload in waterways, which can have a negative impact on entire ecosystems by causing events like algae blooms.

II. Impact of retrofitting existing animal waste management systems to produce biogas on ammonia emissions

Anaerobic digestion (AD) is a method for converting biomass into bioenergy. Livestock manure is a commonly used biomass material for production of bioenergy.

Many livestock (hog and cattle) manure treatment systems rely on open lagoons where the CH_4, CO_2, NH_3 (ammonia) and other gases, such as reduced sulfur compounds, volatile organic compounds (VOCs) are emitted into the atmosphere. When these open systems are covered, gaseous emissions except ammonia are reduced, which results in the effluent leaving the anaerobic digester, known as digestate, with a modified chemical content (e.g. total solids, carbon, ammonia, ammonium (NH_4^+), and pH), relative to waste from a conventional open lagoon system. TAN content and pH in digested slurry are higher than in untreated slurry. Thus, potential for ammonia emissions during subsequent slurry storage are increased (Baines, 2021). The digestate contains more ammonium (NH_4^+) due to reduction in ammonia emissions from the anaerobic digester (i.e. covered lagoon) to the atmosphere, and has less degradable biomass carbon than the substrate in an open lagoon resulting in changes in GHG and NH_3 emissions (Baines, 2021).

The production of biogas through AD of livestock manure is a complex process. It involves a variety of physiological and biochemical metabolic pathways, the essence of which is the material and energy metabolism of microorganisms under anaerobic conditions. AD may be classified typically into three stages according to the utilization and transformation of organic matter (Baines, 2021):

1. Hydrolysis;

2. Acidogenesis; and

3. Methanogenesis.

In the hydrolysis step, macromolecular organic matters (fat, carbohydrate, protein, etc.) are hydrolyzed into small molecules such as monosaccharides, amino acids, fatty acids and so on by the action of extracellular enzymes. In the Acidogenesis step, the small molecule organic compounds are converted to a volatile organic acid, ethanol etc. by the acidified bacteria. H_2, CO_2 and acetic acid are then formed under the action of hydrogenic bacteria and acetogenic bacteria. Finally, in the Methanogenesis step, the methanogenic bacteria synthesize methane using acetic acid, H_2, CO_2 etc. in the methanogenesis stage.

In general, when the digestion process is complete, the pH of the digestate hovers between 7.5 and 8. The pH value in the course of anaerobic digestion is the result of the acid-alkali balance; the pH value decreasing with the increasing of organic acids, and increasing with the increases of Total Ammoniacal Nitrogen (TAN) (TAN = ammonium + ammonia), which is the product of the decomposition of nitrogenous organics (Lorimor and Sawyer, 2004; Grabow; Baines, 2021). The mass of total N is not significantly changed by anaerobic digestion, however the mass of organic nitrogen decreases and the mass of ammoniacal nitrogen increases. Organic N decreases as it is mineralized to TAN (Total Ammoniacal Nitrogen=NH4+N + NH3); i.e. NH3 N expressed as a percentage of TKN increases as manure is digested. Both the TAN and the mineral N (mineral N= TAN + NO3- N) increase. The impact of N transformations is to increase the fraction of total-N in the total ammoniacal form. This is important since the ammoniacal form is composed of both dissolved ammonium (NH4+) and ammonia (NH3) gas. Ammonia gas is emitted into the atmosphere from the open lagoon, i.e. secondary lagoon, during land application (i.e. spraying) of animal waste, and land biogenic emissions of the digested effluent. The amount of NH3 lost during land application of the digestate depends on multiple factors, including the method of application (generally high-pressure spray versus low pressure application or injection) and temperature. (Nyord et al. 2012; Dari et al., 2019).

Anaerobic digesters do not significantly change the nutrient quantity as nitrogen and phosphorus are retained, only the carbon is reduced through conversion and degassing of methane and carbon dioxide. The mass of organic nitrogen is decreased, and it is mineralized to TAN. Thus, ammonia and ammonium are found at higher concentrations in liquid digestates than raw manure (Nkoa, 2014). Therefore, anaerobic digestates stored in open secondary lagoons and land-applied to fields have higher NH3 emission potential than undigested animal manures and slurries (Aneja et al., 2008; Alburquerque et al., 2012; Nkoa, 2014) especially as the temperature increases. An increase in NH3 emissions during the summer from a secondary lagoon filled with digestate relative to conventional open lagoons was documented in North Carolina in 2008 as part of the North Carolina State University Animal and Poultry Waste Management Center's evaluation of potentially environmentally superior technologies. (Aneja 2008). Factors such as temperature and pH may alter the equilibrium between ammonia and ammonium. For example, increasing temperature and pH will enhance ammonia emissions. (Angelidaki et al., 2003; Weaver et al., 2012; Nkoa, 2014). Air movement across an open lagoon surface also enhances NH3 loss. (Dari et al., 2019).

Once digestate is removed from lagoons and applied to fields it has the potential to emit ammonia at a greater rate than conventional hog waste, as depicted in Figure 2. (Nyord et al., 2012). Most studies evaluating ammonia emissions from land-applied digestate have evaluated land-application methods such as drag-hose irrigation or injection. (Nyord et al. 2012; Chantigny et al. 2009). It is well-established that these methods of land-application produce substantially less ammonia emissions than high-pressure spray hoses, (Grabow 2007), which are the land-application method of choice on hog operations in North Carolina. Some studies evaluating ammonia emissions from land-applied digestate have also used data from much colder climates than North Carolina. (Chantigny et al. 2009). It is well-established that low temperatures inhibit NH3 volatilization. (Dari et al., 2019). Therefore, it is reasonable to believe that land-application of digestate effluent through spraying in North Carolina, particularly during the summer, is likely to cause greater ammonia emissions than documented in these studies.

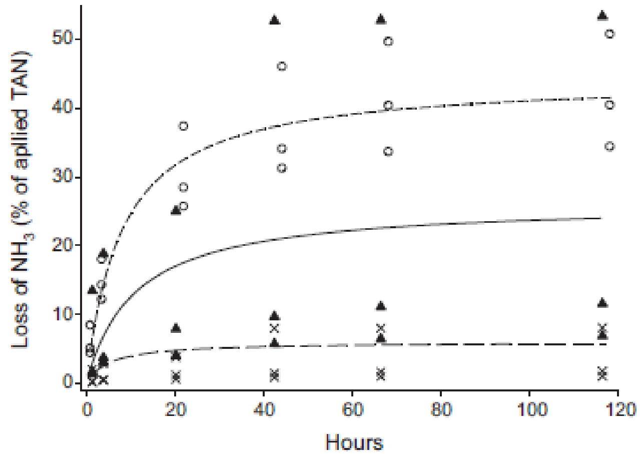

Fig. 3. Ammonia emissions 2008. Cumulative percentage loss of total applied TAN through emission over 116 h after application of pig slurry by trailing hoses. Regression lines and symbols represent cumulative losses of NH_3 emission from each measuring period; ---- and ○: digested slurry; — and ▲: untreated slurry; — — and ×: separated slurry.

Figure 2: Cumulative Ammonia loss by digestate, cattle, and pig slurry spread onto land under identical conditions (Nyord et al. 2012)

III. Impact of DEQ's issuance of permits to M-B to incorporate anaerobic digesters (covered lagoon) into the lagoon & sprayfield system

The permits issued by DEQ for the Waters, Kilpatrick, Benson, and Farm 2037/2038 hog operations authorize Murphy-Brown to modify its existing waste management systems to produce biogas, store digestate in open secondary lagoons, and apply digestate to fields. Instead of flushing hog urine and feces from barns into open lagoons the permits allow the hog operations to store the urine, feces, and water in covered lagoons where, as described in the previous section, biogas will be produced through the process of methanogenesis. The biogas along with other gases trapped under the lagoon cover will be siphoned off to be conditioned and then processed at a central plant.

The digestate will have a different composition from conventional waste, including a significantly higher concentration of NH3/NH4+. The digestate will be transferred to a secondary open lagoon. Ammonia emissions from the secondary lagoon are likely to exceed those expected from a similarly situated conventional lagoon system. (Aneja et al., 2008; Alburquerque et al., 2012; Nkoa, 2014). When the digestate effluent is land-applied, primarily through spraying, this higher rate of ammonia emissions is likely to continue. (Nyord et al., 2012).

The increased ammonia emissions from the secondary open lagoons and land-applied digestate effluent relative to a conventional lagoon and sprayfield system means that a technology intended to benefit the environment, biogas production and capture, may worsens air and water pollution coming from these four hog operations (Harper et al., 2010). The anticipated increase in ammonia emissions could cause more ammonia to be deposited onto nearby soil, where it can seep into groundwater or runoff into surface waters, and directly into surface waters, where it causes algal blooms, low oxygen conditions, and harms aquatic ecosystems.

IV. Availability of technology that mitigates ammonia emissions from lagoons & sprayfield system

Emissions of reactive nitrogen in animal waste can be reduced through various technologies and practices. (Aneja et al., 2009; Szogi et al., 2014). Farm-specific feed management practices cannot be enforced by regulators, but waste management technology requirements can. For example, in the Netherlands, Denmark, and UK, manure injection into soil, rather than spraying, has long been mandated to reduce ammonia emissions. However, technological fixes must be assessed for potential pollutant swapping, i.e., the increased emission of one pollutant resulting from abating another. One example of pollution swapping is increased nitrate leaching that may result from switching to manure injection without reducing the nitrogen application rate. (Aneja et al., 2009).

Over a decade ago, an engineered waste management system known as "Super Soils" was developed and tested in North Carolina. (Aneja et al., 2008). The system included a module that removed nitrogen from waste through a process known as nitrification-denitrification. The system reported a 73% reduction in ammonia emissions from hog operations. (Szogi et al., 2006). The Super Soils system also created an additional income stream for farmers by allowing them to sell concentrated nutrient byproducts of the system as fertilizer. The Super Soils technology has been improved upon twice. (Szogi et al., 2014). Though there is no lagoon in the Super Soil System for storage of the animal manure, the system's modules have been adapted elsewhere to work alongside covered lagoons producing biogas. (Schmidt, 2009).

V. Conclusion

In sum, hog waste lagoons and sprayfields are a significant source of ammonia emissions, which harm local air and water quality and enhance formation of PM2.5, which is harmful to human health. The system permitted by DEQ, which includes a covered lagoon anaerobic digester, secondary uncovered lagoons that store digestate, and land application of the digestate through spraying, is likely to increase those ammonia emissions. The process of anaerobic digestion alters the composition of hog waste such that the digestate that comes out of the covered lagoon has a higher concentration of total ammoniacal nitrogen (TAN) than conventional waste. This change in composition increases ammonia emissions from lagoons and sprayfields fertilized with digestate relative to conventional lagoon and spray waste management systems. The expected increase in ammonia emissions, may in turn exacerbate air and water quality impacts. There are technologies available that reduce the nitrogen content of digestate and can therefore decrease ammonia emissions, avoiding significant environmental and public health impacts.

<u>Exhibit 4</u>

Summary of Expert Opinions
Dr. Shane W. Rogers
September 10, 2021

1. **The lagoon and spray swine waste manure management system used at swine concentrated animal feeding operations (CAFOs) in North Carolina leads to negative environmental and public health consequences.**[1]

   A. The U.S. Environmental Protection Agency defines an Animal Feeding Operation (AFO) as one in which animals have been, are, or will be stabled or confined and fed or maintained for a total of 45 days or more in any 12-month period, and crops, vegetation, forage growth, or post-harvest residues are not sustained in the normal growing season over any portion of the lot or facility."[2] Concentrated Animal Feeding Operations (CAFOs) are generally identified as the largest of the AFO operations owing their potential for significant pollution. Large swine CAFOs are those operations that confine at least 2,500 swine weighing over 55 pounds, or that confine more than 10,000 swine weighing less than 55 pounds.[3]

   B. It takes about 24 to 29 weeks for a hog to reach an average market weight of 283 pounds from birth, including about 3 weeks to wean, 6 weeks in a nursery stage, and then 16 to 20 weeks for the finishing stage.[4] A typical finishing operation for Smithfield may have 2.5 sellouts (rotation of hogs) per year. To get from birth to 283 pounds in 200 days means that the hogs must gain weight rapidly; industry reports reflect average daily weight gains of as much as 1.95 pounds as of the year 2001.[5] This requires significant food and water intake, and with that comes significant manure production. Based on reported manure production characteristics, hogs produce multiple times more waste than humans. As shown in Table 1, a 283-pound finishing hog can be expected to produce on average about 1.67 gallons (13.8 pounds) of manure each day.[6]

   C. Most swine CAFOs in North Carolina, including (at present) the subject swine CAFOs, use a lagoon and spray system of manure waste management. There are three primary

[1] Swine CAFOs may also be referred to as industrial hog operations in some scientific literature.
[2] See https://www.epa.gov/npdes/animal-feeding-operations-afos
[3] According to the U.S. EPA regulatory definitions of Large CAFOs, Medium CAFOs, and Small CAFOs, swine AFOs that are smaller than this size threshold may also be designated a CAFO owing a manmade ditch or pipe discharge of manure or wastewater to surface water, if there is direct contact of animals with surface water that passes through the confinement area, or if the permitting authority finds an operation to be a significant contributor of pollutants. See https://www.epa.gov/npdes/npdes-afos-policy-documents-0 for more details.
[4] United States Department of Agriculture, Economic Research Service, web page, Hogs and Pork, available at http://www.ers.usda.gov/topics/animal-products/hogs-pork/background.aspx (chart showing that it may take 2 to 3 weeks to wean a pig, then nursery stage for 6 weeks, then 16 to 20 weeks for the finishing stage = 24 to 29 weeks total = 168 to 203 days).

sources of concern regarding pollution in this system that include the swine housing facilities, anaerobic lagoons, and spray application of swine wastes.

Table 1. Manure production characteristics of swine[7]

Life Stage	Animal size	Daily Manure Production		
	Pounds	Pounds	Gallons	Liters
Nursery	25	1.9	0.23	0.87
	40	3.0	0.37	1.40
Finishing	150	7.4	0.89	3.37
	180	8.9	1.07	4.05
	220	10.9	1.31	4.96
	260	12.8	1.55	5.87
	300	14.8	1.79	6.78
Gestating	300	6.8	0.82	3.10
	400	9.1	1.10	4.16
	500	11.4	1.37	5.19
Lactating	375	17.5	2.08	7.87
	500	23.4	2.78	10.5
	600	28.1	3.33	12.6

Animals housed in swine CAFOs continually defecate. As swine manure waste is produced in the swine houses, it falls, or is pushed through (by the animals), slots in the concrete floor into pits or flush lanes under the floor. Removal of manure waste from underfloor of the swine houses occurs 4-8 times per day (typical). This is accomplished by flushing the manure that accumulates under the slotted portion of the floors out to the lagoon using wastewater drawn from near the top of the anaerobic lagoon.

D. An anaerobic lagoon is an in-ground manure holding structure, commonly left uncovered and open to the air. The subject swine CAFO sites have historically relied on open lagoons to store manure. Aside from rain that may fall over the anaerobic lagoons, no additional water aside from that contained in swine manure is typically added to the lagoon - by design. The high waste load rapidly depletes oxygen, and thus decomposition of the waste occurs under anaerobic conditions. Anaerobic bacteria in well-functioning anaerobic lagoons break down and stabilize the organic fraction of materials. When this process is upset due to a number of potential factors such as overloading with wastes, solids accumulation and reduction of treatment volume, pH changes or other upsets, the stabilization process is greatly reduced or eliminated.

E. Anaerobic decomposition in anaerobic lagoons generates significant quantities of methane gas, carbon dioxide, ammonia, nitrous oxide, and other noxious gases that are emitted to the atmosphere along with other pollutants. Methane, a greenhouse gas, is a

[7] Source: Midwest Plan Service, 2004 Manure Characteristics, MWPS-18 Section 1, Second Edition, Jeff Lorimor, Wendy Powers, and Al Sutton (eds.). Manure Management Systems Series, Iowa State university, Ames, IA.

significant component of the biogas produced during anaerobic decomposition.[8] The quantity of ammonia nitrogen emitted is also large and of concern.[9] Its uncontrolled emission reduces the nitrogen content of the waste and poses a risk to the environment and public health. It has been estimated that 80-90% of the total ammonia emitted from livestock operations is redeposited uncontrolled within 10 km of the source, while the remainder is dispersed into the atmosphere contributing to the haze, acid rain, acidification of terrestrial and aquatic ecosystems, and eutrophication of surface water bodies.[10]

F. Swine manure wastes are held, exposed to the atmosphere, in anaerobic lagoons until such time they can be applied to land. Land application of manures is permitted in North Carolina so long as it is done in accordance with a certified animal waste management plan (CAWMP). The purpose of the CAWMP is to assure that manure is applied at a rate to meet, but not exceed, the nutrient requirements of the crop to receive the manure as a nutrient source. In general, CAWMPs consider application history and nutrients contents of the soil, nutrient content of manure, infiltration rates and application equipment used (effect on nutrient delivery to the plants), and land area over which the crop(s) will be grown. Like for most swine CAFOs in North Carolina, the subject swine CAFO sites are permitted to apply their manure waste at an agronomic rate for nitrogen. This does not assure that overapplication of phosphorus, an important nutrient that affects water quality, does not occur. It also does not assure that nitrogen and other pollutants in swine manure do not affect nearby water quality.

Available at http://www.hsi.org/assets/pdfs/farming_climate_impact.pdf (page 7 – "Storing and disposing vast quantities of manure can produce anthropogenic methane and nitrous oxide emissions. According to the Pew Center on Global Climate Change, farm animal manure management currently accounts for 25% of agricultural methane emissions in the United States and 6% of agricultural nitrous oxide emissions. As noted above, methane has 23 times the GWP of carbon dioxide, and its concentrations have increased by approximately 150% since 1750. Globally, farm animals are the most significant source of anthropogenic methane, responsible for 35-40% of methane emissions worldwide."

Vanderzaag (2020) Ammonia and greenhouse gas emissions from slurry storage – A review, Agriculture, Ecosystems and Environment, 300: 106963; these authors report from a sample of 40 reports of ammonia emissions measurements from swine waste anaerobic lagoons an average emission of 13,000 kg-N/ha/yr. See also Aneja, V.P., S.P. Arya, D.-S. Kim, I.C. Rumsey, H.L. Arkinson, H. Semunegus, K.S. Bajwa, D.A. Dickey, L.A. Stefanski, L.Todd, K.Motlus, W.P. Robarge, C.M. Williams (2008) Characterizing Ammonia Emissions from Swine Farms in Eastern North Carolina: Part 1 – Conventional Lagoon and Spray Technology for Waste Treatment, Journal of the Air & Waste Management Association, 58:1130-1144 ; these authors report ammonia emissions from three anaerobic lagoons were temperature dependent, ranging from as low as 2.2 kg-N/ha/d in the winter to as great as 57.8 kg-N/ha/d in the summer. See also Nkoa. R. (2014) Agricultural benefits and environmental risks of soil fertilization with anaerobic digestates: a review, *Agronomy for Sustainable Developmen*t, Springer Verlag/EDP Sciences/INRA, 34 (2):473-492. 10.1007/s13593-013-0196-z hal-01234816; on page 480 - "NH_3 emission inventories from several countries have shown that agriculture produces approximately 90% of the total emission of NH_3 to the atmosphere."

[10] See Nkoa. R. (2014) Agricultural benefits and environmental risks of soil fertilization with anaerobic digestates: a review, *Agronomy for Sustainable Developmen*t, Springer Verlag/EDP Sciences/INRA, 34 (2):473-492. 10.1007/s13593-013-0196-z hal-01234816, page 481.

G. When anaerobic manure lagoon effluents and solids are land-applied, nutrients, oxygen-demanding materials, metals, odors, particulates, endotoxins, bacteria, ammonia, and other harmful pollutants are released into the environment. Ammonia and other pollutants emitted to the atmosphere can move downwind or deposit uncontrolled onto land, physical structures, or waterbodies nearby. Land-applied pollutants can run off from fields in surface drainages, move via groundwater, or through tile drainage flows to affect water quality.[11] In a recent study of the U.S. Geological Survey, an overall measurable effect of swine CAFO waste manures on stream water quality in watersheds containing swine CAFOs was reported. Land application of waste manure at swine CAFOs influenced ion and nutrient chemistry in many of the North Carolina Coastal Plain streams that were studied, and the effect was directly related to higher swine barn densities and (or) higher total acres available for applying waste manure at swine CAFOs.[12]

H. In a lagoon and spray system, including the system permitted for the subject swine CAFOs, waste application is typically completed using methods of application that spray waste through the air, for example, using a pump and reel or center pivot spray applicator. Less frequently, operators may choose to use alternative application techniques such as low height or drag hose spreading or injection. The operators at the subject swine CAFOs use a combination of spraying waste and drag hose spreading.

I. Spraying swine manure through the air results in significant ammonia emissions. Direct injection of manure, such as can be accomplished with Aerway spreaders, is one alternative to spray irrigation that can reduce potential for off-site transport of harmful pollutants in manures or anaerobic digester effluents. Reduction in hydrogen sulfide emissions is estimated to be between 50-75%, but there may be a slight increase in greenhouse gas emissions (up to 10%) owing a slight increase in nitrous oxide emissions from decomposition by soil microbes. Injection also results in greater preservation of nutrients (up to 90% reduction in ammonia volatilization compared to spray application), which reduces the amount of anaerobic lagoon effluent that must be applied to land to meet crop nutrient requirements. Lower mass of anaerobic lagoon effluent applied per land area means less pollutant loading and emissions.

2. **Well-designed anaerobic digestion technologies for swine manure treatment can reduce select environmental pollution and public health risks of concern relative to anaerobic lagoons, but may exacerbate others.**

   A. Anaerobic digestion is a rapidly growing technology for farm waste management in the United States. The process of anaerobic digestion uses microbes to produce biogas, which is a mixture of methane, carbon dioxide, and trace gases. While anaerobic digestion occurs in an anaerobic lagoon, an anaerobic digester differs in that it is covered with an impermeable material rather than left open to the atmosphere and it is not exposed to diluting rainfall. Because anaerobic digesters are covered, the methane, a powerful greenhouse gas with high emissions from anaerobic lagoons, is captured rather than emitted to the atmosphere, thus reducing emissions that contribute to global warming. Owing the absence of diluting rainwater and other efficiencies, anaerobic digesters are more efficient at waste decomposition than anaerobic lagoons. Gas capture in anaerobic digesters may also reduce the amount of pathogens in the waste.

   B. Nutrients in manure are conserved during anaerobic digestion, but are converted to more readily available and mobile forms with higher potential to move with water.[13] Organic nitrogen is converted to ammoniacal nitrogen, which is not only inhibitory of the anaerobic digestion process, but can also result in higher ammonia emissions during subsequent storage if left uncovered, and during land application if not incorporated when applied.[14] For example, relative to anaerobic lagoons, ammonia emissions from anaerobically digested swine manure stored in open lagoons in one study increased by 46%. This was hypothesized to be caused by reduced methanogenesis and its reduced effect on the chemical conversion of ammonium to dinitrogen gas.[15]

---

[13] See United States Department of Agriculture - Natural Resources Conservation Service, Conservation Practice Standard: Anaerobic Digester, Code 366, October 2017, 10 p. On page 6: "Consider the effects of digestion upon nutrient availability. Land application of digester effluent, compared with fresh manure, may have a higher risk for both ground and surface water quality problems. Compounds such as nitrogen, phosphorus, and other elements become more soluble due to anaerobic digestion and therefore have higher potential to move with water."

[14] See Westerman, P., M. Veal, J. Cheng, and K. Zering "Biogas Anaerobic Digester Considerations for Swine Farms in North Carolina" North Carolina State University, A&T University Cooperative Extension, 8 p.; See also Aguirre-Villegas, H., R.A. Larson, M.D. Ruark (2016) Dairy Anaerobic Digestion Systems and their Impact on Greenhouse Gas and Ammonia Emissions, Sustainable Dairy Fact Sheet Series, University of Wisconsin Extension, 5 p. See also Kupper. T., C. Häni, A. Neftel, C. Kincaid, M. Bühler, B. Amon, A. Vanderzaag (2020) Ammonia and greenhouse gas emissions from slurry storage – A review, Agriculture, Ecosystems and Environment, 300: 106963; p. 1 "Anaerobically digested slurry shows higher emissions during storage for NH_3 while losses tend to be lower for CH_4 and little changes occur for N_20 and CO_2 compared to untreated slurry. All cover types are found to be efficient for emission mitigation of NH_3 from stores."

[15] Harper, L. T.K. Flesch, K.H. Weaver, J.D. Wilson (2010) The effect of Biofuel Production on Swine Farm Methane and Ammonia Emissions, Journal of Environmental Quality, 39:1984-1992. In the abstract on pg 1984: "NH_3 emissions in the biofuel farms increased by 46% over the conventional farms. These studies show that what is considered an environmentally friendly technology had mixed results and that all components of a system should be studied when making changes to existing systems."

3. **Subject swine CAFO characteristics as currently operating and with modifications to the waste treatment system: minimal changes in the permits and certificates of coverage are not protective of air and water quality.**

A. Thousands of Smithfield hogs are being kept in each of the subject swine CAFOs as summarized in Table 2, along with the number and types of anaerobic lagoons at each site. Each of the subject swine CAFOs currently employ the lagoon and spray system of swine manure management. The subject swine CAFOs' irrigation records indicate that the predominant method of waste application is spraying using pump and reel and center pivots.[16] Murphy-Brown has indicated that there is also some limited use of drag hoses at these sites. Table 3 presents the basic characteristics of the proposed anaerobic digestion systems for each subject swine CAFO.

Table 2. Production characteristics and anaerobic lagoon characteristics of the subject swine CAFOs[17]

Facility	Operation type	Permitted hog counts	Number and type of anaerobic lagoons
Benson	Feeder to finish	6,120	One single stage
Goodson 2037/2038	Feeder to finish	20,992	One single stage and one 2-stage (primary and secondary)
Kilpatrick	Wean to Finish	13,336	One 2-stage (primary and secondary)
Merritt	Wean to Finish	5,083	One single stage
M&M	Wean to finish	12,308	Three single stage

Notes: Permitted hog count is the allowable annual average count calculated pursuant to the permit, not the number of hogs present at any particular time.

Table 3. Lagoon characteristics at each of the subject swine CAFOs[18]

[16] Data acquired from the most recent irrigation design plans provided including Benson: MB000788; Goodson 2037/2038: MB000127; Kilpatrick & Merritt: MB001143; M&M: MB001851. Document identification is by the first page number of the document.

[17] Data acquired from lagoon design information provided including Benson: MB000741; Goodson 2037/2038: MB000092 and MB000085; Kilpatrick & Merritt: MB001092 and MB001104; and M&M: MB001733, MB001741, and MB001748.

[18] Data acquired from the most recent nutrient utilization plans (NUPs), anaerobic digester permit applications, and permits or certificates of coverage issued by the DEQ provided for each of the subject swine CAFOs. These include (i) NUPs: Benson: MB000798; Goodson 2037/2038: MB000160 and MB000179; Kilpatrick: MB001154 and MB001184; M&M: MB001836; (ii) Permit / COC applications: Benson: MB000667; Goodson 2037/2038 MB000001; Kilpatrick: MB001016; M&M: MB001632; and (iii) DEQ Permits / COCs: Benson: MB000720; Goodson 2037/2038: MB000065; Kilpatrick: MB001090; M&M: MB001730 and MB001711. Note that the "MBXXXXXX" document identification is by the first page number of the document.

Facility	Proposed Anaerobic Digester (AD) Size *gallons*	New AD Construction or New anaerobic digester or Lagoon Cover	Proposed number of anaerobic digestate storage lagoons
Benson	1,693,156	New	One single stage, soil improved or clay lined
Goodson 2037/2038	5,044,114	New	One 2-stage, clay lined
Kilpatrick	9,121,716	Cover	One single stage, synthetically lined
Merritt	NA	NA	NA
M&M	2,672,790	New	One single stage synthetic, two single stage clay lined

NA = not applicable. Note that an anaerobic digester will not be installed to serve the Merritt farm, which will continue to be served by the existing single stage lagoon.

B. Reviewing the permit applications and permits issued by the North Carolina Department of Environmental Quality, it is evident that some discrepancies exist. For example, the DEQ issued permit for the Benson Farm indicates that one existing clay-lined lagoon will be used to store anaerobic digester effluent, whereas the permit application submitted by Cavanaugh & Associates on behalf of Smithfield Foods identifies the lagoon having a soil improved liner rather than a clay liner.[19] While investigation of historical satellite imagery catalogued on Google Earth could not reveal such detail, it does reveals an interesting feature of the lagoon, what looks to be a divide running through the center, the reduced volume for which is not reflected in the lagoon design information provided by Smithfield, and dated December 17, 2008.[20] Satellite imagery reported in Figure 1 dating from February 1998 through July 2018 clearly show a divide that is deep enough to affect water quality differences from one side of the lagoon to the other. Other discrepancies between permit applications and actual lagoon liner details for Goodson 2037/2038 and M&M Waters & Riverbank exist, but were corrected in the final permits.

[19] Compare the DEQ issued Permit no. AWI310039 dated March 31, 2021 (MB000720), page 3: "…consisting of a 1,693,156 gallon synthetically lined anaerobic digester with an 80 mil HDPE synthetic cover, one existing clay lined lagoon, one influent pump station…") to the permit application stamped MB000667 and dated 12-19-19, page 2, which identifies the existing lagoon having a soil improved liner.

[20] See the Benson Farm Anaerobic Waste Lagoon Design document dated 12/17/08 (starting on MB000741).

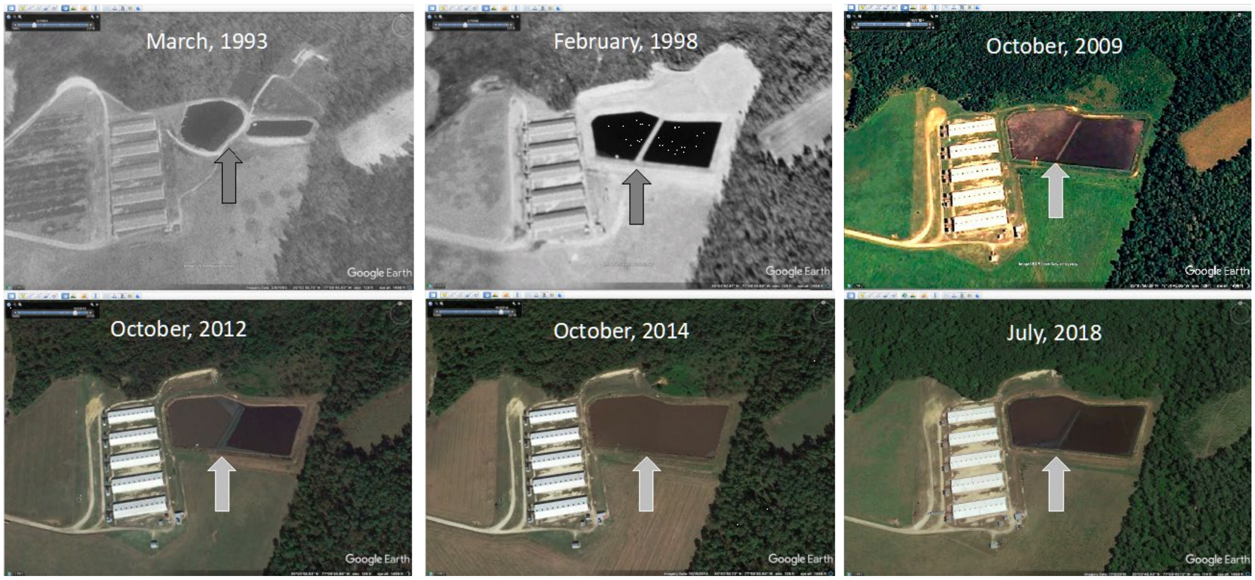

Figure 1. Google Earth historical satellite imagery of the Benson swine CAFO anaerobic lagoon showing a divide in the lagoon center (see February 1998) that roughly correlates to a historic drive (see March 1993), and which is large enough to also be visible and cause water quality differences between the two sides of the lagoon as seen in the subsequent images. This divide is not accounted or in the calculation of the lagoon design volume as reported in in documents provided by Smithfield (see Benson Lagoon Design, dated December 17, 2008 and identified MB000741 on page 1).

C. Permits in North Carolina prohibit siting of the swine CAFO housing units and waste treatment systems in the 100-year flood plain; the same is not true for swine manure application areas. These areas are subject to increased risk of leaching manure pollutants into the waters of North Carolina during and following rainfall. Figure 2 shows satellite imagery of the Goodson 2037 and 2038 swine CAFO and spray fields. As can be seen in the image to the left of this figure, the 100-year flood plain intersects portions of spray fields at this swine CAFO. Historical satellite images suggest that these spray irrigation fields are subject to flooding.

Figure 2. Satellite imagery of the Goodson 2037 / 2038 swine CAFO and manure spray fields. Left: overlay of the 100-year flood plain and the irrigation system map reveals spray irrigation of swine manure occurs in areas subject to flooding, increasing runoff potential of manure pollutants. Right: Historical satellite images from Google Earth reveal recurrent saturation of spray fields within the 100-year flood plain.

D. The permits issued by the North Carolina State Department of Environmental Quality authorize the waste treatment systems of the subject swine CAFOs to change; however, the permits included very few substantive changes to accommodate the new anaerobic digestion waste treatment systems, even though the new technology can alter the waste composition and nutrients as described above. The subject swine CAFOs must continue to monitor their manure wastes as usual and adjust application rates based upon either total nitrogen or total Kjeldahl nitrogen results. Notably, increased ammonia volatilization from lagoon storage of anaerobically digested manure may increase uncontrolled air emissions of ammonia nitrogen, reducing the nitrogen content of the waste to be applied, and allowing for increased concentration of waste application considering that crop nutrient requirements will not change. Owing to changes in the form of the nutrients, increased mobilization may occur. The permits issued for Goodson 2037 & 2038 and Benson swine CAFOs mandate two years of quarterly monitoring and reporting of influent and effluent total nitrogen, total Kjeldahl nitrogen, nitrate nitrogen, ammonium nitrogen, total phosphorus, copper, sulfur, zinc, and fecal coliform bacteria. The nutrient management plans must be modified as needed based on performance of the anaerobic digestion system, and if performance is not as predicted, immediate measures must be taken. Regardless, these measures will only monitor changes in composition at the source. Notably, permits for swine CAFOs in North Carolina, including the four at issue here, do not generally require monitoring of nearby groundwater, surface water, or air emissions to detect potentially increased pollutant mobilization, and thus associated air and water quality degradation by such changes will go undocumented and unaddressed.

E. Other changes in the permits or Certificates of Coverage are not clearly related to changes in the swine manure waste treatment technology. For example, changes in the Certificate of Coverage at the Kilpatrick & Merritt and the permit for Benson swine CAFOs include a directive to review the facilities' CAWMP with respect to land application areas in landscape positions that are in close proximity to public roads, dwellings, and wells, and provide within 180 days a report to the division to describe what, if any, additional BMPs are to be implemented in these areas to improve protections and further reduce risk of off-site impacts. Nothing more is required than a paper exercise. The permit for the Benson swine CAFO also includes a mandate to limit application on fields with a high phosphorus loss assessment rating to crop nutrient requirements for phosphorus, and restricts swine manure application on fields with very high phosphorus loss assessment rating.

4. Biogas-compatible technologies that could mitigate environmental impacts from the subject swine CAFOs by decreasing nutrients in land-applied waste and reducing ammonia emissions are available.

A. Considerable progress has been made in manure treatment technology development in the last 24 years. There are several technologies readily available and in development that can reduce significantly gaseous emissions from anaerobically digested swine CAFO manure. At a basic level, impermeable covers could be installed on the lagoons that will store anaerobic digestate and reduce ammonia volatile losses from the lagoon by nearly 90%.[21] Volatile losses of ammonia can be reduced 70-90% upon application by injection of the anaerobically digested swine manure waste into the ground rather than spray applying. Conservation of the nitrogen in the manure rather than emission into the atmosphere can reduce nearby effects of uncontrolled ammonia deposition as well as public health risks.

B. Other treatment technologies are also available and currently used at other swine CAFO operations that can remove or recover nutrients, significantly reducing environmental and public health risks. One high achieving set of developments stemmed from the Super Soils / Terra Blue technology developed in North Carolina under the Smithfield Agreement.[22] Since that time, advancements from the research group have included development of more efficient two-stage and then one-stage ANAMMOX bioreactors to replace nitrification/denitrification and gas permeable membranes to recover ammonia and phosphate minerals from swine wastewater.[23] An advanced waste treatment technology developed in a joint venture with Embrapa (Brazil) known as Sistrates has successfully implemented the Terra Blue technology with anaerobic digestion at a 9,500 head swine CAFO in Brazil.[24] Swine waste anaerobic digestion-compatible membrane separations technologies have also matured, such as that of Digested Organics LLC which can recover nutrients in higher value streams and simultaneously produce water of sufficient quality for livestock.[25]

5. Conclusion.

A. For all of the reasons stated above, it is my opinion, within a reasonable degree of scientific certainty, that the anaerobic digestion systems to be implemented at the subject swine CAFOs are more likely than not to exacerbate ammonia emissions relative to the current anaerobic lagoon and spray system. Resulting unregulated emissions and

increased nutrient mobilization are more likely than not to negatively affect environmental quality and public health.

B. For all of the reasons stated above, it is my opinion, within a reasonable degree of scientific certainty, that the subject permits authorizing swine CAFO waste management systems known to change the nature of the waste material in ways that may exacerbate water quality impacts from land application, and increase atmospheric ammonia emissions, fail to prevent cumulative effects on water quality and allow adverse environmental impacts.

C. For all of the reasons stated above, it is my opinion, within a reasonable degree of scientific certainty, that technologies to abate these pollution sources are readily available.

D. All of my opinions are expressed to a reasonable degree of scientific certainty.

Re: New general permits for biogas projects for confined animal feeding operations in North Carolina

To whom it may concern:

It is my understanding that the North Carolina Department of Environmental Quality is undergoing a process to prepare a new general permit that would authorize biogas projects for confined animal feeding operations, including the large number of industrial hog operations in the state.

The pollution from industrialized hog operations in the state of North Carolina is both an environmental problem and a social justice concern that has garnered significant global exposure for many years. The moratorium on the expansion of new hog operations in the state, particularly those employing lagoon and spray systems, has not resulted in the desired effect of significantly reducing environmental and public health burdens. More than 20 years later, waterways of the state are still polluted by the practices of these operations. Poor and non-white communities remain exposed to pollution and nuisances caused by these operations near their homes.

Anaerobic digestion systems may be a step in the right direction. However, while anaerobic digestion and associated biogas technologies can be designed and operated in such a way as to reduce these burdens,[1] their inappropriate or incomplete application can exacerbate selected environmental problems and significantly reduce their potential to resolve public health threats and nuisance issues.

Solutions exist that should be included in the permit

Undeniably, anaerobic digestion with biogas capture technologies will improve waste stabilization and reduce methane emissions over uncovered anaerobic lagoons. However, continued and new problems associated with biogas projects at confined animal feeding operations will occur if they are designed for maximum monetization of the biogas without appropriate consideration of needed pollution mitigation. For example, installation of a new anaerobic digester or conversion of an existing anaerobic lagoon to a covered lagoon without additional treatment of the waste to reduce pollutants or changes in other practices such as spray application of digested wastes will not resolve uncontrolled atmospheric emissions of ammonia.

The mass of nutrients in manure wastes remains largely unaffected by anaerobic digestion, but the nutrients are altered in form. Improved waste stabilization means greater production of ammonium and ammonia during anaerobic digestion versus anaerobic lagoons. Large amounts of nitrogen from manure wastes emitted through ammonia volatilization to the atmosphere are well documented from uncovered anaerobic lagoons and spray application of waste. Once in the

[1] For example, covered anaerobic digestate storage and proven technological solutions that work in concert with, or as an alternative to, biogas systems can be implemented that reduce meaningfully their air emissions, improve the conservation of resources, and reduce their potential to pollute the environment and cause nuisance issues. Working examples exist at large-scale confinement operations globally.

atmosphere, ammonia can react to form fine particulates that threaten air quality, public health, and the environment. Much of this ammonia deposits uncontrolled within a small radius of the farm where it can contribute to water quality problems as well.

Because nutrient mass is largely unaffected by anaerobic digestion, simply installing anaerobic digestors cannot resolve nutrient loading issues from hog manure application that affects North Carolina waters. Indeed, the conversion of nitrogen to more mobile forms may exacerbate water quality issues upon application.

Improved nutrient conservation practices and established nutrient removal and nutrient recovery technologies congruent with anaerobic digestion technology presently exist and can mitigate these issues. There exists a suite of anaerobic digestion-compatible technologies available for nutrient removal or recovery. Many of these well-understood and well-practiced technologies are already in use for treatment of livestock manures globally. For example:

- **Nitrification - denitrification technology** has been used in wastewater treatment for decades; working examples exist at hog operations in the United States, including at Smithfield/Murphy-Brown hog operations producing biogas in Missouri. The first step of this biological process converts ammonium nitrogen in waste to nitrate under aerobic conditions. In the second step, denitrifying bacteria respire nitrate to support maintenance energy production under anoxic conditions. In this process, they convert the nitrate into harmless dinitrogen (N_2) gas. The resulting treated waste has greatly reduced nitrogen content and improved characteristics that are less offensive than anaerobic digestate. Land application can then occur at greater application rates, lowering land area requirements.[2] Dinitrogen gas is odorless and comprises 78% of our atmosphere; it poses no threat to public health, to the environment, or to nuisance conditions on the part of neighbors.

- **Anaerobic ammonium oxidation** (ANAMMOX), a biological process that converts ammonium to dinitrogen gas in an anaerobic environment, has been implemented successfully with many anaerobic digesters globally. While limited anaerobic ammonium oxidation may occur naturally in anaerobic digesters or anaerobic lagoons for livestock wastes, engineered processes have been designed to operationalize this process in a meaningful way towards nitrogen removal from wastes with lower costs and space requirements than nitrification – denitrification technologies.

- **Alkaline precipitation** is a widely used chemical process in which hydrated lime is added to wastewater facilitating precipitation of calcium phosphate as solids that can be recovered for beneficial reuse. The technology has been used widely for wastewater treatment, and has been proven in full-scale hog waste treatment systems as described below. Solids in the wastewater (including pathogenic microorganisms) act as nucleation sites upon which precipitation can initiate. The combined effects of entrapment in solid precipitates and

[2] This technology can thus allow operations that would otherwise have to reduce stocking density by ammonia conservation practices such as covered storage for anaerobic digester effluent owing limited land available for manure application at nitrogen limited rates to continue to operate with the same livestock numbers. Added waste neutralization afforded by the technology such as lowered odor reduces its potential to cause nuisance conditions as well.

increased pH upon alkaline stabilization leads to significant decimation of pathogenic microorganisms as a co-benefit to application of this phosphorus removal technology.

- **Struvite precipitation** is a chemical treatment technology used to recover phosphorus from wastewater at several municipal wastewater treatment plants in saleable form. This technology has also been used safely at concentrated animal feeding operations. Struvite is a phosphorus-containing mineral that works as a slow-release fertilizer when used to fertilize land. It naturally precipitates in many anaerobic digesters, thus can be a nuisance to their operation. However, controlled struvite precipitation in concert with anaerobic digestion can reduce its potential to cause a nuisance in the anaerobic digestion process while producing a valuable phosphorus fertilizer.

- **Super Soils / Terra Blue**: Several of the above processes have been employed in conjunction with one another to treat industrialized livestock agriculture wastes to a high standard. Indeed, many high achieving developments stemmed from the Super Soils / Terra Blue technology first developed and ground-truthed over a decade ago in North Carolina.[3] This advanced technology was capable of achieving 97.6% removal of suspended solids, 99.7% removal of biochemical oxygen demand (BOD), 98.5% removal of total Kjeldahl nitrogen (TKN), 98.7% of soluble ammonia, 95% of total phosphorus, 98.7% of copper, and 99% of zinc. It also removed 97.9% of odor compounds in the liquid effluent and reduced pathogen indicator bacteria to non-detectable levels. The produced water was of sufficient quality for reuse to clean swine houses and for safe reuse for crop irrigation. Since that time, advancements from those developers have included ANAMMOX bioreactors such as those described in the prior paragraph for treatment of livestock wastes, and gas permeable membranes to recover ammonia and phosphate minerals from swine wastewater, such as those discussed below.[4]

- **Sistrates (Swine Effluent Treatment System)** is an advanced waste treatment system developed in a joint venture between Embrapa (Brazil) and the developers of the Terra Blue technology to successfully implement it with anaerobic digestion technology at a 9,500 head swine CAFO in Brazil. [5] This modular technology first removes solids from swine barn flush system water by a sieve and rotating brush. Separated solids are anaerobically digested in a high-rate digester, while liquids are treated in a covered anaerobic lagoon (ambient temperature digester). Anaerobic digestate is treated to remove

5 See Tápparo, D.C., D. Cândido, R.L. Radis Steinmetz, C. Etzkorn, A. Cestonarodo Amaral, F. Goldschmidt Antes, A. Kunz (2021) Swine manure biogas production improvement using pre-treatment strategies: Lab-scale studies and full-scale application, Bioresource Technology Reports, 15:100716 (8p.)

ammoniacal nitrogen through the process of nitrification-denitrification described above. Phosphorus is recovered for beneficial reuse from the waste as calcium phosphate by alkaline precipitation, as designed for the Super Soils / Terra Blue technology. Produced wastewater has greatly reduced nitrogen content, improving the ability of operators to custom blend recovered phosphorus with produced water and chemical nitrogen fertilizer to meet specifically crop nutrient requirements.

- Anaerobic digestion-compatible **membrane separation and solids recovery technologies** have also matured, such as that of Digested Organics LLC. This system can recover nutrients in higher value streams and simultaneously produce water of sufficient quality for reuse for livestock[6]. Briefly, when used in conjunction with anaerobic digestion, their modular system first uses a spiral brush screen filter recover large solids from anaerobic digestate prior to down-stream pressure-driven membrane processes. Phosphorus recovered with the dewatered solids amounts to approximately 15-30% that in the anaerobic digester effluent. In dairy manure digester applications, the recovered dewatered fibrous solids are of sufficient quality for reuse as bedding compost. Suspended solids removal by the spiral brush screen facilitates treatment of the permeate by stainless steel ultrafiltration. The retentate (concentrate) from ultrafiltration is a useful nitrogen and phosphorus rich fertilizer. It is much reduced in volume, thus facilitating smaller covered storage than otherwise would be needed to limit fugitive emissions. These first two steps of the process remove greater than 99.9% of the suspended solids and pathogens, greater than 95% of total phosphorus, and 30-40% of total nitrogen (predominantly organic nitrogen) from the waste stream. The high quality permeate (product water) stream produced from the ultrafilters are then passed through a two-step reverse osmosis system to recover much of the remaining total nitrogen and remove color, dissolved solids, and metals from the waste. The nitrogen-rich retentate from the two-step reverse osmosis process can be custom blended with the phosphorus-rich retentate from the stainless-steel ultrafiltration units to meet specifically the unique fertilization requirements of different crops, thus reducing risks of overapplication of phosphorus when meeting crop nitrogen requirements. The product water of the two-step reverse osmosis system is of high quality. Greater than 99% total solids, ammoniacal nitrogen, phosphorus, potassium, and several metals, 92% of TKN, and 86% of organic nitrogen can be removed from anaerobic digester effluent by these three combined processes. When product water is treated with their ultraviolet disinfection system, it is of sufficient quality for reuse as livestock drinking water or can be discharged safely to a waterway.

While the above focus on technological solutions for waste treatment and resource recovery, it is important to note that additional options exist to reduce environmental, public health, and nuisance issues while conserving valuable nutrients in hog manure wastes.

- **Nutrient conservation:** Most simply, mandating that secondary lagoons used for anerobic digestate storage be covered with impermeable covers to capture fugitive methane and other volatile emissions[7] and limiting application practices that encourage volatile

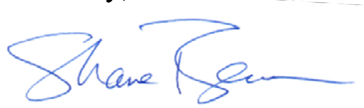
[6] For more details, see https://digestedorganics.com/manure-and-digestate-management/

[7] Impermeable covers on the lagoons used to store anaerobic digestate can reduce ammonia volatile losses considerably. See: Kupper. T., C. Häni, A. Neftel, C. Kincaid, M. Bühler, B. Amon, A. Vanderzaag (2020)

pollutant losses (e.g., spray gun application) in lieu of low height spreading or injection[8] can help hog operations with methane capture to achieve its greater potential for pollution reduction. The nutrient conservation (lowered ammonia volatile losses) will lead to greater fertilization potential and lower manure application rates. This will reduce co-pollutant loading rates to land that can runoff and emissions of nuisance odors that can improve conditions for neighbors of industrial hog operations. Nutrient conservation through covered anaerobic digestate storage will benefit those operations that presently supplement their crop fertilization requirements with chemical fertilizers, reducing their reliance upon them. Further, covered storage will improve timing and frequency of application, being less subject to wet weather conditions and risks of freeboard violations that plague uncovered lagoons in North Carolina -- especially during the hurricane the season.

Considering the above, there are myriad options to facilitate the implementation of biogas systems at concentrated animal feeding operations in North Carolina in ways that will reduce, rather than exacerbate, the pollution problems associated with these projects. New general permits that include rules to assure that technology interventions are fully reflective of modern practices and capabilities globally, and address meaningfully the environmental emissions, public health concerns, and nuisance issues that surround pollution emanating from CAFO operations, will better protect North Carolina's waterways and communities.

Sincerely,



Dr. Shane Rogers
Rogers Environmental Consulting

Ammonia and greenhouse gas emissions from slurry storage – A review, Agriculture, Ecosystems and Environment, 300: 106963; Table 11, page 10.

8 Volatile losses of ammonia can be reduced 70-90% upon application by injection of the anaerobically digested swine manure waste into the ground rather than spray applying. Conservation of the nitrogen in the manure rather than emission into the atmosphere can reduce nearby effects of uncontrolled ammonia deposition as well as public health risks.

EPA File No. 11R-14-R4

William G. Ross, Jr.
Acting Secretary
North Carolina Department of Environmental Quality
1601 Mail Service Center
Raleigh, NC 27699-1611

Re: Letter of Concern

Dear Acting Secretary Ross:

We are writing to you to provide the North Carolina Department of Environmental Quality (NC DEQ) preliminary information related to the United States Environmental Protection Agency's (EPA) External Civil Rights Compliance Office's[1] (ECRCO) investigation into alleged discriminatory impacts from NC DEQ's operation of the Swine Waste Management System General Permit (Swine Waste General Permit). ECRCO has not concluded its investigation of EPA File No. 11R-14-R4 (Complaint) or reached final conclusions of fact or law. However, in light of the preliminary information gathered, ECRCO has deep concern about the possibility that African Americans, Latinos, and Native Americans have been subjected to discrimination as the result of NC DEQ's operation of the Swine Waste General Permit program, including the 2014 renewal of the Swine Waste General Permit.

EPA recognizes that there is new leadership at NC DEQ who were not involved in the events and correspondence described below relating to this Complaint and who will understandably need to come up to speed. ECRCO looks forward to sitting down with NC DEQ's new leadership in the next few weeks to provide any necessary background on NC DEQ's obligations under the federal nondiscrimination statutes and to discuss issues raised by ECRCO's investigation to date; any additional information NC DEQ may have relevant to the issues under investigation; the recommendations ECRCO has made below; and how to move forward on a constructive path to informally resolve the Complaint in the near future and ensure NC DEQ is in compliance with the applicable nondiscrimination statutes and regulations.

[1] Formerly the Office of Civil Rights. To eliminate confusion, except where quoting another document, this letter will use the Office's current name, rather than its name at the time of any particular action or correspondence.

Procedural Background of Complaint

On September 3, 2014, Earthjustice filed a complaint under Title VI of the Civil Rights Act of 1964, as amended, 42 U.S.C. §§ 2000d et seq., and the EPA's nondiscrimination regulations found at 40 C.F.R. Part 7, on behalf of the North Carolina Environmental Justice Network, Rural Empowerment Association for Community Help (REACH), and the Waterkeeper Alliance, Inc. alleging discrimination based on race and national origin by NC DEQ. The complaint alleged that NC DEQ's 2014 renewal of the Swine Waste General Permit without adequate measures to control, dispose of, and monitor animal waste from industrial swine feeding operations subjects African Americans, Latinos, and Native Americans to discriminatory impacts (*e.g.*, health issues, noxious odors, nuisances, increased expenses, social and psychological harms, declining property values).

On February 20, 2015, EPA opened an investigation into:

> Whether the North Carolina Department of Environmental Quality's (NC DEQ) regulation of swine feeding operations discriminates against African Americans, Latinos, and Native Americans on the basis of race and national origin in neighboring communities and violates Title VI of the Civil Rights Act of 1964 and the Environmental Protection Agency's implementing regulation.

On March 6, 2015, the Complainants and NC DEQ entered into an Alternative Dispute Resolution (ADR) process funded by EPA. ECRCO placed the investigation on hold pending the outcome of the ADR process. On March 7, 2016, the Complainants informed ECRCO that they were withdrawing from the ADR process.

On May 5, 2016, ECRCO informed NC DEQ that the ADR process between NC DEQ and the Complainants concluded without resolution; therefore, consistent with ECRCO procedures, ECRCO's investigation was reinitiated. On July 11, 2016, the Complainants filed an additional complaint alleging NC DEQ violated EPA's regulation prohibiting retaliation, intimidation, and harassment of Complainants (40 C.F.R. § 7.100). Among other events, Complainants point to events involving the Pork Councils' attempt to intervene at the January 2016 ADR session.

On August 1, 2016, NC DEQ submitted a response to the retaliation allegations. On August 2, 2016, ECRCO informed NC DEQ that it will also investigate:

> Whether NCDEQ's actions or inactions, including those associated with the presence and activities of the Pork Councils related to the January 2016 mediation session, violated 40 C.F.R § 7.100 which prohibits intimidating, threatening, coercing, or engaging in other discriminatory conduct against any individual or group because of actions taken and/or participation in an action to secure rights protected by the non-discrimination statutes OCR enforces.

On September 2, 2016, NC DEQ requested that ECRCO dismiss the original complaint. After reviewing the information provided by NC DEQ, ECRCO notified NC DEQ that the Complaint would not be dismissed. On December 5, 2016, NC DEQ submitted a response to the Complaint.

ECRCO's investigation is being conducted under the authority of Title VI of the Civil Act of 1964, and EPA's nondiscrimination regulations (40 C.F.R. Part 7), and consistent with ECRCO's Interim Case Resolution Manual (https://www.epa.gov/ocr/case-resolution-manual) Title VI provides that "[n]o person in the United States shall, on the ground of race, color, or national origin, be excluded from participation in, be denied the benefits of, or be subjected to discrimination under any program or activity receiving Federal financial assistance." 42 U.S.C. § 2000d. As implemented by EPA's regulation, these prohibitions include intentional discrimination as well as practices that have a discriminatory effect on the bases of race, color, or national origin. See 40 C.F.R. §§7.35(a), 7.35(b). The EPA regulation at §7.35 (b) prohibits a recipient from using criteria or methods of administering its program or activity which have the effect of subjecting individuals to discrimination. The EPA regulation also prohibits intimidation and retaliation against any individual or group for the purpose of interfering with a right protected by Title VI or because the individual has "filed a complaint, or has testified, assisted or participated in any way in an investigation, proceeding, or hearing" under EPA's regulation or has opposed any practice prohibited by the regulation. See 40 C.F.R. § 7.100.

ECRCO's investigation thus far has included an on-site visit to interview residents; reviewing information submitted by the Complainants including declarations prepared by residents and other witnesses; reviewing scientific and other literature and interviewing the authors when appropriate, and, a review of NC DEQ's responses to the Complaint dated August 1, 2016, September 2, 2016, and December 5, 2016. NC DEQ's December 5, 2016, letter requested that ECRCO "...provide any relevant information in its possession on the issue of discrimination by the State's regulation of Swine feeding operations." Below is a summary of information gathered thus far through ECRCO's investigation.

Adverse Impacts from Industrial Swine Operations on Communities of Color

On-Site Interviews and Declarations

ECRCO conducted an on-site visit to North Carolina (November 13-15, 2016) and interviewed over 60 residents living near industrial swine operations permitted under the Swine Waste General Permit. ECRCO's interviews were conducted mostly in Duplin and Sampson counties which have the highest concentration of industrial swine operations. To investigate the effects of the permitting program more broadly throughout the state, ECRCO also conducted interviews in other counties including Northampton County on the Virginia border and Pender County near the South Carolina border.

Some of the people interviewed had previously submitted declarations to ECRCO as exhibits to the Title VI complaint, some had not. The issues raised in the declarations and the impacts they discussed are similar or identical to those heard during the interviews. Many of those interviewed who had previously provided declarations provided updates to their declarations. ECRCO found credible all those interviewed thus far in the investigation. So far, ECRCO has heard in writing and/or orally from 85 witnesses in North Carolina who live near and described problems caused by their proximity to the industrial hog operations.

Residents, many of whom have lived in these communities for generations, described problems caused by their proximity to the industrial hog operations that have negatively changed their lives and communities, including those impacts described in studies referenced or discussed below. The residents described an overpowering stench, pests -- including a constant large number of flies, and the truck traffic all associated with the hog operations have forced residents to keep doors and windows closed and significantly limit any outdoor activity. Residents said the stench permeates homes, cars, and clothing. Some residents said the strength of the odor can be so strong it causes gagging, nausea and/or vomiting. For some residents who live near large numbers of industrial swine operations, they said stench is a weekly event lasting several days. They also stated they have no warning of when confinement house fans, spraying of the hog waste, or trucks transporting live or dead hogs will again bring the stench and actual waste onto their homes, property or themselves. Some described feeling as though they are prisoners in their own homes.

Residents described the loss of community that has occurred since the industrial hog farms began operating. They reported that young adults leave and do not return because of the odors, fear of health impacts from the air and drinking water, and other impacts. Prior to the arrival of the industrial hog operations, many of their family, community, and church gatherings had been held outdoors. Now they said those events are rarely held outdoors or if attempted outdoors, they are marred or forced to end early due to odors, flies, and other impacts.

Residents described increases in cases and severity of asthma and other respiratory illnesses, nausea, headaches and other health conditions. They stated these impacts have been compounded by the increase in industrial poultry operations, as well as the operation of landfills and waste disposal sites for hog sludge and carcasses. Those who had hunted and fished for both food and enjoyment, said they no longer do so because of the odors and fear of the contamination of wild sources of food such as fish. Residents stated they no longer keep gardens or grow their own vegetables for fear of contamination. Some residents are still on well water and are concerned about the safety of their drinking water. Some residents would prefer to use their private wells rather than public drinking water, but said they have either been told not to drink it or are afraid that it is contaminated. Residents also discussed increased expenses from buying and using public water, bottled water, clothes dryers, air fresheners, pesticides, air conditioning units, and food.

When asked whether they had filed complaints with NC DEQ or local governments about the odors, pests, and waste sprayed on them or their property, some residents said they did not know how or where to file complaints. ECRCO was told the filing of complaints with NC DEQ would be pointless and has resulted in retaliation, threats, intimidation, and harassment by swine facility operators and pork industry representatives. Several residents said that for more than 15 years, the government has been well aware of the conditions they have to live with, but has done nothing to help, so complaining to NC DEQ would be futile.

ECRCO also interviewed residents who live near an industrial swine operation that began operation using the lagoon and spray field method under a Certificate of Coverage under the Swine Waste General Permit. When discussing the impacts that occurred while the facility operated under the General Permit, the residents described the same impacts as those currently living near facilities operating under the General Permit, including nausea; headaches; odors that permeated their homes and prevented them from enjoying their yards and the outdoors; concerns about impacts to groundwater and surface water; and increased numbers of flies and other pests.

After several years of operation, the operator installed innovative technologies and practices to reduce the odor and other impacts from his operation including covering the waste lagoons; not spraying in the evenings and on weekends; and not using dead boxes. When asked to describe the current impacts from that industrial swine operation, for the most part the residents who live nearby said they rarely notice intense odors and that the number of flies has been greatly reduced. The exception was that one bordering neighbor said that the smell was unbearable during spraying. Other neighbors pointed out that the smell could also be from other industrial swine operations near that resident's property that still employ open lagoons and spray fields. ECRCO and other EPA staff who toured the operation including the confinement houses and the edge of the lagoons were surprised at how little odor there was given the number of swine housed there at that time and the presence of more than one waste lagoon.

Other Information on Adverse Impacts of Industrial Swine Operations on Nearby Residents

EPA recognizes that industrial hog operations have a negative impact on nearby residents, particularly with respect to objectionable odors and other nuisance problems that can affect their quality of life. (EPA, *Animal Feeding Operations Consent Agreement and Final Order*, 70 FR 4957, 4959 (Jan. 31, 2005)). The adverse impacts of offensive odors from North Carolina's industrial hog operations have been a known issue for more than 20 years. In 1994, the North Carolina legislature established a Blue Ribbon Panel, the Swine Odors Task Force, to study "the problem of swine odors and how to reduce them."[2] The report of the Swine Odors Task Force stated protests had been "numerous and well publicized."[3]

In part to protect North Carolina's travel and tourism industry and allow time for the completion of the studies of odor and other problems associated with swine operations, the state legislature implemented a moratorium effective March 1, 1997, on the construction or expansion of swine operations[4] that use "an anaerobic lagoon as the primary method of treatment and land application of waste by means of a spray field as the primary method of waste disposal."[5] Any new or expanding swine operations were required to eliminate or reduce a number of impacts from the lagoon and spray field methods including <u>substantially eliminating</u> ammonia emissions and odors detectable beyond the boundaries of the swine operation.[6] The moratorium was made permanent in 2007. However, the industrial hog operations using the lagoon spray field configuration already operating at the time of the moratorium were allowed to continue to operate under the Swine Waste General Permit without the requirements to <u>substantially eliminate</u> ammonia emissions and odors. Today, in a handful of counties mostly in eastern North

[6] G.S. § 143-215.10I (b)(2)-(3).

Carolina there is a total of more than 9 million hogs allowed in the more than 2000 industrial hog facilities operating under the Swine Waste General Permit.

North Carolina established a rule specifically to control objectionable odors from industrial swine operations.[7] "Objectionable odor" means any odor present in the ambient air that by itself, or in combination with other odors, is or may be harmful or injurious to human health or welfare, or may unreasonably interfere with the comfortable use and enjoyment of life or property. Odors are harmful or injurious to human health if they tend to lessen human food and water intake, interfere with sleep, upset appetite, produce irritation of the upper respiratory tract, or cause symptoms of nausea, or if their chemical or physical nature is, or may be, detrimental or dangerous to human health."[8] North Carolina's definition of "objectionable odor" encompasses the panoply of negative effects experienced by North Carolina residents, as told to ECRCO and discussed above.

Review of Reports and Studies

The adverse impacts on nearby residents from the lagoon spray field method of treatment and disposal of waste from industrial swine operations are documented in numerous peer reviewed scientific studies, including more than thirty conducted in North Carolina.[9] At ECRCO's request, EPA's Office of Research and Development (ORD) recently reviewed seven reports published by or with federal agencies.[10] ORD stated that the reports provide consistent support for the occurrence of potential health hazards (*e.g.*, eye, nose, and throat irritation; headaches; respiratory effects including asthma exacerbation; waterborne disease) at industrial swine operations and in their waste. Even while there is significant uncertainty regarding the levels of exposure in nearby communities to the identified contaminants and the risk of health effects attributable to those exposures, the risk for specific health effects in communities near industrial swine operations is a concern.

North Carolina's 1994 Swine Odors Task Force stated "it is not surprising to learn that living near a swine operation can affect mental health" when discussing a Duke University study of "the moods of people exposed to odors from commercial swine operations in North Carolina. Forty-four neighbors of hog operations . . . had less vigor and were significantly more tense, depressed, angry, fatigued, and confused."[11]

Additionally, ECRCO considered the findings of the analysis prepared by Drs. Steve Wing and Jill Johnston, *Industrial Hog Operations in North Carolina Disproportionately Impact African-Americans, Hispanics and American Indians*, (revised October 19, 2015) (*Complainants' Disproportionate Impact Analysis*). While the *Complainants' Disproportionate Impact Analysis* has not undergone peer review, it uses a study protocol and methodology that are substantially similar to peer reviewed studies by Wing et al. and Johnston et al.[12] The

[12] *See* Steve Wing, et al., *Environmental Injustice in North Carolina's Hog Industry* (Mar. 2000), ENVIRONMENTAL HEALTH PERSPECTIVES, https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1637958/; Jill E. Johnston, et al.,

Complainants' Disproportionate Impact Analysis concludes that the impacts from the manner in which waste is disposed of, and other impacts tied to industrial swine facilities operating under the Swine Waste General Permit, detrimentally affect those who live in neighboring properties and communities.

The *Complainants' Disproportionate Impact Analysis* also concluded, when examining those neighboring properties that African-Americans, Hispanics, and Native Americans are more likely than Whites to live near industrial swine operations granted COCs. Specifically, the *Complainants' Disproportionate Impact Analysis* concluded that, both state-wide, and in only-rural areas, African-Americans, Hispanics, and Native Americans living in North Carolina are more likely than Whites to live within 3 miles of an industrial swine operations granted COCs, and therefore suffer those detrimental effects. The *Complainants' Disproportionate Impact Analysis* looked at the steady state live weight (SSLW) of hogs within 3 miles of the center of census blocks. The SSLW was used as an indicator of density of hogs/the amount of swine feces and urine produced by the hogs in that 3-mile area. The *Complainants' Disproportionate Impact Analysis* found that for each 10 percent increase in the combined African-American, Hispanic, and Native American population and for each 10 percent increase in population for each of those census categories individually, the SSLW of hogs within 3 miles increases by anywhere from 47,000 to 165,000 pounds. This analysis concludes that there is a linear relationship between race/ethnicity and the SSLW or density of hogs.

Intimidation/Retaliation

The Complainants raised allegations of intimidation and harassment in their written submissions to ECRCO and during interviews related to the appearance of and actions by national and local representatives of the pork industry at what was to be a confidential ECRCO-sponsored alternative dispute resolution mediation session between NC DEQ and the Complainants. Complainants claim that, although NC DEQ representatives knew that complainants did not want representatives from the National Pork Producers Council and North Carolina Pork Council (Pork Councils) at this confidential meeting, NC DEQ representatives appeared to encourage their attendance and participation.

NC DEQ's responses in its letters dated August 1, 2016, and December 5, 2016, in part question whether complainants felt intimated by the Pork Council representatives' presence at the January 2016 mediation session. NC DEQ stated in both letters that "it strains credulity that these individuals were intimidated by the fact that they would be identified by representatives of organizations whom these individuals routinely criticized at public forums."[13] The following information provided to ECRCO may assist NC DEQ to better understand in part the context within which the Complainants have raised concerns about harassment, retaliation, and intimidation.

Wastewater Disposal Wells, Fracking, and Environmental Injustice in Southern Texas (Mar. 2016), AMERICAN JOURNAL OF PUBLIC HEALTH (2016), https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4816143/.

[13] Letter to Lilian S. Dorka, Acting Director, EPA Office of Civil Rights from Sam M. Hayes, General Counsel, North Carolina Department of Environmental Quality (Dec. 5, 2016), at 8-9.

During interviews, residents including REACH members, and current and former Riverkeepers working in the eastern North Carolina rivers recounted first hand incidents of harassment, intimidation, and retaliatory behavior, including physical and verbal threats, by swine facility owners and/or operators and their employees. The accounts ranged from sustained tailgating; driving back and forth in front of the houses of residents who have complained; filming or photographing residents who are taking photos or videos of spraying; being yelled at; confronted in parking lots and at intersections; and threatened with guns and other physical violence.

Those interviewed stated that these are regular events, rather than an exception, creating a climate where residents believe that if they file an environmental complaint with NC DEQ, they will likely be retaliated against by neighboring swine facility operators or employees. The Riverkeepers stated that they are subjected to this type of harassment and intimidation two or three times every couple of weeks. Particularly egregious instances brought to ECRCO's attention include a local industrial swine facility operator entering the home of an elderly African American woman and shaking the chair she sat in while threatening her and her family with physical violence if they continued to complain about the odors and spray; the firing of a gun in the air when an African American REACH member tried to speak to a person sitting on their porch; and a truck that sped up and swerved toward a Riverkeeper who was standing on the side of a public road teaching a group of volunteers how to sample water from public ditches. Those interviewed believe that the NC DEQ's lack of response to their complaints lends to the hostile environment and emboldens local facility owners and operators to act in a threatening and intimidating manner.

ECRCO has grave concerns about these reports indicating a potential hostile and intimidating environment for anyone seeking to provide relevant information to NC DEQ or EPA. Also, ECRCO is concerned about the circumstances surrounding the attendance by pork industry representatives during the mediation session.

Under certain circumstances, Title VI's prohibition on retaliation extends to third parties, which may include lower-level recipient employees, program beneficiaries or participants, organizations with a relationship to the recipient such as contractors, and others. EPA Title VI regulations provide that "[n]o recipient or *other* person" may retaliate. 7 C.F.R. § 7.100. Recipients themselves have two key obligations related to third party retaliation: first, to protect individuals from potential retaliation, recipients are obligated to keep the identity of complainants confidential except to the extent necessary to carry out the purposes of the Title VI regulations, including conducting investigations, hearings, or judicial proceedings; and second, recipients must investigate and respond when a third party engages in retaliatory conduct that Title VI prohibits. As with other types of third party conduct, such as harassment, the extent of the recipient's obligation is tied to the level of control it has over the bad actor and the environment in which the bad acts occurred. *See Davis v. Monroe Cty. Bd. of Educ.*, 526 U.S. 629, 644 (1999). EPA makes these determinations on a case-by-case basis in light of the facts and totality of circumstances in a particular case.

NC DEQ's Response to the Complaint[14]

In part, NC DEQ's December 5, 2016 letter responding to the Complaint reiterated arguments in favor of dismissal previously submitted to ECRCO by letter dated September 2, 2016. ECRCO has considered the information in both letters concerning the alleged reduction of adverse impacts by the permit renewal. As ECRCO pointed out previously, NC DEQ itself explained that the majority of the changes from the 2009 permit to the "current permit are structural and grammatical in nature"[15] and "do not make the Permit more stringent, costly or burdensome."[16] NC DEQ's responses did not state or explain how the 2014 Permit will reduce adverse impact from the source, significantly or otherwise; therefore, as stated in ECRCO's letter dated October 5, 2016, ECRCO does not believe that the argument constitutes a proper basis for dismissal of the complaint.

Similarly, NC DEQ's December 5, 2016 letter raised again a concern that the Complainants did not pursue an administrative appeal of the Swine Waste General Permit. NC DEQ explained that the permit appeal process under state law is an appropriate forum for "those who believe that the terms of the General Permit failed to comply with state law, or if a more effective means of pollution control should have been incorporated into the General Permit."[17] The allegation raised to EPA by the Complainants is that the Swine Waste General Permit fails to comply with federal law, namely Title VI of the Civil Rights Act of 1964. For almost 30 years, recipients of EPA financial assistance have been required under EPA's Title VI implementing regulation to have in place a grievance process. 40 C.F. R. § 7.90. The NC DEQ administrative forum to investigate and resolve exactly the issues of discrimination alleged in the Complaint that should have been available to Complainants did not exist when they filed their Complaint with EPA. Regardless, as NC DEQ previously acknowledged in its October 5, 2016 letter, there is no requirement under Title VI that Complainants exhaust administrative remedies before filing a discrimination complaint with EPA.

NC DEQ's response did not deny or refute the allegation that the industrial hog facilities operating under the Swine Waste General Permit were creating discriminatory impacts, rather, NC DEQ points to siting decisions by operators and changing demographics as reasons why certain communities may be more impacted than others. The impacts of concern in this investigation flow from the operation of the facilities. While an industrial swine facility operator may apply for an individual permit or certificate of coverage to operate in a particular location, it is NC DEQ that determines whether that facility will be allowed to operate and under what type of permit and its conditions.

NC DEQ also pointed out that the population has grown and the demographics have changed in areas of high concentration of industrial swine facilities since the first Swine Waste General

[14] ECRCO is not specifically addressing all of the points NC DEQ raised in its December 5, 2016 letter, but this should not be interpreted as ECRCO accepting those arguments.
[15]State of North Carolina, Department of Environmental and Natural Resources, *Report of the Proceedings on the Proposed Renewal of the State General Permits for Animal Feeding Operations, Public Meeting, November 12, 2013, Statesville, North Carolina, Public Meeting, November 14, 2013, Kenansville, North Carolina,*" p. 4.
[16] *Id.*, at pp. 5 and 8.
[17] Letter to Lilian S. Dorka, Acting Director, EPA Office of Civil Rights from Sam M. Hayes, General Counsel, North Carolina Department of Environmental Quality (Dec. 5, 2016), at 2.

Permit was issued. NC DEQ discussed the population growth in Duplin and Sampson Counties, highlighting in particular the rapid growth of the Latino population, and speculated that the population growth may have been due to jobs created by the industrial hog industry. The reasons for an increase in the minority population in the past 20 plus years in Duplin and Sampson Counties does not change NC DEQ's obligation to ensure that its current programs and activities do not have the effect of subjecting individuals to discrimination based on race, color or national origin.

NC DEQ requested information ECRCO has on anecdotal as well as systemic concerns relative to the Swine Waste General Permit Program. With regard to concerns about individual facilities, based on interviews of Riverkeepers working in eastern North Carolina, it is our understanding that for more than a decade they have provided NC DEQ documentation of hundreds of instances of waste spray or drift entering play areas; landing on people in their gardens, on their cars, and on their houses; runoff of hog waste entering streams and ditches; and improper spraying of waste after issuance of a National Weather Service Flood Watch. Riverkeepers stated they have provided NC DEQ the information through eyewitness accounts, photographs with time, date, and GPS coordinates embedded in the metadata, and/or video. Some of this information has been shared with ECRCO as well. Witnesses have stated that, to their knowledge, very few of these reports have received any mitigating action or resulted in enforcement action by NC DEQ. The temporal and geographic breadth of the anecdotal instances documented by Riverkeepers, points to systemic issues about which NC DEQ is aware.

Nondiscrimination Procedural Safeguards

At the time the Complaint was filed, NC DEQ was not in compliance with EPA's longstanding requirements under 40 C.F.R. Part 7, Subpart D which form the foundational elements of a recipient's program to implement the federal non-discrimination statutes.[18] These regulatory requirements include a continuing notice of non-discrimination under 40 C.F.R. § 7.95, grievance procedures available to the public, and the designation of at least one person to coordinate its efforts to comply with its non-discrimination obligations under 40 C.F.R. § 7.85(g).

At some point during the summer of 2016, NC DEQ appears to have begun the process of establishing its non-discrimination program. However, it is unclear whether NC DEQ has put in place the foundational elements of a properly functioning nondiscrimination program. ECRCO has attached a Procedural Safeguards Checklist (Attachment C) to assist NC DEQ in evaluating whether it has in place the appropriate foundational elements to ensure that it will meet its obligations under the federal nondiscrimination statutes.

Mitigation

As NC DEQ's December 5, 2016 letter noted, the study of the feasibility of environmentally superior swine waste technologies to the lagoon and spray field method began back in 2000.

[18] Title VI of the Civil Rights Act of 1964, Section 504 of the Rehabilitation Act of 1973, the Age Discrimination Act of 1975, Section 13 of Federal Water Pollution Control Act of 1972, and Title IX of the Education Amendments of 1972 (hereinafter referred to collectively as the federal non-discrimination statutes).

Some reviews of particular technologies were concluded more than a decade ago. According to the designee who made the decisions regarding the economic and environmental feasibility of the technologies, "[S]ubsequent research has focused on improving the economics of targeted technologies while maintaining the environmental performance."[19] EPA's ORD found in its review of reports discussed above that a number of risk management options are available to reduce potential health risks to nearby communities. EPA, USDA, and academia have continued to work on new processes, methods, and technologies to reduce impacts from industrial swine operations and waste since the review of available technology mentioned in NC DEQ's letter was completed.

Recommendations

ECRCO has not concluded its investigation and this letter does not contain ultimate findings of facts or law. Rather, ECRCO has summarized some of the information gathered to date to explain why ECRCO continues to be concerned about possible discriminatory impacts.

The totality of the information ECRCO has collected to date in its investigation, including NC DEQ's response to the complaint, indicates that the types of adverse impacts described above are being felt by large segments of the communities of color and are potential evidence of systemic concerns, not purely anecdotal claims. The information raises a concern that Swine Waste General Permit Program may run afoul of Title VI and EPA's Title VI regulations. NC DEQ's responses thus far have not provided a reason to dismiss the complaint or halt the investigation, nor has the information or arguments provided served to diminish ECRCO's level of concern.

On this basis, EPA makes a series of preliminary recommendations and requests a meeting to explore informal resolution. The recommendations are designed to focus an inquiry that will help them determine whether the problems are being caused by: (1) structural problems with the General Permit Program; (2) a lack of enforcement of the requirements of the permit (for example, no odors, no discharges, no spray beyond borders); or, (3) both.

ECRCO recommends that NC DEQ:

- Conduct an assessment of current Swine Waste General Permit to determine what changes to the Permit should be made in order to substantially mitigate adverse impacts to nearby residents. Determine which changes are currently within NC DEQ's authority to make and develop a timetable for adopting them. For Permit changes necessary to substantially mitigate the adverse impacts that NC DEQ cannot adopt, determine the source of the impediment to their adoption.
- Conduct an assessment of current regulations applicable to facilities operating under the Swine Waste General Permit to determine what if any changes to the regulations would be required to substantially mitigate adverse impacts to nearby residents. Determine which changes are currently within NC DEQ's authority to make and develop a timetable

[19] Williams, C.M. Williams, "*C.M. "Mike" Williams: Waste economics.*" The News & Observer, 8 June 2015. http://www.newsobserver.com/opinion/letters-to-the-editor/article23534074.html.

to adopt them. For regulatory changes necessary to substantially mitigate the adverse impacts that NC DEQ cannot adopt, determine the source of the impediment to their adoption.

- Evaluate the feasibility of risk management options available to reduce adverse impacts to nearby communities, including covering the waste lagoons; not spraying in the evenings and on weekends; not using dead boxes; and others described in this letter.
- Conduct an assessment of current mitigation technologies that would satisfy NC DEQ's performance criteria for new or expanding industrial swine operations and what if any impediments exist to adopting those technologies.
- Conduct a self-evaluation of the sufficiency of NC DEQ's enforcement and compliance efforts for existing rules governing the operation of its Swine Waste Management Program, including its response to odor and adverse health effects complaints, to determine whether implementation of any corrective measures are necessary including those to ensure a prompt and appropriate response to odor and other complaints. Determine which corrective measures are currently within NC DEQ's authority to make and develop a timetable for adopting them.
- Conduct an evaluation of NC DEQ's current policies and adjust them as appropriate to ensure the protection of confidentiality and identities of residents who provide information to NC DEQ about either environmental or civil rights complaints.
- Conduct a self-evaluation of its new non-discrimination program using the attached Procedural Safeguards Checklist to determine whether it has in place all the foundational elements listed to ensure that NC DEQ will meet its obligations under the federal nondiscrimination statutes. If any of the elements are not in place, NC DEQ should correct those deficiencies.

ECRCO looks forward to working with NC DEQ and would like to discuss with NC DEQ as soon as possible: the concerns previously outlined regarding the impacts on residents and communities; any additional information NC DEQ believes is relevant to the issue of whether Title VI has been violated; ECRCO's preliminary recommendations; NC DEQ's non-discrimination program; and the potential for informal resolution of this Complaint.

I will be contacting you in the next day or so to schedule a meeting to occur in the next two weeks. It is our goal to be able to reach informal resolution as soon as possible. We believe that through productive conversations over the next 60 days, we can negotiate an Informal Resolution Agreement that would address the concerns discussed in this letter and that would include a plan for moving forward on the above recommendations. If after discussion with NC DEQ, ECRCO does not believe informal resolution is possible, ECRCO will move forward to conclude its investigation and issue formal findings. If you have any questions, please feel free to contact me at (202) 564-9649, by e-mail at dorka.lilian@epa.gov, or U.S. mail at U.S. EPA, Office of General Counsel, External Civil Rights Compliance Office (Mail Code 2310A), 1200 Pennsylvania Avenue, N.W., Washington, D.C., 20460.

Sincerely,

Lilian S. Dorka

A grievance procedure that:			
• Clearly identifies the Non-Discrimination Coordinator, including contact information			
• Explains the role of the Non-Discrimination Coordinator relative to the coordination and oversight of the grievance procedures			
• States who may file a complaint under the procedures			
• Describes which formal and informal processes are available, and the options for complainants in pursuing either			

[20] 40 C.F.R. § 7.85(g)
[21] 40 C.F.R. § 7.95(a).
[22] 40 C.F.R. § 7.90.

Item	Yes & Supporting Documentation	Not Yet	Checking
• Explains that an appropriate, prompt and impartial investigation of any allegations filed under federal non-discrimination statutes will be conducted			
• States that the preponderance of the evidence standards will be applied during the analysis of the complaint			
• Contains assurances that retaliation is prohibited[23] and that claims of retaliation will be handled promptly if it occurs			
• States that written notice will be promptly provided about the outcome of the investigation, including whether discrimination is found and the description of the investigation process[24]			
• Is published in print in general publications distributed to the public			
Non-Discrimination Coordinator[25]			
At least one Non-Discrimination Coordinator to ensure compliance with the federal non-discrimination statutes			
Non-Discrimination Coordinator or other individual responsible for:			
• Providing information internally and externally regarding rights to services, aids, benefits, and participation without regard to race, national origin, color, sex, disability, age or prior opposition to discrimination			
• Providing notice of your Agency's formal and informal grievance processes and the ability to file a discrimination complaint			
• Establishing grievance policies and procedures or mechanisms (e.g., an investigation manual)			
• Tracking all complaints filed with your Agency under federal non-discrimination statutes including any patterns or systemic problems			

[23] 40 C.F.R. § 7.100.
[24] Whether OCR considers complaint investigations and resolutions to be "prompt" will vary depending on the complexity of the investigation and the severity and extent of the alleged discrimination. For example, the investigation and resolution of a complaint involving multiple allegations and multiple complainants likely would take longer than one involving a single allegation of discrimination and a single complainant.
[25] 40 C.F.R. § 7.85(g).

Item	Yes & Supporting Documentation	Not Yet	Checking
• Semiannual reviews of all complaints filed with your Agency under federal non-discrimination statutes in order to identify and address any patterns or systemic problems			
• Appropriate training for your Agency's employees on your Agency's non-discrimination policies and procedures and obligations to comply with federal non-discrimination statutes			
• Updating complainants on the progress of their complaints filed with your Agency under federal non-discrimination statutes and any determinations made			
• Periodic evaluations of the efficacy of your Agency's efforts to provide services, aids, benefits, and participation in any of your Agency's programs or activities without regard to race, national origin, color, sex, disability, age or prior opposition to discrimination			
Public Participation			
Written and published public participation process/procedures that provide that when your Agency prepares a public participation plan for a specific action, it will include:			
• A description of the community (including demographics, history, and background)			
• A contact list of Agency officials with phone numbers and email addresses to allow the public to communicate via phone or internet			
• A list of past and present community concerns (including any complaints filed under the federal non-discrimination statutes)			
• A detailed plan of action (outreach activities) your Agency will take to address concerns			
• A contingency plan for unexpected events			
• Location(s) where public meetings will be held (consider the availability and schedules of public transportation			

Item	Yes & Supporting Documentation	Not Yet	Checking
• Contact names for obtaining language assistance services for limited-English proficient persons, including, translation of documents and/or interpreters for meetings			
• Appropriate local media contacts (based on the culture and linguistic needs of the community			
• Location of the information repository			
Access To Programs And Activities by Persons with Limited English Proficiency			
Has your Agency conducted an appropriate analysis described in OCR's LEP Guidance found at 69 FR 35602 (June 25, 2004) and http://www.lep.gov to determine what language services it may need to provide to ensure that individuals with limited-English proficiency can meaningfully participate in the process?			
Has your Agency developed a language access plan consistent with the details found in OCR's training module for LEP. http://www.epa.gov/civilrights/lepaccess.htm?			
Does your Agency have written and published procedures that:			
• Ensure meaningful access to all of your Agency's programs and activities to persons with limited-English proficiency and individuals with disabilities			
• Make communities you serve aware that foreign language services are available			
• Translate standardized documents			
• Provide for simultaneous oral interpretation of live proceedings such as town hall meetings or public hearings			
Access To Programs And Activities by Persons with Disabilities			
Does your Agency have written and published procedures to ensure to provide access to your programs, services, and activities for individuals with disabilities that:			
• Provides at no cost appropriate auxiliary aids and services including, for example, qualified interpreters to individuals who are deaf or			

Item	Yes & Supporting Documentation	Not Yet	Checking
hard of hearing, and to other individuals as necessary to ensure effective communication or an equal opportunity to participate fully in the benefits, activities, programs and services provided by your Agency in a timely manner and in such a way as to protect the privacy and independence of the individual			
• Ensures that your Agency's facilities and non-Agency facilities utilized by your Agency (*e.g.*, if your Agency holds a public hearing at a school) are physically accessible for individuals with disabilities			
• Makes communities you serve aware that services for individuals with disabilities are available			

NOTICE OF NON-DISCRIMINATION RECOMMENDED TEXT

[Agency Name] does not discriminate on the basis of race, color, national origin, disability, age, or sex in the administration of its programs or activities, as required by applicable laws and regulations.

[Insert name and title of Non-Discrimination Coordinator] is responsible for coordination of compliance efforts and receipt of inquiries concerning non-discrimination requirements implemented by 40 C.F.R. Part 7 (Non-discrimination in Programs or Activities Receiving Federal Assistance from the Environmental Protection Agency), including Title VI of the Civil Rights Act of 1964, as amended; Section 504 of the Rehabilitation Act of 1973; the Age Discrimination Act of 1975, Title IX of the Education Amendments of 1972, and Section 13 of the Federal Water Pollution Control Act Amendments of 1972.

If you have any questions about this notice or any of [Agency Name]'s non-discrimination programs, policies or procedures, you may contact:

> [Insert name and title of Non-Discrimination Coordinator]
> [Insert Agency Name and Address]
> [Insert phone number of Non-Discrimination Coordinator]
> [Insert email address of Non-Discrimination Coordinator]

If you believe that you have been discriminated against with respect to a [Agency Name] program or activity, you may contact the [insert title of Non-Discrimination Coordinator] identified above or visit our website at [insert] to learn how and where to file a complaint of discrimination.

SENT VIA EMAIL

October 22, 2021

Elizabeth S. Biser, Secretary
N.C. Department of Environmental Quality
217 W. Jones Street
Raleigh, NC 27603

Dear Secretary Biser:

The Environmental Justice and Equity (EJE) Advisory Board was chartered to assist the Department of Environmental Quality (DEQ) in ensuring fair and equal treatment and meaningful involvement of all North Carolinians, regardless of race, color, national origin, or income, in the development, implementation, and enforcement of environmental laws and policies. In this role, we strive to ensure access to clean air, clean water, and clean soil, and the opportunity to live in safe and healthy communities for all North Carolina families.

Today, we write to you about pollution from hog operations, a long-standing environmental justice issue that has affected thousands of North Carolina families for decades. We respectfully request that DEQ take steps to protect these families, their health, and the environment.

Under the 2021 North Carolina Farm Act, N.C. Sess. L. 2021-78, DEQ must develop a general permit for hog operations that will produce swine waste-to-energy (biogas) by July 2022. As we expressed in our August 26, 2021 letter to you, the EJE Advisory Board has significant concerns about the pollution and public health implications of this general permitting scheme.

In addition to the procedural recommendations we provided in our August 26, 2021 letter, we advise DEQ to ensure the new general permit include robust substantive protections against hog waste pollution and its disparate impacts on surrounding communities. Cleaner technologies and practices that reduce water and air pollution—and that are compatible with biogas production—are available and practicable. In fact, some of these technologies are used by Smithfield Foods, the nation's largest pork producer, in other states. North Carolinians deserve the same protections.

In North Carolina, biogas is produced by capturing methane from hog waste lagoons using covered anaerobic digesters. To date, DEQ has allowed hog operations to dispose of waste from these digesters by transferring the digester waste to open "secondary" lagoons, and spraying the digester waste on fields.[1] The biogas is sent off-site for processing and eventually used to produce energy. Biogas produced using the lagoon and sprayfield system is not a clean source of energy.

---

[1] *See, e.g.*, Permit No. AWI310039 Benson Farm (Mar. 31, 2021) (authorizing the use of a Waste-to-Energy system, which includes a covered anaerobic digester; a clay-lined lagoon; pumps, pipes, and other equipment to transfer waste; and sprayfields).

The lagoon and sprayfield waste management system used at industrial hog operations pollutes waterways,[2] contaminates drinking water,[3] and dirties the air people breathe.[4] This pollution and the resulting harms to human health have burdened neighbors—mainly people of color and low wealth communities--for decades.[5] As such, this is one of the most significant and well-studied environmental injustices in North Carolina; public health and environmental experts agree on the harm that this system causes for people and the environment.

Producing biogas from hog waste using anaerobic digesters, open secondary lagoons, and sprayfields does *not* address many of the longstanding, serious pollution problems of using open lagoons and sprayfields to store and dispose of hog waste. The use of digesters is likely to *increase* ammonia emissions when the digester waste is stored in open secondary lagoons and sprayed on fields.[6] Airborne ammonia from hog operations deposits in surrounding waterways, causing

AIR

pollution that can lead to algae blooms and fish kills.[7] Airborne ammonia also deposits on the ground, where it can seep into the soil and cause nitrate pollution in drinking well water, which can harm infants and pregnant women.[8] Airborne ammonia also forms fine particulate pollution that causes serious health problems and premature deaths in surrounding communities.

In fact, a recent study published by the National Academy of Sciences attributes an astounding 95 premature deaths in Sampson County and 83 premature deaths in Duplin County to the emissions from hog operations every year.[9] This is already an unacceptable situation that must be stopped. And the prospect of *increasing* the rates of sickness or death, resulting from sending more ammonia and fine particulate pollution into the surrounding environment, is simply unacceptable. DEQ must not allow hog waste pollution to continue harming more people in our most vulnerable communities.

Communities in eastern North Carolina have been complaining about pollution from industrial hog operations for decades. Since DEQ began considering permits for the first large-scale biogas project almost two years ago, hundreds of people across eastern North Carolina and beyond participated in public hearings, submitted comments, and appealed to DEQ to protect their communities and the environment from pollution from lagoons and sprayfields. To date, DEQ has failed to heed these calls.

In developing the conditions of the biogas general permit, DEQ must address this environmental injustice and protect families and the environment in eastern North Carolina. To start, DEQ's environmental justice analysis must be more than a formality intended to inform agency outreach. Instead, DEQ must conduct a comprehensive environmental justice analysis that translates into substantive permit conditions to minimize disparate impacts from cumulative impacts of the general permit and other DEQ-permitted operations on surrounding communities, including

[9] Nina G.G. Domingo et al., *Air quality-related health damages of food*, 118 PROCEEDINGS OF THE NAT'L ACAD. SCIS. 1 (May 2021), https://www.pnas.org/content/118/20/e2013637118.

communities of color and low-wealth communities that are already overburdened by pollution from multiple industries.[10] To be clear, it is not enough for DEQ to evaluate the cumulative effects of permitting decisions on water quality, as required under state environmental law; the agency, as a recipient of federal funding, also has obligations under Title VI of the Civil Rights Act of 1964, which require the agency to address harm to vulnerable North Carolinians.

In addition, as part of the general permit, we strongly advise DEQ to require the following:

- Cleaner technology and practices that are compatible with biogas production *and* address water and air pollution caused by the lagoon and sprayfield system, particularly given the increased ammonia pollution associated with open storage of biogas digester waste;

- Robust groundwater and surface water monitoring at every hog operation to identify pollution to rivers, streams, and groundwater, which is a source of drinking water for many rural residents;

- Updated nutrient management plans that account for the changes in the land-applied waste after digestion; and

- More protective freeboard requirements, such as automated lagoon/storage pond waste-level monitors and recorders, to reduce the likelihood that flooding or inundation of lagoons due to increasing frequent and severe storms will result in the discharge of the more harmful digester waste.

Thank you for your attention to this important matter.

Respectfully submitted by the EJE Advisory Board

James H. Johnson, Jr., Chair
Marian Johnson-Thompson, Vice Chair

[10] DEQ must scrutinize the environmental impact of the poultry industry as part of this analysis, as poultry operations with 30,000 or more birds are deemed permitted under state law, are often co-located in communities hosting swine operations, and have proliferated most rapidly in recent years in communities of color.

ATTACHMENT 4

SENT VIA EMAIL

August 26, 2021

Elizabeth Biser, Secretary
N.C. Department of Environmental Quality
217 W. Jones Street
Raleigh, N.C. 27603

Dear Secretary Biser:

The Environmental Justice and Equity Advisory Board (EJE) was created to bridge the gap between the Department of Environmental Quality (DEQ) and the communities of North Carolina. The EJE Advisory Board's primary charge is to advise you as the Secretary and assist DEQ in achieving fair and equal treatment as well as meaningful involvement of all North Carolinians--regardless of race, color, national origin, or income--in the development, implementation and enforcement of environmental laws, regulations and policies. Our shared goal is to mitigate adverse impacts of environmental policymaking on communities burdened disproportionately by environmental harms.

For some time now the EJE Advisory Board has been aware of the environmental concerns regarding concentrated animal feeding operations (CAFOs). With the enactment of the 2021 North Carolina Farm Act (SL 2021-78), the EJE Advisory Board has become more aware of the fact that placement of anaerobic digester systems will further exacerbate conditions for residents living near swine CAFOs. This is a critical environmental justice concern because the harm caused by swine waste mismanagement is disproportionately borne by Black, Latino, and Native American residents of North Carolina.[1, 2] Multiple studies have shown that living near CAFOs adversely affects the health and quality of life of fellow North Carolinians.[3, 4, 5, 6] We, as the EJE Advisory Board, cannot remain silent considering these facts.

6 Wendee Nicole, *CAFOs and Environmental Justice: The Case of North* Carolina, 121 Envtl. Health Perspectives A182, A 186 (2013), ("Even without spills, ammonia and nitrates may seep into groundwater, especially in the

Further, we have heard and shared the public's concerns about biogas and the development of a general permit that will allow CAFOs to install anaerobic digesters under one-size-fits all conditions.[7] Production of biogas must not be allowed to exacerbate known harms caused by lagoon and sprayfield systems, which are disproportionately borne by vulnerable North Carolinians.[8] And the permitting process must take into account local realities such as community demographics, environmental and health risks, and the cumulative impacts of other DEQ-permitted activities in the vicinity.

Moreover, with regard to Biogas systems, such as those recently proposed and permitted, far better waste treatment and disposal alternatives exist, which do far less harm to the environment. Other states have required the industry to use such superior waste management technology. DEQ should do the same to protect its citizens.

DEQ is now tasked with developing permit conditions for a new general permit that would authorize the construction and operation of farm digester systems to generate biogas. While DEQ has advised members of the General Assembly that it has the authority to further scrutinize any applicant/application perceived to present a danger to community, it has failed thus far to exercise that authority to protect impacted North Carolinians. For instance, the four individual biogas permits approved earlier this year do not require any regular air or water monitoring to assess the nature or volume of any emissions or discharges or the impact thereof on public health or the local environment. DEQ must take the steps necessary, during the process of developing and issuing coverage under this general permit, to assure that there is adequate and meaningful public participation such that the issues raised here are appropriately understood, evaluated, and addressed by the agency.

DEQ cannot assure that the protection afforded under the permit is adequate if it fails to provide sufficient opportunities for participation of affected communities to inform the permit conditions. DEQ staff may inspect permitted facilities once a year, but neighbors bear witness to permitted operations on a daily basis. This lived experience can help inform permit conditions and the scrutiny of permit applications, but only if community input is solicited and considered by DEQ permitting staff. Past efforts have failed to be inclusive of all affected community members. That should not be the case in this instance; DEQ has ample time to develop and implement an inclusive process. As recognized in DEQ's public participation plan and limited English proficiency plan, where additional steps are needed to assure participation, then DEQ should take them to give the public meaningful opportunity to comment before the agency develops the proposed permit.

The hope of the EJE Advisory Board is that no affected community is left out of the conversation due to a lack of access to dependable broadband service, especially in light of the digital divide

---

coastal plain where the water table is near the surface."), https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3672924/.

[7] Phoebe Gittelson, et al., *The False Promises of Biogas: Why Biogas is an Environmental Justice Issue*, Environmental Justice 3 (2021), https://www.liebertpub.com/doi/pdf/10.1089/env.2021.0025.

[8] DEQ Environmental Justice Report, *Swine Farm Modifications 3* (Dec. 22, 2020) (noting that, of four biogas projects under consideration, one would cover a single lagoon but retain uncovered lagoons, while 3 would excavate new lagoons and still retain/use existing uncovered lagoons to manage waste).

acknowledged by the Cooper Administration in the creation of the new Office of Digital Equity and Literacy. Considering the limited access by impacted community members to online fora, meaningful engagement can only be accomplished by conducting face-to-face meetings. Using WebEx or some other virtual platform is not an adequate substitute.

In developing this permit, DEQ should consider both the procedural and the substantive process. This advisory statement is intended to address the concerns that the Board has about the process for engaging the impacted communities. That process should be open and transparent at all times. It should be inclusive, and communities should have adequate notice of any and all actions of DEQ in this matter. The Board will conduct a special meeting to solicit additional input to inform a future advisory statement regarding the substance of the general permit.

To accomplish meaningful engagement of affected communities the EJE Advisory Board unanimously consents to offer the following recommendations to DEQ.

1. Conduct at least four public meetings. At least two should be public face-to-face meetings in the counties most affected – one in Duplin County and one in Sampson County. All meetings should be held in accordance with CDC COVID-19 guidelines to protect the health and safety of all attendees.
2. Alternatively, if it is not feasible to conduct a scheduled face-to-face meeting, DEQ should extend the date for any scheduled meetings until it is safe to conduct in-person meetings to receive public input during the development of the general permit.
3. Provide at least a 60-day notice of any planned public meeting to allow impacted communities to plan their participation.
4. Extend the period for public comment on the draft permit for at least 90 days to allow adequate time for local community members to provide comments for consideration by DEQ.
5. Provide Spanish interpretation services for participants with limited English proficiency. Demographic data reveal Hispanic residents are 1.39 times more likely to live near CAFOs than their white counterparts.[9]
6. Provide Spanish translation of draft permits, EJ analyses and related notices, as well as interpretation of hearing dialogue.
7. Engage an independent consultant to facilitate dialogue between stakeholders and agency staff at all meetings.
8. Respond in writing to community concerns expressed during the permitting process so that agency decision-making is transparent and reflects consideration, not merely invitation, of public input.
9. Consult with the NC Department of Health and Human Services to evaluate the health impacts of existing swine CAFOs including but not limited to those employing directed biogas technology.

Thank you in advance for your consideration in this matter.

Tracing nutrient pollution from industrialized animal production in a large coastal watershed

Colleen N. Brown · Michael A. Mallin · Ai Ning Loh

Received: 28 January 2020 / Accepted: 18 June 2020 / Published online: 14 July 2020

Abstract One of the highest concentrations of swine and poultry concentrated animal feeding operations (CAFOs) in North America is located on the Coastal Plain of North Carolina, in which the Cape Fear River basin is located. The CAFOs produce vast amounts of manure causing loading of nutrients and other pollutants to receiving waters. With the Cape Fear River basin vulnerable to nutrient pollution, as are many other watersheds with CAFOs, $\delta^{13}C$ and $\delta^{15}N$ stable isotopic signatures were identified from water samples collected within the Northeast Cape Fear, Black, and lower Cape Fear River watersheds to trace nutrient sources and their distribution downstream. The spatial and temporal variability of nutrients and isotopic signatures were also identified to understand water quality impacts of animal waste spraying season and proximity to CAFOs. Our results showed that significantly enriched $\delta^{15}N$ signatures characterized sites in close proximity to CAFOs as well as point-source wastewater discharge areas, while the opposite was true for an unimpacted control stream and two estuarine sites. Additionally, the impacted sites yielded significantly ($p < 0.05$) higher nitrate concentrations than control and estuarine sites. Statistical analyses demonstrated that nitrate concentrations were positively correlated with heavier $\delta^{15}N$ signatures, suggesting that animal waste, as well as human wastewater, are relatively more important sources of N to this large watershed than fertilizers from traditional row crop agriculture. Our results also suggested that during appropriate hydrological conditions CAFO-derived N can be detected many kilometers downstream from freshwater sources areas to the estuary.

Introduction

Industrial agriculture has become a norm for sustaining food production demands in recent decades and has been particularly congregated in certain rural communities in the USA. Industrialized livestock farms, recognized as concentrated animal feeding operations or CAFOs, have largely replaced the traditional agricultural practices of farrow-to-finish farms (McBride and Key 2013). Large corporations own swine, cattle, or poultry, and contract animals out to individual landowners to raise hundreds to thousands of livestock and poultry in close confinement. This technique allows for mass production with lower costs. In the USA, North Carolina has the third highest industrial animal production concentration by state with 1222 registered CAFOs, only exceeded by Minnesota with 1300 and Iowa with 3588 (USEPA 2017). The environmental and water quality impacts of such industrialized production techniques have been documented in the literature (Burkholder et al. 2007; Mallin et al. 2015), but the impacts of such production on waterways farther downstream are less well-defined, and thus assessed in this study.

Swine and poultry CAFOs

The Cape Fear River watershed, the largest watershed in North Carolina, has the highest concentration of swine CAFOs in the world as well as numerous poultry CAFOs (Cahoon et al. 1999; Mallin and Cahoon 2003). The magnitude of livestock and poultry in this area increases the demand for large quantities of animal feed, mainly comprised of soybeans and cornmeal (Choi 2007). These primary feed grains are imported to Mid-Atlantic states from outside states that specialize in corn and soybean agriculture because facilities cannot grow enough of their own feed to meet the demand themselves, and feed importation is a low-cost option. CAFOs located within the Cape Fear River basin in North Carolina import over 90% of soybeans for animal feed (Cahoon et al. 1999). While low-cost feed imports have facilitated the growth of CAFOs in North Carolina, they have also increased external, "new," nitrogen (N) and phosphorus (P) influxes to affected watersheds. With the uneven distribution of swine CAFOs across the USA, 13% concentrated in North Carolina, the Cape Fear River watershed is biogenically stressed with excess nutrient and fecal microbial influxes (Kellogg 2000; Harden 2015).

One of the leading environmental concerns brought about by the industrial agriculture system is the quantity and management of waste produced (USEPA 2004). The high-density animal confinement of CAFOs yield industrial levels of waste that have surpassed human waste production 13-fold (Burkholder et al. 2007). CAFO manure specifically threatens water quality degradation with nutrient contamination (USEPA 2004). Concentrated swine waste management and storage practices are generally characterized by the disposal and storage of waste water, comprised of swine feces and urine, in outdoor lagoons which are seasonally pumped out and sprayed on surrounding fields, termed "spray fields" (Mallin et al. 2004; Mallin et al. 2015). Within the common swine CAFO, waste accumulates in each individual stall and throughout the containment facility. The floors are comprised of slats that have slits allowing for manure to be hosed down through and drop into an underground conveyance below for storage, prior to being flushed out into the waste lagoons (Mallin et al. 2015). Anaerobic lagoons act as a treatment of wastewaters, converting organic material into stable compounds such as carbon dioxide and methane that are volatized (USEPA 2002). After the treatment period, in which dense organic sludge settles out and separates from supernatant liquid wastewater, the supernatant is sprayed on nearby fields containing a cover crop, usually Bermudagrass; spraying is permissible March through September (Mallin and McIver 2018). The nutrients from the concentrated waste are assumed to be absorbed by the cover crops on the swine waste spray fields. In traditional, farrow-to-finish farms, this method was viable because manageable waste amounts could be upcycled into fertilizer for their own swine forage (Hribar 2010). However, when this common practice is transitioned to CAFOs, the manure quantity exceeds land and/or soil nutrient capacity (Haines and Staley 2004).

Poultry CAFOs are also abundant in North Carolina, though the exact number remains unknown as dry litter poultry operations are not required to obtain permits. There are currently 19 wet-litter poultry CAFOs with permits in North Carolina (egg-laying facilities) while the vast majority of poultry CAFOs utilize dry litter waste disposal. Dry litter poultry farms are defined in that manner as the poultry waste (i.e., litter) is dried and spread on surrounding fields or shipped to other sites to be applied as nutrient fertilizer (Harden 2015). Overall, environmental contamination from swine and poultry CAFOs results from oversaturated spray field soils leaching into ground water during routine spraying, runoff from over capacitated lagoons or freshly sprayed fields during precipitation events and hurricanes, or leakage from poor lagoon construction (Amini et al. 2017; Burkholder et al. 2007). The magnitude of environmental impacts that CAFO wastewater imposes depends on the contaminants involved, soil properties, and proximity to waterways (Huddleston 1996; Burkholder et al. 2007). Close proximity of numerous CAFOs to streams and floodplains, apparent in North Carolina, facilitates vulnerability to wastewater runoff contaminants during storms and lagoon overflow (Wing et al. 2002; Martin et al. 2018).

Cape Fear River watershed

The Southeastern region of North Carolina, in which the Cape Fear River watershed is located, is physiographically characterized as Coastal Plain (NCDC 2018). The Coastal Plain is comprised of two main sub-areas, tidewater and interior portion (NCDC 2018). Tidewater areas, closest to the ocean, are characteristically flat, swampy, and poorly drained. The interior region has a gentle slope with good drainage. Overall, the Coastal Plain soil composition is soft sediment with generally no hard rock substrate beneath the surface (NCDC 2018). Wetlands dominate the Coastal Plain, particularly the tidewater areas, and have demonstrated water quality benefits through sediment and nutrient sequestration (Robinson 2005). The central region of North Carolina is described as Piedmont, located between the Coastal Plain and Mountain regions. The Cape Fear River watershed originates within the Piedmont and flows southeast crossing the fall line into the Coastal Plain and eventually emptying into the Atlantic Ocean. The lower 40 km of the river comprises the Cape Fear Estuary.

Watersheds with swine CAFOs have been found to contain streams with considerably higher inorganic and organic N concentrations than unimpacted streams (Harden 2015; Mallin et al. 2006, 2015). Anaerobic waste lagoons with large quantities of organic N produce high concentrations of ammonium-N through deamination (Mallin and Cahoon 2003), some of which is nitrified following discharge into the environment. The ability for nitrate to leech into groundwater depends on underlying soil composition and groundwater depth. High permeability soil (i.e., gravel, sandy gravel, and coarse sand) and relatively low aquifer depth are associated with high nitrate concentrations in groundwater (USEPA 2004). The North Carolina Coastal Plain generally has porous soils and a high water table, around 0–2 m below the surface, which create vulnerability to nutrient leeching (Mallin et al. 2015; USGS 2019). Thus, underlying geological and hydrological conditions exacerbate off-site transport of nutrients to downstream water bodies. Tracing of off-site nutrient loading can be accomplished through stable isotope studies.

The Cape Fear River region and surrounding coastal areas have been ranked most vulnerable to manure nutrient pollution within the USA (Kellogg 2000). Over 50% of North Carolina's swine production is located in the Cape Fear River Basin, where lagoon effluent is able to enter the blackwater streams that dominate such watersheds (Mallin et al. 2015; Martin et al. 2018). Unimpacted blackwater systems are characteristically inorganically nutrient poor and have low dissolved oxygen levels in comparison to anthropogenically induced streams (Smock and Gilinsky 1992). Phytoplankton production in these systems is stimulated by N, rather than P; however, P inputs directly stimulate bacterial growth; thus these systems are susceptible to biochemical oxygen demand (BOD)-induced oxygen depletion from loading of either nutrient (Mallin et al. 2004, 2006). CAFO-dominated watersheds of blackwater streams have the potential to drain substantial nutrient loads into the two major 5th-order tributaries (Northeast Cape Fear River and Black River) of the Cape Fear River, which subsequently enters the Atlantic Ocean through its estuary (Fig. 1). It is essential to assess nutrient concentrations and sources within the watershed to understand and mitigate nutrient pollution to the larger rivers and estuary.

Particulate organic matter ($\delta^{15}N$ and $\delta^{13}C$)

Particulate organic matter (POM) is characterized as particles that range from 0.054 to 2.0 mm, and physically cannot pass through a 7-μm filter pore (Cambardella and Elliott 1992; Nebbioso and Piccolo 2013). Organic carbon (C) and nitrogen (N) stable isotope ratios have been identified as natural tracers for organic matter origins and seasonal influxes (Thornton and McManus 1994). These isotopic ratios are assumed to reflect a distinct end-member that correlates with the biogeochemical process that alters their composition. Organic matter pools within river sediments are a conglomerate of biogenic processes, and isotopic mixing models estimate contributions from the assortment of various organic sources.

As mentioned previously, the application and storage of manure is associated with ammonia volatilization. When ammonia volatizes during wastewater degradation, the lighter $\delta^{14}N$ is removed leaving a majority of heavier $\delta^{15}N$ isotopes in the soil or waste ponds (Macko and Ostrom 1994). Bacterial nitrification in soil produces nitrate from ammonium, still rich in $\delta^{15}N$. POM $\delta^{15}N$ signatures have been distinguished for various nitrogen

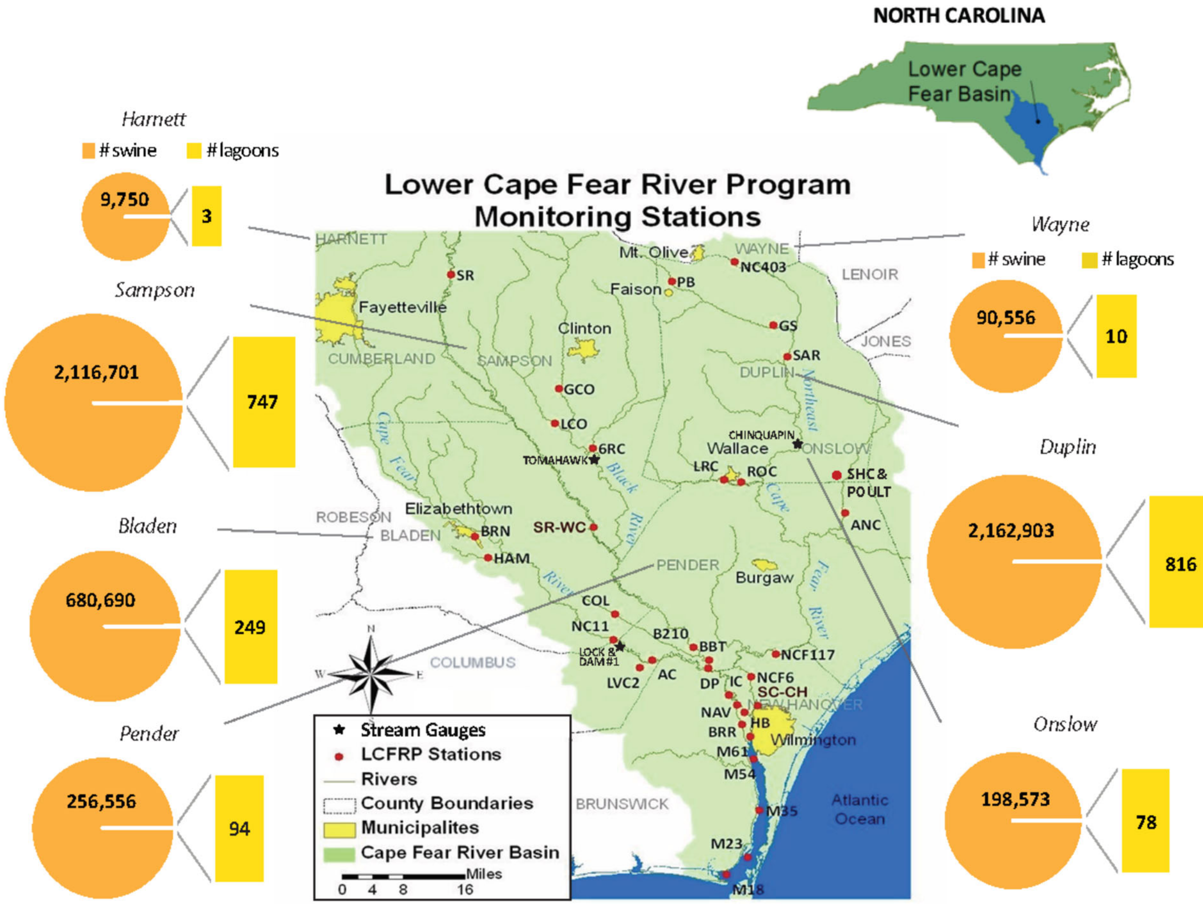

Fig. 1 Map of the Lower Cape Fear River Program monitoring stations showing sampling locations for this study. Inset shows location of sampling area within North Carolina, USA. Additional information includes standing crop of swine and number of waste lagoons per county (NCDEQ 2016)

source inputs (Table 1). Fixation of atmospheric N produces δ^{15}N signatures near zero (Kendall and McDonnell 1998), and atmospheric deposition of N produced signatures around − 3.0‰ (Heaton 1986). Synthetic fertilizers are generally in the − 2.0 to + 2.0‰ range (Bateman and Kelly 2007). Signatures of both human and animal waste are generally in the + 10.0 to > + 20.0‰ range, depending on degree of treatment or amount of microbial conditioning in the soil (Heaton 1986; Costanzo et al. 2001). The poultry waste signature generally ranges between + 8.0 and + 16.0‰, centered around + 8.0 to + 9.0 (Wassenaar 1995); although poultry manure pellets have displayed δ^{15}N signature as low as + 5.0‰ (Bateman and Kelly 2007). Thus, for human and animal waste, there is a considerable overlap, and distinguishing specific sources of N pollution can be aided by knowledge of the watershed land use and pollution sources (Lapointe et al. 2017). With deposition from atmospheric nitrogen, groundwater δ^{15}N typically ranges from + 2 to + 8‰ (Macko and Ostrom 1994). Marine aquatic sources have a broader range of δ^{15}N, from − 15 to + 20‰ (Fernandes et al. 2016).

In addition to δ^{15}N, the δ^{13}C signatures identify plant characteristics of specific water types (i.e., freshwater, estuarine, or seawater) to better understand the origin of carbon throughout the watershed. Freshwater plankton typically exhibit δ^{13}C signatures from − 30 to − 25‰, while C3 and C4 estuarine plants have heavier δ^{13}C signatures ranged − 27‰ to − 13‰ (Fry 2006). Carbon source nutrients from livestock and poultry waste can be identified through δ^{13}C signatures that reflect the plant material they eat, generally within the range of − 27‰ to − 22‰ (North et al. 2004). Overall, isotope tracing holds the potential to determine sources of environmental impact related to CAFO pollution distributed throughout a watershed.

Table 1 Overview of $\delta^{15}N$ signatures from various sources (from Heaton 1986; Wassenaar 1995; Costanzo et al. 211; Bateman and Kelly 2007; Lapointe et al. 2017)

Source	Range
Natural N-fixation	0‰
Atmospheric N	− 3‰ to + 1‰
Synthetic fertilizer	− 2‰ to + 2‰
Human wastewater (depends on degree of treatment)	+ 3‰ to + 19‰
Livestock waste	+ 10‰ to > + 20 ‰
Poultry waste (depends on poultry diet)	+ 5‰ to + 16 ‰

The CAFO-rich Cape Fear River watershed is vulnerable to the spread of nutrient pollution throughout the system (Mallin et al. 2004, 2006), and thus the primary objective of this study was to track and assess the presence of swine and poultry CAFO nutrient pollutants in the Cape Fear River watershed downstream through the Cape Fear River Estuary using $\delta^{15}N$ and $\delta^{13}C$ isotopic tracers. Additionally, the wide distribution of CAFOs throughout the watershed and periodic spraying of manure suggests the presence of seasonal and geographic distributions in water quality. Thus, the secondary objective was to assess spatial and temporal variability of nutrients (nitrogen and phosphorus), and isotopic signatures of POM in various streams and tributaries within the Cape Fear River watershed in relation to CAFO influence.

Materials and methods

Study sites

The lower Cape Fear River Basin is comprised of a series of rivers, streams, and tributaries that are subject to water quality fluctuations resulting from traditional agriculture, the numerous CAFOs present in the basin, and human and industrial point-source waste discharges permitted by the National Pollution Discharge Elimination system (NPDES). Ten sites were selected for sampling based on CAFO or point-source influence or lack thereof (Table 2). These sites are a subset of a greater and ongoing (since 1995) monitoring effort called the Lower Cape Fear River Program (Fig. 1). Two fifth-order blackwater streams, the Black River, and the Northeast Cape Fear River, together house approximately 5,000,000 head of swine and numerous poultry operations and flow downstream to connect with the main Cape Fear River upstream of the port city, Wilmington, NC (Fig. 1). The Black River is fed by tributaries, such as Six Runs Creek (6RC) that mainly drains watersheds used for CAFOs and agriculture, and Colly Creek (COL) which drains primarily undeveloped forest area and is considered a control site (Mallin et al. 2004, 2006). Station NC403 is a site in the headwaters of the Northeast Cape Fear River and receives influence from one NPDES point-source discharge (total 1.4 MGD), several CAFOs, and a cattle farm. Panther Branch (PB) and Stockinghead Creek (SHC) are tributaries of the Northeast Cape Fear River. PB is primarily impacted by an NPDES wastewater treatment plant outfall (0.5 MGD). The SHC watershed contains approximately 13 swine and 11 poultry CAFOs (Mallin and McIver 2018). A large poultry CAFO (POULT) was sampled in a perennial ditch that drains the facility and enters public waters. The main Cape Fear River watershed includes two tributaries selected for this study. One is the Browns Creek (BRN) watershed which contains three swine CAFOs but also encompasses 3500 resident Elizabethtown. The other is Hammond Creek (HAM) watershed which contains four poultry CAFOs and 13 swine CAFOs, including one very large CAFO (2500 or more swine heads). The watersheds of both creeks also are used for crop agricultural purposes (tobacco, sweet potatoes, corn, hay). The mainstem of the Cape Fear River flows downstream through Wilmington, and eventually discharges into the Atlantic Ocean in Southport, NC. Channel Marker 61 (M61) in downtown Wilmington and Channel Marker 18 (M18) in Southport, NC were sampled to investigate the influence of upstream watershed drainage to the Atlantic Ocean.

Sample collection

Of the ten sites within the Cape Fear watershed (Fig. 1, Table 2), eight were sampled monthly from February to August 2018; all sampling was suspended in September due to the approach of Hurricane Florence. Two sites, SHC and POULT were sampled in March (to represent low sprayfield influence) and in June (2 months after the onset of permissible swine waste spraying).At each site, a YSI Professional Plus unit with Quatro Multiparameter probe was used to measure temperature, salinity, dissolved oxygen (DO), turbidity, pH, and specific conductance (not presented in this paper). Water was collected at the surface using a bucket and rope, as the sites

Table 2 Site locations for sampling including coordinates and description (see also Fig. 1; EWG 2016; Waterkeeper Alliance; site locations on Lower Cape Fear River Program website https://uncw.edu/cms/aelab/lcfrp/)

Site	Coordinates	Description
COL	34.4641, − 78.2569	Colly Creek, 2nd order, control site located in a largely pristine blackwater wetland area; a tributary of the Black River; four swine CAFOs
NC403	35.1784, − 77.9807	Northeast Cape Fear River headwaters, 1st order, drains a watershed that hosts nine swine CAFOs, traditional agriculture; grazing cattle; an NPDES point-source waste water discharge (1 MGD)
PB	35.1345, − 78.1363	Panther Branch, 1st-order tributary of Northeast Cape Fear River, receives a NPDES point-source waste water discharge (0.5 MGD); one poultry CAFO in watershed
6RC	34.7933, − 78.3113	Six Runs Creek, 3rd-order tributary of the Black River, high influence of CAFOs (179 swine and 107 poultry CAFOs)
BRN	34.6136, − 78.5848	Browns Creek, 2nd-order tributary of the Cape Fear River, presence of three swine CAFOs and traditional agriculture; drains Elizabethtown (3500 residents)
HAM	34.5685, − 78.5155	Hammond Creek, 2nd-order tributary of the Cape Fear River; 13 swine CAFOs and four poultry CAFOs, traditional agriculture
M61	34.1938, − 77.9573	6th order, Cape Fear River at the State Port downtown Wilmington- estuarine system that receives water from Cape Fear River and Northeast Cape Fear River confluence
M18	33.913, − 78.017	6th order, Cape Fear River at South Port, lower end of the estuary that opens into the Atlantic Ocean
SHC	34.50305, − 77.51554	Stocking Head Creek, 2nd-order stream, site located along a swine CAFO spray field; 13 swine and 11 poultry CAFOs
POULT	34.50308, − 77.51548	1st-order, perennial drainage ditch with direct poultry CAFO influence; one large poultry CAFO

are located under bridges and are approximately 1–2 m in depth. Water samples were collected in duplicate 2 L, acid-washed (10% HCl) Nalgene bottles. Sample water was filtered on site through baked (550 °C for 4 h) 24-mm Whatman GF/F glass fiber filters (0.7 mm pore size) using a syringe and collected in acid-washed test tubes and baked clear glass vials. Once collected, all tubes and vials were placed on ice and transported back to the lab where they were frozen at − 20 °C until analyses for nutrients and dissolved organic matter.

Upon return to the lab, water samples in the 2-L Nalgene bottles were filtered through baked 47-mm Whatman GF/F filters. At least 500 mL of sample water from each bottle were filtered through an individual filter, and duplicates were produced for each site. The volume of water pumped through each filter was recorded to the nearest 0.1 mL. Once the filter was sufficiently full of organic material that water could no longer pass through, the filter was removed from the tower, wrapped in foil and frozen (− 80 °C) until analyses for $\delta^{13}C$ and $\delta^{15}N$ isotope signatures.

Nutrient analysis

All water samples that were filtered were analyzed for dissolved inorganic and organic nutrients. Dissolved inorganic nitrogen (DIN), as nitrite NO_{2-} nitrate NO_{3-}, and ammonium NH_4+, and total dissolved nitrogen (TDN), as well as dissolved inorganic phosphorus (DIP as orthophosphate, PO_4^{3-}), and total dissolved phosphorus (TDP) were analyzed using the Bran+Luebbe AutoAnalyzer 3. When nitrate is referenced henceforth, it will refer to the concentration of nitrate plus nitrite. TDN was determined using Koroleff's wet alkaline persulfate oxidation analysis where water samples were prepared with recrystallized persulfate solution and autoclaved. Samples with higher organic content were diluted 5:1 or 6:1 deionized water to sample ratios prior to analysis. The samples were digested to nitrate (NO_{3-}) and phosphate during analysis of TDN and TDP. The following equations were used to determine the concentration of dissolved organic nitrogen (DON) and dissolved organic phosphorus (DOP) from TDN, DIN, TDP, and DIP (Koroleff 1983):

$$[DON] = [TDN] - [DIN]$$

$$[DOP] = [TDP] - [DIP]$$

A variety of ancillary physical, chemical, and biological samples are collected monthly at most of the sampled sites and the state-certified data following QA/QC procedures are published on the Lower Cape Fear River Program website: https://uncw.edu/cms/aelab/lcfrp.

POM $\delta^{13}C$ and $\delta^{15}N$ isotopic analysis

For $\delta^{13}C$ and $\delta^{15}N$ isotopic analyses, POM filter samples were removed from the freezer and 15 mm diameter cores were punched from each filter. The glass fiber filter cores were weighed, then dried at 60 °C for 3–5 h and weighed again. Samples were then fumed in a desiccator with concentrated HCl to remove remaining inorganic carbonates present. Once dried again, samples were packed into tin capsules and placed into a sample tray for analysis on the ThermoDelta V Plus/Costech 4010 Elemental Analyzer to determine isotopic signatures of $\delta^{13}C$ and $\delta^{15}N$. The isotopic signatures of carbon and nitrogen were recorded as del notations and calculated using the isotope of the samples and standards as shown below:

$$\delta X = \left(\frac{R_{\text{sample}}}{R_{\text{standard}}} - 1\right) \times 1000$$

Vienna Pee Dee Belemnite was used as the stable carbon isotope standard, and atmospheric nitrogen (N_2) was the measure for the stable nitrogen isotope standard.

Statistical analyses

All data collected were recorded, archived, and organized using Microsoft Excel 2008. Statistical analyses were conducted using SAS statistical software (Schlotzhauer 2009). Nutrient, isotopic and hydrological data were first tested for normality using the Shapiro-Wilk test, with nitrate, ammonium, river discharge, and rainfall requiring log-transformation to achieve normality. Correlation analysis was used to test for associations among chemical and hydrological variables. Analysis of variance (ANOVA) was used to test for differences in mean nutrient concentrations and isotopic signatures among sites. Where significant differences occurred, sites were ranked using the least significant difference (LSD) procedure (Day and Quinn 1989). Statistical tests were considered significant if $P < 0.05$.

River discharge was used as a proxy for streamflow, since most individual streams in southeastern NC are not gauged. Data were used from USGS sites 02105769 (mainstream Cape Fear River at Lock and Dam #1), 02106500 (Black River near Tomahawk, NC), and 02108000 (Northeast Cape Fear River near Chinquapin, NC). The average discharge of the 7 days prior to sampling was used for statistical purposes, with data from Lock and Dam #1 used for BRN, HAM, M61, and M18; Tomahawk data were used for COL and 6RC, and Chinquapin data were used for NC403 and PB. Rainfall data for the day of sampling plus the preceding 48 h was used for statistical purposes, with the nearest official NC rain gauges (either from USGS or the NC State Climate Office) to the site in question used as sources.

Results

Dissolved nitrogen concentrations

Nitrate ($NO_{3-} + NO_{2-}$), exhibited the highest mean concentrations at station NC403 (68.8 μmol/L), followed by station 6RC (47.6 μmol/L) (Figs. 2a and 3d, f). The peak individual nitrate concentration occurred in March at NC403 with 124.8 μmol/L and the lowest nitrate concentrations were found from March to August at the unimpacted site COL (Figs. 2a and 3a). Nitrate concentrations at NC403 were significantly ($p < 0.05$) higher than all other sites except for 6RC, which in turn was significantly higher than all sites except PB and NC403. COL also had the lowest ($p < 0.05$) average concentrations of nitrate (2.24 μmol/L) among sites except for M18, and ammonium levels frequently exceeded that of nitrate more than any other station. March and July at M18 (nearest the ocean) had the lowest concentrations of ammonium (0.99 and 1.58 μmol/L), followed by June and August at 6RC (2.10 and 2.04 μmol/L). The highest values of ammonium occurred at PB in May (35.4 μmol/L) and HAM in February at 19.24 μmol/L. Average ammonium at PB was greater ($p < 0.05$) than 6RC, BRN, M61, and M18, with NC403 > 6RC and M18. Thus, highest inorganic N concentrations occurred at PB, N403, and 6RC. There was a general trend of higher nitrate concentrations during the start of spring (February, March, and April). COL exhibited the highest mean DON concentrations ($p < 0.05$), yet station 6RC had the highest individual DON overall in April (Figs. 2b and 3a, d).

At SHC, nitrate levels increased from March to June with a concentration of 18.6 to 26.5 μmol L^{-1} (Fig. 4a). Ammonium concentrations nearly doubled from March to June at SHC with concentrations of 1.8 to

3.2 μmol L^{-1} (Fig. 4a). DON concentrations for SHC also increased from March to June at 43.9 to 51.3 μmol L^{-1} (Fig. 4a).

At POULT, nitrate concentrations were only 1.05 μmol L^{-1} in March but increased to 28.8 μmol L^{-1} in June (Fig. 4b). Ammonium concentrations at POULT were temporally similar to SHC with 2.04 μmol L^{-1} in March and 3.43 μmol L^{-1} in June (Fig. 4b). There was a small increase in DON concentrations from March with 55.5 μmol L^{-1} to June with 60.7 μmol L^{-1} at POULT (Fig. 4b). Overall, both SHC and POULT showed a considerable increase in nitrate and DON concentrations and a relative increase in ammonium concentrations from March to June. All other stations, except M18, had a general decrease in nitrogen concentrations from March to June.

Dissolved phosphorus concentrations

DIP concentrations ranged from undetectable to 1.87 μmol L^{-1} (Fig. 5a–h). DOP concentrations ranged from 0.26 μmol L^{-1} up to 2.66 μmol L^{-1} (Fig. 5a–h). DIP concentrations were overall highest at COL with the maximum at 2.66 μmol L^{-1}, while DOP concentrations were lowest at COL with only one detectable data point at 0.20 μmol L^{-1} (Fig. 5a). Generally, lowest DIP and DOP concentrations occurred in April and May, and beginning in June there was an increase in both DIP and DOP concentrations that remained higher through August at each station (Fig. 5a–h). PB, BRN, HAM, and 6RC showed the highest concentrations of DP (Fig. 5b–e). The estuarine stations M61 and M18 had the lowest DOP concentrations ranging from 0.00 to 0.85 μmol L (Fig. 5g, h). Lower DIP concentrations were found at stations PB and BRN, with averages of 1.12 and 0.86 μmol L^{-1}. Overall, M18 had the lowest average DIP and DOP, and COL had nearly zero DOP concentrations, yet the highest average DIP. Average DIP concentrations at both COL and NC403 were significantly ($p < 0.05$) higher than DIP at PB, BRN, and M18. Overall, none of the DIP samples was particularly high.

DIP concentrations at SHC doubled from March with 1.05 μmol L^{-1} to June at 2.5 μmol L^{-1} (Fig. 4c). DOP increased substantially from 0.14 μmol L^{-1} in March to 1.49 μmol L^{-1} in June at SHC (Fig. 4c). At POULT, the DIP concentration increased 15× from 0.27 μmol L^{-1} in March to 4.1 μmol L^{-1} in June (Fig. 4d). DOP concentrations at POULT increased temporally from 0.40 μmol L^{-1} in March to 1.67 μmol L^{-1} in June (Fig. 4d).

Isotopic signatures

δ^{15}N POM isotopic signatures ranged from − 3.60 to + 21.7‰ (Table 3; Figs. 2e, 6, and 7). Isotopic signatures at COL never reached above δ^{15}N + 10‰, except for one outlier of δ^{15}N + 10.5‰ in October 2017 (Table 3; Figs. 2e, 6, and 7). M18 δ^{15}N signatures also remained below + 10‰ (Figs. 2e and 6). Station M61 had one δ^{15}N isotopic signature that was + 9.9‰ (Figs. 2e and 6). Stations that showed several instances of isotopic signatures above δ^{15}N + 10‰ include PB, NC403, BRN, HAM, and 6RC (Figs. 2e, 6, and 7). CAFO site 6RC and point-source site PB had particularly elevated mean δ^{15}N signatures at + 10.6 and + 10.5‰ (Table 3). Average δ^{15}N signatures at both point-source sites PB and NC403 were significantly ($p < 0.05$) higher than those of COL, M61, and M18; δ^{15}N signatures at CAFO sites 6RC and HAM were significantly higher than COL. The highest individual δ^{15}N signature was station PB in April at + 21.7‰ (Figs. 2e, 6, and 7). BRN closely followed at a maximum δ^{15}N of + 21.6‰ in April (Table 3). HAM and 6RC also had δ^{15}N signatures above + 20‰ at + 20.1‰ in August and + 20.9‰ in April (Figs. 2e, 6, and 7). Point-source site NC403 also showed heavy δ^{15}N signatures at + 12.8 and + 12.3‰ in May and June (Table 3). Overall, δ^{15}N signatures above + 10‰ generally had the highest values in April and occurred either in the summer months of May, June, or August (Figs. 2e, 6, and 7).

POM signatures of δ^{13}C ranged from − 32.7 to − 20.2‰ (Table 3). The control site COL generally had a narrow δ^{13}C isotopic range of − 30 to − 29‰ (Table 3; Figs. 2f, 6, and 7). M18 had isotopic signatures that ranged from δ^{13}C − 30.1 to − 20.2‰ (Table 3). HAM also exhibited a broad range of δ^{13}C signatures from − 31.3 to − 22.7‰. PB, BRN, 6RC, COL, and M61 all had isotopic signatures ranging from δ^{13}C − 31 to − 27‰, with one outlier point at δ^{13}C − 31.3‰ (Figs. 2f, 6, and 7). Overall, COL had the most specific δ^{13}C signature and the other stations varied temporally and spatially.

As mentioned, normalized data were subject to correlation analyses (n for all correlations below was either 53 or 54). The overall δ^{15}N signature was positively correlated with nitrate concentration ($r = 0.34$, $p = 0.01$) and DIN concentration ($r = 0.29$, $p = 0.04$), but was uncorrelated with ammonium concentration (Table 4). δ^{15}N

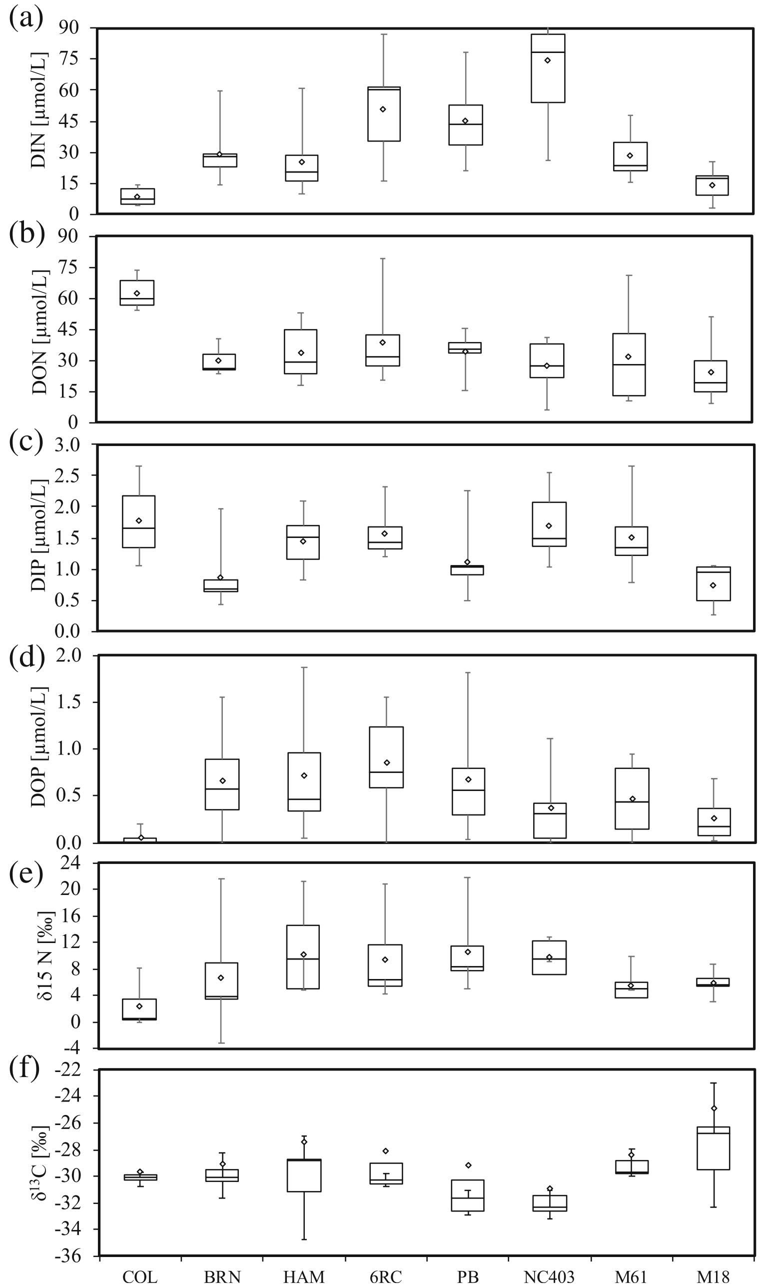

Fig. 2 Box-Whisker plots (minimum, maximum, 75th, 25th percentile, average (open circle), and median) **a** dissolved inorganic nitrogen (DIN), **b** dissolved organic nitrogen (DON), **c** dissolved inorganic phosphorus (DIP), **d** dissolved organic phosphorus (DOP), **e** stable nitrogen, and **f** stable carbon isotopic signatures in POM for the study duration (February through August, 2018)

signatures were not correlated with rainfall or discharge. Among nutrient concentrations, nitrate was negatively correlated with DON ($r = -0.44$, $p = < 0.01$). Ammonium was not significantly related to organic nutrients, but was positively correlated with DIP ($r = 0.36$, $p < 0.01$). Rainfall was not significantly correlated with inorganic nutrients, but was negatively related to DON ($r = -0.38$, $p < 0.01$). River discharge was negatively related to DIP ($r = -0.46$, $p < 0.01$).

Discussion

Spatial nutrient variability

Nutrient concentrations (TN, TP, DON, DOP, $\delta^{13}C$, $\delta^{15}N$) of streams throughout the Cape Fear River Basin vary by CAFO influence. COL drains largely undeveloped wetlands with little CAFO influence from the watershed and was used as a baseline comparison against

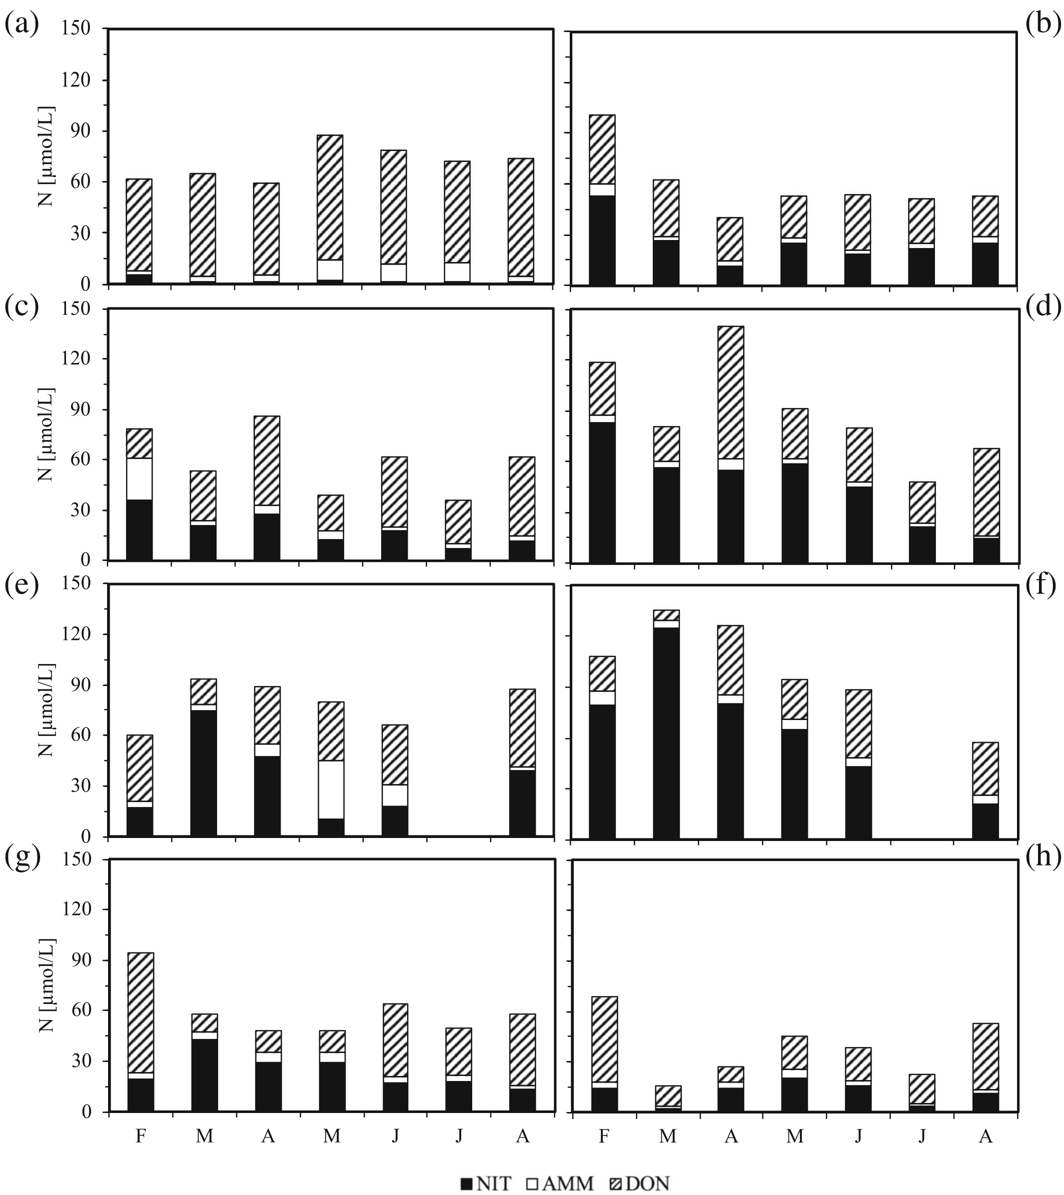

Fig. 3 Total dissolved nitrogen (TDN) concentrations are comprised of dissolved inorganic nitrogen (DIN), in the form of nitrate (NIT; $NO_{3-} + NO_{2-}$) and ammonium (AMM; NH_4+), and dissolved organic nitrogen (DON). The bars in this figure depict the concentrations of DIN and DON for comparison at each station, **a** COL, **b** BRN, **c** HAM, **d** 6RC, **e** PB, **f** NC403, **g** M61, and **h** M18, for the study duration, February through August of 2018. No samples were collected in July from PB and NC403

anthropogenically influenced sites. Though COL has one less CAFO in its direct vicinity than BRN, it is considered unimpacted because BRN's watershed drains the residential and commercial area of Elizabethtown. The consistently low nitrate concentrations (2.24 ± 1.33 μmol L^{-1}) at COL exemplify unimpacted black water systems that have characteristically low nitrogen concentrations as nutrients are not preserved in the floodplain and soils have low N concentrations (Smock and Gilinsky 1992; Mallin et al. 2006). The wetland-rich watershed would be conducive to enhanced denitrification. Total nitrogen values of unimpacted blackwater systems are predominately DON, which was demonstrated at COL with DON concentrations that significantly exceeded concentrations at all other sites (Figs. 2b and 3a–h). The data set as a whole demonstrated a

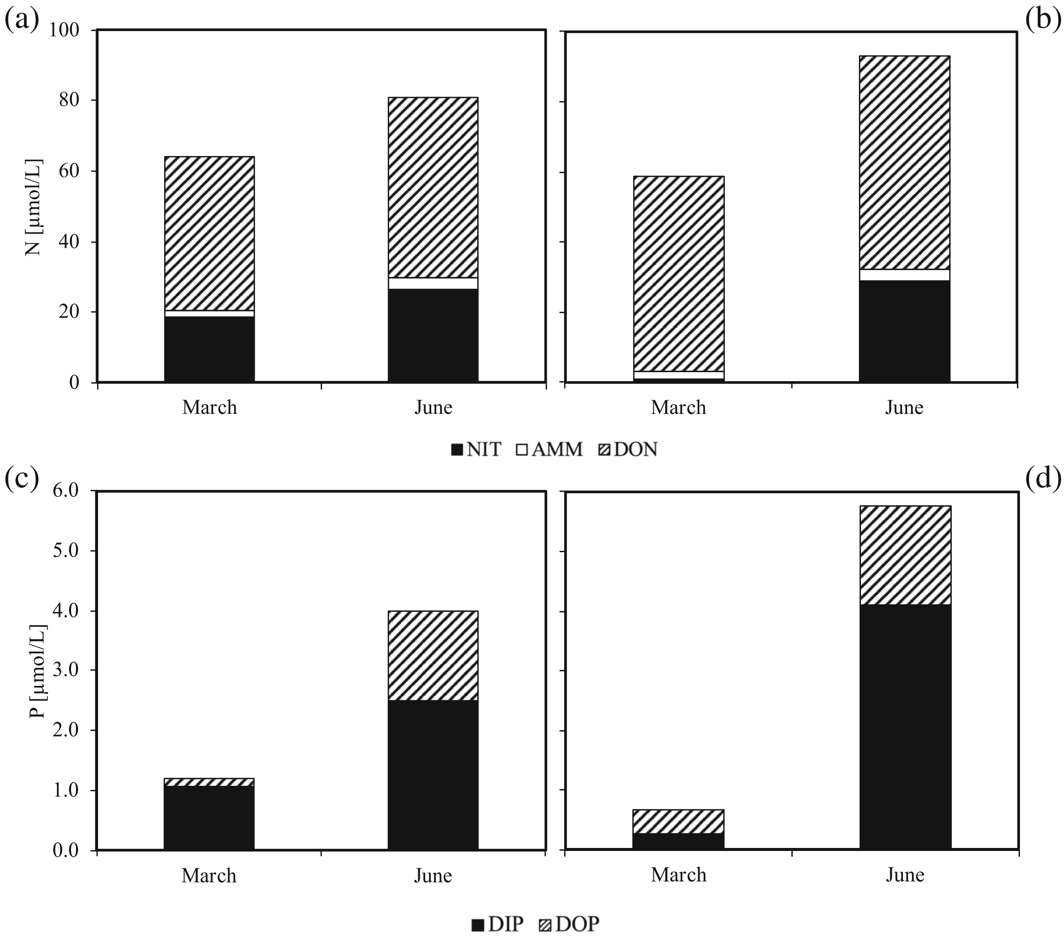

Fig. 4 Nutrient concentrations (N and P) are plotted for CAFO sites, Stocking Head Creek (**a**, **c**) and Poultry (**b**, **d**), prior to lagoon waste being sprayed (March) and after spray (June) of 2018

negative correlation between nitrate and DON; note that nitrate is anthropogenically sourced, while DON can be a product of wetland processes. The majority of total phosphorus concentrations were as DIP (orthophosphate), as DOP levels were nearly undetectable at COL with only one sample detectable at 0.20 μmol L^{-1} (Figs. 2c, d, and 5). Isotopic signatures at COL commonly did not show any influence of animal effluent ($\delta^{15}N < +10‰$), which further exemplified the near-unimpacted condition of this stream. Feral swine have been photographed by the research team in the vicinity of this sampling site and the single abnormally high $\delta^{15}N$ could be attributed to these swine. Additionally, the $\delta^{13}C$ values were consistently ~ 29.5‰, which is indicative of the C3 plants that inhabit a freshwater system such as COL (Fry 2006).

The other freshwater sites displayed inorganic N concentrations and isotopic signatures suggestive of animal effluent and/or human wastewater. CAFO-rich 6RC had elevated DIN and DOP (Fig. 2a, d) an enriched mean $\delta^{15}N$ of + 10.6‰ and a maximum of + 20.9‰ (Table 3). High DIN concentrations also characterized NC403 (Fig. 2a) which had a mean $\delta^{15}N$ of + 9.7‰ and maximum of + 12.8‰ (Table 3). This station drained a watershed containing several CAFOs and a human NPDES point-source wastewater discharge (Table 2) The low variability among $\delta^{15}N$ signatures at NC403 (Table 3) argues for strong watershed human influence (unfortunately the Cape Fear Basin has no TN or TP discharge limits—only the ammonium discharges are limited). The other NPDES site, PB, had elevated DIN and heavy $\delta^{15}N$ signatures (Table 3). Thus, both sites with human wastewater influence showed both elevated DIN and heavy $\delta^{15}N$ signatures, as did CAFO-rich 6RC.

The other site showing heavy $\delta^{15}N$ mean, median, and maximum values was HAM, which has a considerable number of swine and poultry CAFOs in its

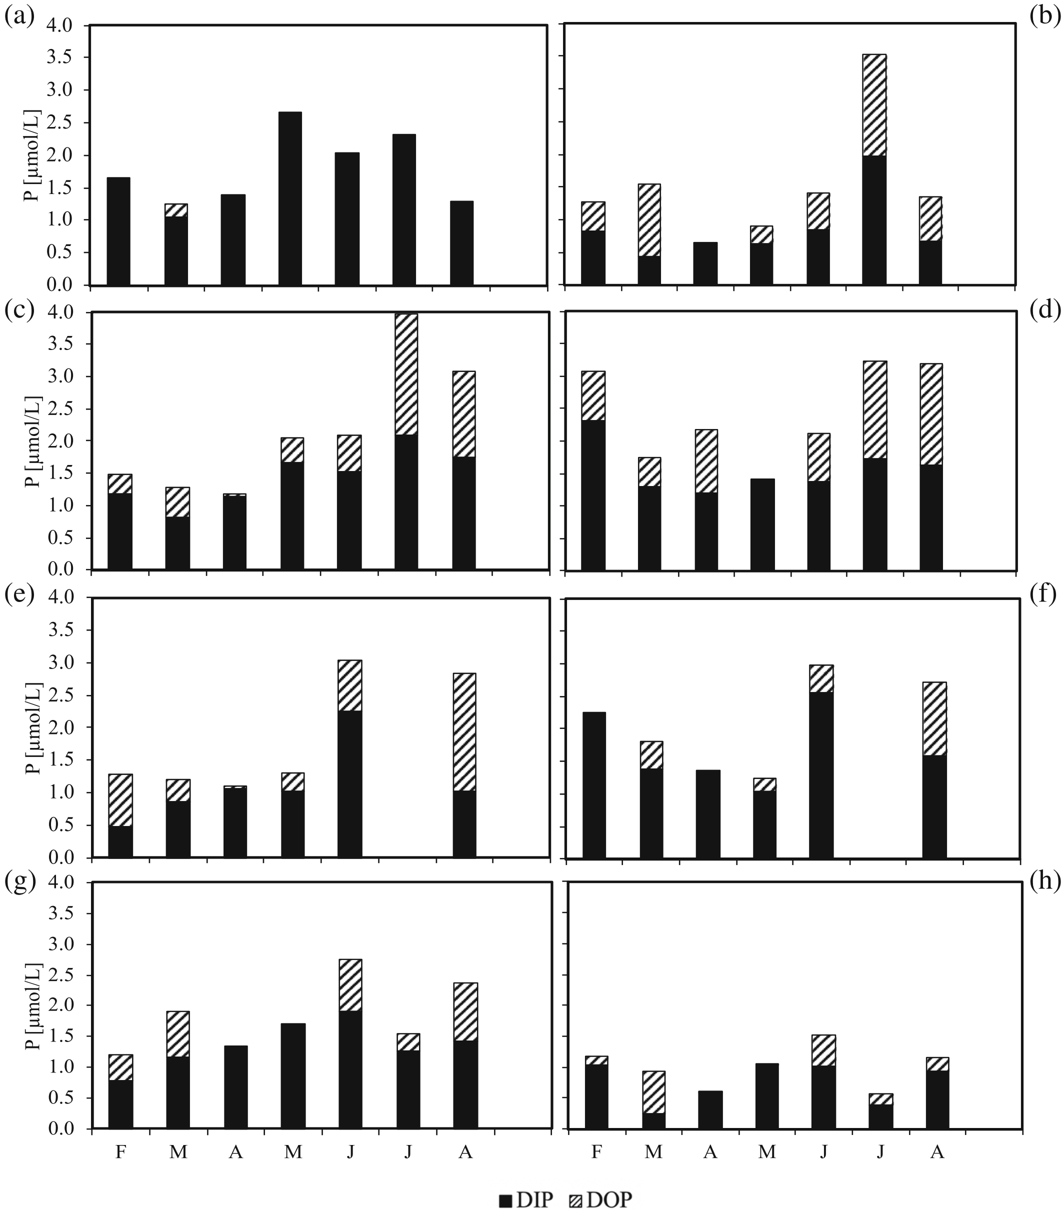

Fig. 5 Total dissolved phosphorus (TDP) concentrations, in the forms of inorganic (DIP) and organic phosphorus (DOP) are shown for each site **a** COL, **b** BRN, **c** HAM, **d** 6RC, **e** PB, **f** NC403, **g** M61, and **h** M18. The TDP concentrations are plotted for each sampling month (February through March, 2018) in the study duration. The bars in each table represent DIP as orthophosphate (PO_4^{3-}) and DIP, to represent TDP. No samples were collected in July from PB and NC403

watershed (Table 2). In contrast, BRN had widely variable $\delta^{15}N$ signatures, with a low median (3.9) and a moderate mean $\delta^{15}N$ signature of 6.7 (Table 3). This watershed contained three CAFOs but also drains the town of Elizabethtown, presumably introducing urban and suburban stormwater runoff into Browns Creek. Note that the town's wastewater treatment plant (1.2 MGD, secondarily treated) outfall discharges directly into the Cape Fear River. Urban stormwater runoff will contain a mixture of fertilizer N, atmospheric N, and nutrients from pet waste. The two estuarine sites showed low to moderate DIN concentrations (Fig. 2a) and lighter $\delta^{15}N$ signatures (except for April—see below).

CAFO source sites, SHC and POULT, showed nutrient concentrations and isotopic signatures that distinguished them from the other streams in the Northeast

Table 3 Isotopic signatures (‰) of the eight primary sampling sites (as mean ± standard deviation/median, range), $n = 8$ months

Site	$\delta^{13}C$ signature	$\delta^{15}N$ signature

	− 25.7, − 30.1 to 20.2	5.5, 2.9 to 8.8

Cape Fear River basin. Swine and poultry-influenced SHC had a $\delta^{15}N$ signature characteristic of swine effluent (+ 18.2) in March and a mixed animal waste signature of + 7.4‰ in June, and POULT showed poultry waste signatures (+ 6.6–7.0‰) in March and June (Wassenaar 1995). Sprayfields and lagoons for swine CAFOs were adjacent to SHC, while POULT was sampled at a perennial ditch draining a large poultry CAFO. The waste disposal system at poultry farms utilize dry litter applied on fields that pose different environmental impacts than hog farms as there is no liquid waste spraying unless the poultry CAFO is an egg-laying facility; there are no NPDES requirements for dry-disposal poultry CAFOs. Dry poultry litter can impose adverse environmental effects from field runoff in rain events or light litter particles carried by wind into adjacent waterways, which increase nutrient concentrations.

A broad-based USGS study found substantially higher nitrogen concentrations (nitrate, ammonium, and TN) in swine and poultry-intensive watersheds compared to those without influence from these agricultural facilities (Harden 2015). The Cape Fear River watershed has significant spatial variability, where stations with high-density CAFO influence (as well as sites with NPDES point-source discharges) had higher nutrient concentrations and $\delta^{15}N$ isotopic signatures indicative of waste effluent than that of the relatively unimpacted blackwater system. While the Cape Fear watershed has considerable acreage under crop agriculture, the positive correlation between nitrate concentrations and heavier $\delta^{15}N$ signatures suggests that animal waste as well as human wastewater play a stronger role in nitrogen pollution than crop fertilizers. We also note that under conditions of elevated streamflow (see next section) swine waste effluent from upstream regions of the watershed can influence the water quality in downstream estuarine regions that have no direct influence of CAFOs.

Seasonal variability

CAFOs follow a seasonal schedule for waste disposal (spraying), and the transitions through the seasons are shown in each sample site's nutrient concentration and isotopic composition, dependent on the proximity to

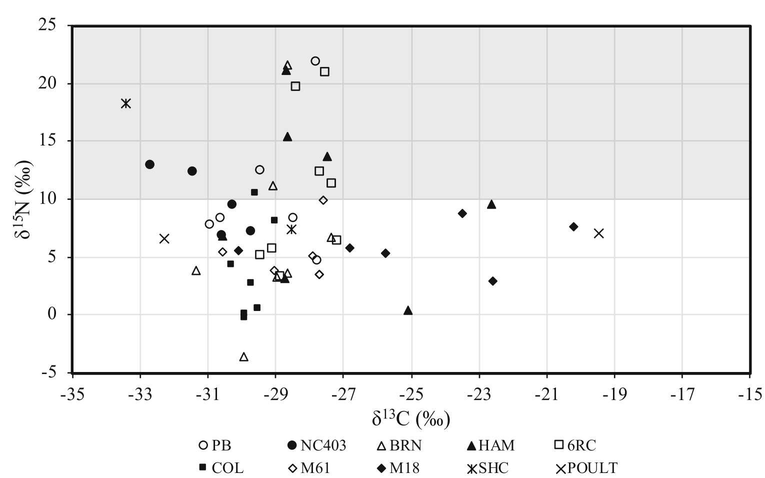

Fig. 6 Particulate organic matter (POM) isotopic signatures plotted for $\delta^{13}C$ and $\delta^{15}N$ at each sampling station from February to August, 2018

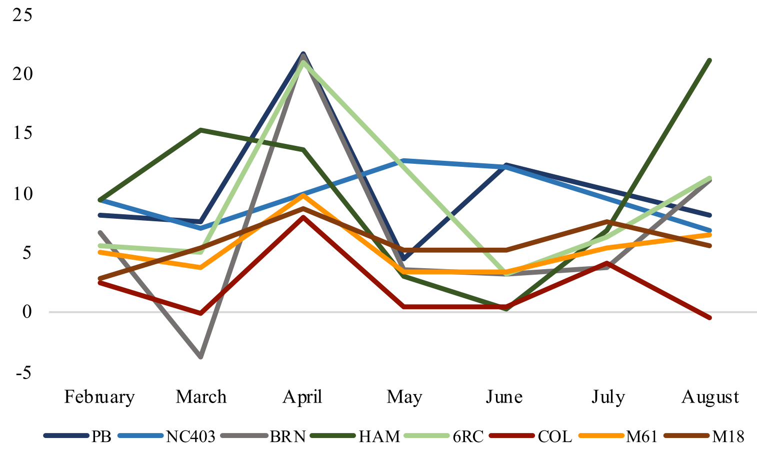
Fig. 7 Monthly variability of isotopic $\delta^{15}N$ signatures for each sampling station



CAFOs. The spraying season for swine farms to relieve waste lagoons onto surrounding Bermudagrass fields occurs during the growing season, from March to September. It was previously demonstrated that nitrate, total nitrogen, and fecal bacteria concentrations in CAFO-rich stream stations rose considerably after the onset of spray season in relation to before (Mallin and McIver 2018). Thus, it was expected for months following the start of spraying season in March to exhibit elevated nutrient concentrations and isotopic signatures characteristic of swine effluent, compared to the fall and winter months exclusive of spraying. The Bermudagrass fields, where waste is sprayed on, are intended to sequester the excess nutrients introduced by swine effluent. Bermudagrass has one of the highest capabilities to uptake nutrients, and thus was chosen as a cover crop on which to spray lagoon waste. However, as shown in this study and others (Harden 2015; Mallin et al. 2015; Mallin and McIver 2018), high concentrations of nutrients still enter adjacent waterways during the spraying season, although in the present study 6RC and NC403 showed decreased concentrations after the initial spraying. The maximum practical nitrogen application rate for Bermudagrass in coastal areas is suggested to be 300 pounds per acre per year, divided into three application times (Conrad-Acuña et al. 2019). This application rate is solely for the maximum growth of Bermudagrass and does not assess the environmental factors of N leaching into the surrounding environment. Overapplication of waste or leaching from applying the maximum N application rate may explain the increased nutrient concentrations. The threshold of nutrient sequestration was likely met in the Bermudagrass field, and excess nutrients leach into groundwater or run off over land into surrounding waterways.

Table 4 All significant correlations between measured parameters ($\delta^{15}N$, DIN, DON ammonium, nitrate, DIP, discharge, and rainfall)

	$\delta^{15}N$	DON	Ammonium	Discharge
Nitrate	$r = 0.34$ $p = 0.01$	$r = -0.44$ $p = < 0.01$		
DIP			$r = 0.36$ $p < 0.01$	$r = -0.46$ $p < 0.01$
DIN	$r = 0.29$ $p = 0.04$			
Rainfall		$r = -0.38$ $p < 0.01$		

Isotopic signatures were not notably characteristic of swine effluent in March; however, in April, there was a large and widespread increase as $\delta^{15}N$ signatures amplified at some sites to + 21.0‰, which is highly indicative of manure-sourced effluent. 6RC, a CAFO-dominated tributary with 179 swine CAFOs, also exhibited its heaviest $\delta^{15}N$ signature in April at + 20.9‰ (Fig. 7). In fact, average $\delta^{15}N$ signatures for the entire sampling set were significantly ($p < 0.05$) higher in April compared to all other months sampled. Nitrogen signatures may not have been expressed in March due to the lag time of leachate to enter waterways. Enriched $\delta^{15}N$ signatures in April may be explained by the demand for farmers to rid an entire winter's worth of waste from the lagoons in March. In April, hydrological conditions changed that favored distribution of swine waste-derived nitrogen well downstream. Local rainfall was elevated; for instance, the total April rainfall at the Wilmington airport was 13.6 cm, which was 6.5 cm over the long-term April average. In addition, monthly Cape Fear River discharge at Lock and Dam #1 (Fig. 1) rose to 2170 CMS, the highest discharge of 2018 until August (2562 CMS). The presence of accumulated spray field nutrients, elevated rainfall, and high river discharge carried swine-sourced N well downstream into the estuary.

Enriched $\delta^{15}N$ signatures at BRN were shown in April (+ 21.6‰) and again in August (+ 11.2‰). Additionally, HAM showed enriched $\delta^{15}N$ signatures in March, April, and August (Figs. 2e, 6, and 7). A lack of effluent signature mid-spraying season (May through July) suggests that waste lagoons were pumped down at the beginning of the spraying season and again later in the season (note the elevated rainfall in August would lead to increased pump-out). It was interesting to note that March $\delta^{15}N$ isotopic signatures at BRN were characteristic of synthetic fertilizer at − 3.6‰, the lightest signature occurring in the data set. As a predominantly rural region, inputs could have originated from surrounding traditional agricultural farms; also note that stormwater runoff from Elizabethtown would be factor as well. The nitrogen concentrations (nitrate, ammonium, and DON) at BRN, HAM, 6RC, and NC403 increased in February. Maximum nitrate concentrations are typical in winter/early spring months in watersheds containing crop agriculture from runoff, whereas summer nitrate concentrations in CAFO areas are generally significantly higher due to waste application on sprayfields (Mallin and McIver 2018).

Previous studies have traced nutrient sources with isotopic techniques and documented limited downstream nutrient transport and (Karr et al. 2001). The present study traced the potential presence of upstream CAFO-derived nitrogen downstream from CAFO-influenced areas to estuarine station M61 at least on one occasion. As previously noted, the stream and river sites had nitrogen signatures characteristic of swine effluent in April (+ 10 to +2 0‰), and estuarine sites M61 and M18 also exhibited unusually elevated signatures ($\delta^{15}N$ + 9.9‰ and + 8.8‰, respectively) in this month of elevated river discharge (Fig. 7). A clear regulatory application from these data is that waste application from lagoons in the spraying season have shown significant month-to-month variability within the basin, which indicates that a singular month of sampling to uphold state and federal water quality regulations would not be truly suggestive of potential environmental threats.

Regulations and impact of findings

Swine-derived isotopic signatures throughout the Cape Fear River basin support the findings of previous studies that showed elevated nutrient concentrations related to CAFO-impacted streams in the Cape Fear River basin. Elevated nitrogen concentrations and isotopic signatures characteristic of swine effluent have entered surface waters throughout the Cape Fear River watershed, which under the Clean Water Act G.S. 143-215.10E deems discharge of waste in surface waters illegal. CAFO facilities that intend to discharge waste into waterways are issued NPDES permits to mitigate and control waste discharge. However, only 14 of 1222 registered CAFOs claim to discharge waste into waterways and have obtained these permits. Presence of waste-derived nutrients throughout the watershed suggests that more than 14 CAFO facilities have waste that is discharged into surrounding waterways that have not obtained permitting. Nevertheless, violations of this regulation suggest that there is an enforcement issue with NPDES permits. A solution to this is mandated NPDES permits for all facilities which will aim to alleviate nutrient pollution in waterways and adverse human health impacts. In addition, a current permit monitoring only includes sampling lagoon waste to uphold regulatory standards; however, adjacent stream quality assessments should be required with permits to ensure waste is not illegally leeching into surrounding waterways. The permitting requirements for animal waste discharges vary considerably across states and suffer from lack of required stream water sampling (Rosov et al. 2020). Finally, the two point-source influenced stations in the data set displayed both elevated DIN concentrations and enriched $\delta^{15}N$ signatures in stream sites well downstream of the facilities, demonstrating that wastewater treatment in generally rural watersheds contributes to problematic nutrient loading as well as animal waste discharges.

Conclusions

Nutrient concentrations, isotopic signatures, and correlation analyses indicated that nitrogen inputs in the Northeast Cape Fear River, Black River, and the Cape Fear River are largely derived from CAFO swine effluent, with additional contributions from human discharges. CAFO-derived nutrients from watershed tributaries, under appropriate hydrological conditions (i.e., periods of elevated rainfall during swine waste spray season), can be traced downstream as far as the Cape Fear estuary near the City of Wilmington, NC. Spatial variability was shown throughout the basin as the unimpacted blackwater and estuarine systems revealed significantly lower N concentrations and lighter isotopic waste signals than animal waste and human wastewater-impacted waterways upstream. Significant seasonal variability was identified as months with waste application to spray fields (March through August) had maximum nitrate concentrations and isotopic signatures indicative of waste effluent. Adjustments to current regulations enforcing pollution permits or monitoring of adjacent streams could aid in management and overall health of basin's waterways and the community that uses it.

Acknowledgements We thank Matthew McIver, Nick Iraola, Amy Grogan, Kim Breen and Adam Lucas for their assistance in collecting and processing samples. Additionally, we thank Kim Duernberger and UNCWiRMS for the generous help in running the isotope analyses. We thank Kerry Mapes for providing CAFO data for POULT and the Environmental Working Group (ewg.org) and Waterkeeper Alliance (waterkeeper.org) for permissions to use this licensed data pertaining to locations of North Carolina poultry operations. We further thank Drs. L.B. Cahoon and S.A. Skrabal for valuable study input.

Funding information Funding for this project was provided by UNCW Department of Earth and Ocean Sciences, Center for the Support of Undergraduate Research and Fellowships (CSURF), and the Lower Cape Fear River Program.

Industrialized Animal Production—A Major Source of Nutrient and Microbial Pollution to Aquatic Ecosystems

Michael A. Mallin
Lawrence B. Cahoon
University of North Carolina at Wilmington

Livestock production has undergone massive industrialization in recent decades. Nationwide, millions of swine, poultry, and cattle are raised and fed in concentrated animal feeding operations (CAFOs) owned by large, vertically integrated producer corporations. The amount of nutrients (nitrogen and phosphorus) in animal manure produced by CAFOs is enormous. For example, on the North Carolina Coastal Plain alone an estimated 124,000 metric tons of nitrogen and 29,000 metric tons of phosphorus are generated annually by livestock. CAFO wastes are largely either spread on fields as dry litter or pumped into waste lagoons and sprayed as liquid onto fields. Large amounts of nitrogen and phosphorus enter the environment through runoff, percolation into groundwater, and volatilization of ammonia. Many CAFOs are located in nutrient-sensitive watersheds where the wastes contribute to the eutrophication of streams, rivers, and estuaries. There is as yet no comprehensive Federal policy in place to protect the environment and human health from CAFO generated pollutants.

KEY WORDS: swine; poultry; nutrients; pathogens; eutrophication.

INTRODUCTION

Humans first domesticated a number of animal species in several regions of the world ca. 4–6,000 years ago (Diamond, 1997). Early domes-

tication of animals allowed humans to exploit their abilities to convert otherwise inaccessible resources into useful products and services. Animal production was necessarily resource-limited and since production was tightly coupled to the productivity of the landscape, animal waste production would seldom have exceeded the assimilation capacity of the landscape.

In recent decades livestock production, particularly that of swine, cattle and poultry, has undergone a major change toward industrialization. The industrialization of the cattle and poultry industries began in the late 1950s while industrialization of swine production began in the 1970s (Thu & Durrenberger, 1998). Industrialization of livestock production basically consists of moving animals from pastures and lots into large buildings, where they are confined and fed throughout their lives until they are ready for market. Adoption of confined feeding techniques, together with the availability of large quantities of feedstuffs and efficient transportation systems, now allow animal producers to circumvent the ecological constraints otherwise imposed by the landscape. As a consequence, animal waste production often exceeds the assimilatory capacity of the landscape both locally and regionally.

Individual concentrated animal feeding operations (CAFOs) now house hundreds to thousands of animals in each confinement structure, and vast amounts of animal waste are generated by these facilities. Swine waste is deposited on the floor of the structures by the animals, where it is periodically washed between slats in the floor into a system of trenches and pipes beneath the buildings. From there it is conveyed outside and into a cesspit called a "waste lagoon." Some anaerobic treatment occurs in the lagoon and the liquid waste is periodically applied on surrounding fields by surface spraying, surface spreading, or in some cases subsurface injection. Crops planted on the fields, such as Bermuda grass, cotton, corn, and soy take up some of the plant nutrients in the waste material. Some poultry CAFOs utilize the lagoon system, but the majority of poultry CAFOs dispose of dry litter on the fields (Williams et al., 1999). In any case, concentrated waste material is spread onto fields, from where it can enter the environment through surface runoff or groundwater infiltration (Edwards & Daniel, 1992; Mallin, 2000). Thus, individual CAFOs represent an ecologically anomalous concentration of animals whose waste production can easily exceed the assimilatory capacity of the local landscape.

Regional concentrations of CAFOs create circumstances in which very large imbalances of waste production versus waste assimilation capacity can arise (Barker and Zublena, 1995; Jackson et al., 2000). The use of carefully formulated feeds, the need for large amounts of these feeds, and transportation cost considerations have led to the regional concentration of CAFOs around feed mills and meat packing facilities (C. Wright, personal communication). Swine CAFOs are abundant on the North Carolina Coastal Plain, and in Midwestern states such as Iowa, Minnesota, Michigan, and Indiana, and are moving into western areas such as Utah and Colorado (Thu & Durrenberger, 1998). Poultry CAFOs are abundant in Iowa, Arkansas, Georgia, Maryland, Virginia, Delaware, North Carolina, California, and Mississippi (Edwards & Daniel, 1992). Cattle CAFOs are rare on the east coast but common in Texas and several midwestern states. The environmental challenge of regional concentration has been recognized explicitly for some time, e.g., in legislation introduced by Sen. Harkin (D-Iowa) in 1997 (the Animal Agriculture Reform Act, S.B. 1223). Sen. Harkin (1997) cited the Department of Agriculture as reporting: "The continued intensification of animal production systems without regard to the adequacy of the available land base for manure recycling presents a serious policy problem."

CAFOs have also had many acute pollution problems with their waste disposal systems, including lagoon ruptures and major leaks caused by mismanagement or weather (Mallin, 2000). For example, 25 million gallons of liquid swine waste entered North Carolina's New River and its estuary following a waste lagoon rupture in 1995, polluting 22 miles of the river and much of the upper estuary. The pollution load caused freshwater and estuarine fish kills and algal blooms, and polluted the river and its sediments with fecal bacteria for months (Burkholder et al., 1997). That same year a poultry lagoon breach and a large swine waste lagoon leak also caused algal blooms, fish kills, and microbial contamination in North Carolina's Cape Fear River basin (Mallin et al., 1997). In all of these cases large quantities of nutrients (nitrogen and phosphorus) entered downstream water bodies from the CAFO sites. Major CAFO accidents have also occurred in Iowa, Maryland, and Missouri (Thu & Durrenberger, 1998; Mallin, 2000). While the acute pollution caused by CAFOs is well documented, the sheer magnitude of their distribution and abundance merits an examination of the chronic effects that these facilities may have on our water resources.

North Carolina presents an excellent example of the effects of rapidly increasing industrialized livestock production, particularly that of swine. Industrialization of North Carolina's swine production began in the 1980s, and continued rapidly until the mid to late 1990s (Burkholder et al., 1997). The lagoon waste disposal system was deployed with little foresight for the environmental consequences, and CAFOs were constructed with little regulation until lagoon construction standards, siting regulations, and waste management plans were legally required in 1993 (Burkholder et al., 1997).

A moratorium on new CAFO production was begun in 1997; however, this did not take full effect until nearly 10,000,000 head of swine were present in eastern North Carolina, the vast majority in CAFOs (Burkholder et al., 1997; Mallin, 2000).

This large number of swine (currently exceeding the North Carolina human population of 7,900,000), as well as poultry and cattle, requires vast amounts of animal feed, which contains nitrogen (N) and phosphorus (P), nutrients that can lead to the eutrophication of water bodies (Carpenter et al., 1998; Correll, 1998; Cahoon et al., 1999; Glasgow & Burkholder, 2000; Mallin, 2000). Cahoon et al. (1999) noted that as of 1995 the animal production industry in North Carolina's Cape Fear River basin produced some 82,700 metric tons of N and 26,000 metric tons of P as waste in this watershed. Glasgow and Burkholder (2000) computed that in 1998 North Carolina's Neuse River watershed received 41,000 metric tons of N and 16,000 metric tons of P from CAFOs in that basin. Since the vast majority of feed for swine and poultry is shipped into these watersheds from midwestern states (Thu & Durrenberger, 1998; Cahoon et al., 1999), most of the nutrients added to the watershed through animal manures are considered "new" nutrients, imported into the system rather than recycled within it. The purpose of this paper is to describe the magnitude of industrialized animal production in a large region of the North Carolina Coastal Plain (see Figure 1), assess the potential contribution of nutrients and microbial pollution to this region, and describe the realized and potential effects of this pollutant load.

METHODS

An assessment of animal waste contributions to pollutant loads on the North Carolina Coastal Plain required computation of livestock numbers by animal category in the region, and estimates of the amount of N, P, and bacteria excreted by each species of livestock on an annual basis. The Coastal Plain contains over 90% of the State's swine population, the vast majority of its turkeys, and about 30% of the chicken population. For each of the 38 counties in the region, the most recent available data on annual production of several types of livestock (swine, broiler chickens, other chickens, turkeys, and cattle) were obtained from the website of the North Carolina Department of Agriculture (NCDA, http://www.agr.state.nc.us/stats/cntysumm). On an annual basis, there are approximately 2.9 turkey generations (cohorts) and 6.5 broiler chicken generations produced. Thus, the turkey and broiler production figures provided on the NCDA website for each

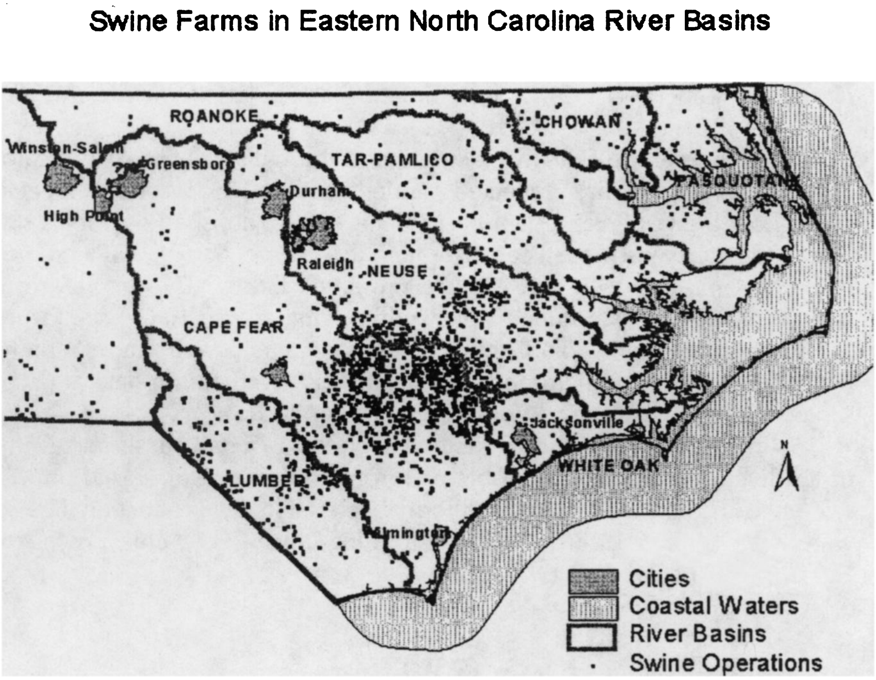

FIGURE 1. Location of swine CAFOs (operations with 250 or more head) on the North Carolina Coastal Plain by river basin.

county were divided by these numbers to yield average annual standing stock (total animals present at any one time), and subsequent annual manure production.

Animal waste N and P production rates were calculated using recent published information or data from industry sources. Swine waste N and P contents were calculated using data supplied by T. van Kempen (North Carolina State University): 15.9 kg N/yr and 5.3 kg P/yr for sows, 11.1 kg N/yr and 2.3 kg P/yr for grower-finisher pigs, and are similar to those reported elsewhere, e.g., Powers and Van Horn (1998). Total swine N and P excretion rates were then calculated using the proportion of sows and grower-finisher pigs (0.103 and 0.897, respectively in 1998 (NCDA, 1999). Turkey and broiler chicken N excretion were calculated using data from Powers and Van Horn (1998); they report N excretion as 0.395 kg N/turkey produced and 0.017 kg N/broiler produced. Using N:P ratios of 3.57:1 for turkey waste and 3.23:1 for broiler chicken waste (NRCS, 1996, Chapter

4), P excretion was calculated as 0.11 kg P/turkey produced and 0.0053 kg P/broiler produced. Annual N and P excretion rates for cattle were calculated as in Cahoon (1999), using estimates of 46.8 kg N/cow and 11.7 kg P/cow.

The Lower Cape Fear River Program at the University of North Carolina at Wilmington has collected nutrient data at 35 locations located throughout the Cape Fear River basin since 1995. Published data for a station in the Northeast Cape Fear River near the town of Sarecta (GPS coordinates N34 43.365, W77 51.752) are presented below. These data are of interest because of that station's proximity to numerous CAFOs (see Figure 1). Since ammonium volatilization is most active during warm months (NCDAQ, 1997), summertime (May–September) ammonium data are presented for a six-year period from 1996 through 2001.

Estimates of fecal coliform bacteria excreted on a daily basis for several of the livestock species were obtained from Sobsey (1996). Based on this reference the following fecal coliform bacterial daily production figures were used for pigs (1.2×10^{10} colony-forming units (CFU)), chickens (1.4×10^{8} CFU), and cows (6.0×10^{9} CFU).

RESULTS

The North Carolina Coastal Plain produces large numbers of swine, broiler chickens, and turkeys, and smaller but significant numbers of other chickens and cattle (Table 1). Swine production in North Carolina is second

TABLE 1

Population of Livestock by Category on the North Carolina Coastal Plain, 2000–2001 (About 6.5 generations of broilers and 2.9 turkey generations are produced per year. Dividing broiler chicken and turkey production by these factors provides standing stock, or numbers present at any one time on the Coastal Plain.)

Animal Category	Numbers Used in Nutrient Calculations
Swine	8,700,000 (standing stock)
Broiler chickens	210,000,000 (produced)
Other Chickens	3,480,000 (produced)
Turkeys	31,800,000 (produced)
Cattle	149,000 (standing tock)

in the United States only to Iowa (Burkholder et al., 1997; USNASS, 1997). North Carolina ranks fourth in the United States in broiler chickens sold, and first in the United States in turkeys sold (USNASS, 1997). The vast majority of the swine and poultry are in CAFOs, whereas many of the cattle are grazed on open lands.

Our computations show that swine and turkey production contribute the greatest amount of N and P in the annual waste stream (Table 2). Swine alone generate 101,000 metric tons of N and turkeys 12,600 metric tons. Swine also generate 22,700 tons of P and turkeys 3,500 metric tons. Thus, swine are by far the largest producers of nutrients in comparison with other livestock on the Coastal Plain, and the manner of their waste disposition deserves attention. Swine waste from CAFOs is invariably pumped into lagoons, some of which are located on river floodplains. In North Carolina liquid waste from the lagoons is typically then sprayed out on adjoining fields, from which surface drainage to waterways or subsurface drainage to groundwaters can occur. The nutrients produced by poultry CAFOs as manure are largely spread as dry litter on fields, with some pumped into waste lagoons, from which they are sprayed as liquid waste onto fields. Secondary treatment of livestock waste for nutrient removal is seldom practiced.

This analysis does not take into account nutrients produced by the decomposition of dead animals. Following Hurricane Floyd in October 1999, the news media published numerous photographs of drowned swine and poultry from CAFOs in areas inundated by floodwaters. The numbers of drowned livestock may have been very large, as Wing et al. (2002) determined that 241 CAFOs were within the geographical coordinates of the areas inundated by post-Floyd floodwaters according to satellite imagery.

TABLE 2

Estimated Amounts of Nitrogen and Phosphorus (metric tons) Excreted Annually by Various Livestock Categories on the North Carolina Coastal Plain, 2000–2001

Animal Category	Nitrogen	Phosphorus
Swine	101,000	22,700
Broiler chickens	3,570	1,110
Other Chickens	60	20
Turkeys	12,600	3,500
Cattle	7,000	1,750
Grand Total	124,230	29,080

N.C. Department of Agriculture statistics report over 1 million swine mortalities per year as of 1998, not counting piglets lost (N.C. D.A., 1999); thus, animal carcasses are likely another significant source of nutrients to the environment.

Data published by the Lower Cape Fear River Program (available at the website http://www.uncwil.edu/cmsr/aquaticecology/laboratory/lcfrp) demonstrate that there was a statistically significant increase in ammonium levels at a Northeast Cape Fear River station (Sarecta) during the period 1996–2001 (see Figure 2). Ammonium comprises the largest portion of total N in swine and poultry liquid waste (Burkholder et al., 1997; Mallin et al., 1997; Williams et al., 1999). Along with transport of ammonium in runoff or subsoil movement, it can be volatilized and transported in the gaseous ammonia form (Edwards & Daniel, 1992; Williams et al., 1999; Mallin, 2000). The station at Sarecta has 344 swine CAFOs within a 20 km radius, and 587 swine CAFOs within a 30 km radius (we have no data on poultry CAFOs). This station likely receives ammonium inputs from overland runoff and lateral groundwater flow, and airborne deposition. The implications of nutrient increases to downstream waters are discussed below.

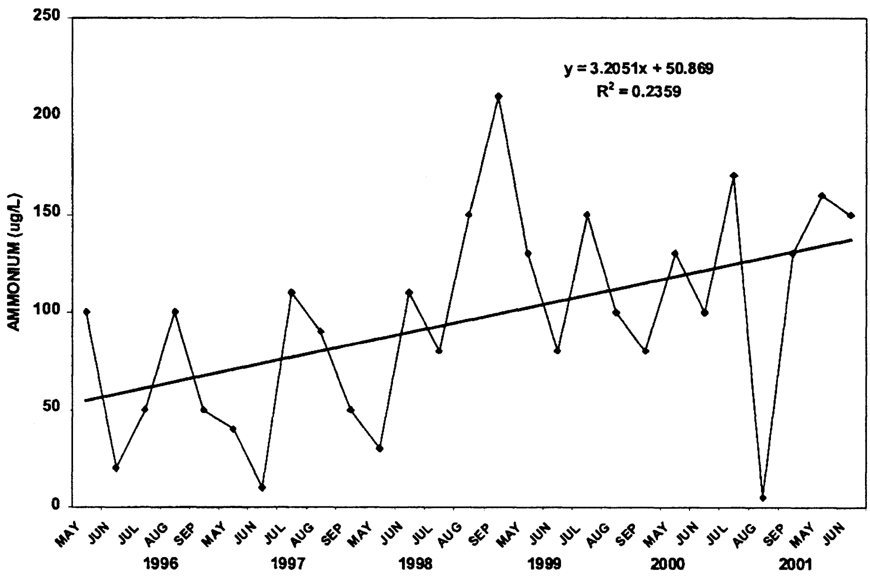

FIGURE 2. Summer ammonium concentrations at Sarecta, a water quality station on the Northeast Cape Fear River in a location near numerous CAFOs, data from 1996 to 2001.

Applying Sobsey's (1996) conversion factors figures to livestock populations on North Carolina's Coastal Plain yields estimated annual excretion of fecal coliform bacteria of 3.8×10^{18} from swine, 1.7×10^{18} CFU from broilers, 1.8×10^{17} from other chickens, and 3.3×10^{17} from cattle.

DISCUSSION

Fate of Excreted Nutrients

As mentioned earlier, major storms and accidents are documented mechanisms by which large amounts of nutrients have been abruptly transported from CAFOs to receiving waters (Burkholder et al., 1997; Mallin et al., 1997; 1999; Mallin, 2000). However, CAFOs also chronically export nutrients to water resources through several means. Normal rain events carry nutrients from swine sprayfields to nearby streams through surface and subsurface runoff (Evans et al., 1984; Westerman et al., 1987) where these inputs have caused stream nitrate-N to rise above 5 mg N/L and P above 1 mg P/L (Stone et al., 1995; Gilliam et al., 1996). Nutrients, mainly nitrate and ammonium, also leach downwards into groundwater from animal waste lagoons, sprayfields, and litter fields. In a set of 11 North Carolina swine lagoons, Huffman and Westerman (1995) found average inorganic (ammonium and nitrate) N concentrations of 143 mg/L in nearby groundwater, and found that through leakage the lagoons exported on average 4.7 kg N/day to groundwater. Also in North Carolina Westerman et al. (1995) found average concentrations of ammonium in downslope well fields that exceeded 50 mg N/L, compared with upslope wells that were less than 1 mg N/L. The nitrate form of N is especially mobile in soils and can pass readily through soils to contaminate groundwater. Liebhardt et al. (1979) found high levels of nitrate in soil groundwater beneath Delaware cornfields where poultry waste was applied as the sole fertilizer, with evidence that the nitrate moved laterally toward a nearby stream. Using nitrogen isotopic techniques Karr et al., (2001) have traced nitrate generated from swine waste spray fields through shallow groundwater into receiving stream waters, and at least 1.5 km downstream. Phosphorus is much less mobile, and binds readily to soil particles. However, when the P content of soils is built up dramatically through excessive manure application, both surface export and subsurface loss of P occurs (Sharpley et al., 1999).

Anaerobic treatment of swine wastes with high concentrations of organic N promotes deamination, resulting in high concentrations of ammonium-N in lagoon liquid. Liming is used to maintain a pH above about 7, favoring ammonia formation. Ammonia volatilizes from sprayfields and waste lagoons, and is transported downwind (McCulloch et al., 1998; Aneja et al., 2000; Walker et al., 2000). The North Carolina Department of Air Quality estimates that 70–80% of all swine waste N and a somewhat lesser percentage of poultry waste N is thus volatilized (N.C. D.A.Q., 1997). It is notable that the Neuse River watershed, which contains approximately 25% of North Carolina's swine population and numerous poultry production facilities and is downwind of a large concentration of CAFOs in the Cape Fear watershed, registered a 14% increase in total N and a 34% increase in nitrate over the seven year period 1990–1997 (Glasgow & Burkholder, 2000). While other anthropogenic sources of N undoubtedly contributed to this loading, the large recent rise in CAFOs in those watersheds would suggest that animal production is a significant cause of these nutrient inputs. Walker et al. (2000) and Mallin (2000) have documented a trend of increasing ammonium deposition in the coastal region of North Carolina, which they attribute to animal production sources. At Sarecta on the Northeast Cape Fear River a steady rise in river ammonium concentrations from 1996–2001 is evident (see Figure 2). There are no new or large wastewater treatment facilities in that area that can account for this increase. The single major land use change in that area has been the rapid proliferation of CAFOs during the 1980s and 1990s (see Figure 1).

Potential Impacts on Water Resources

Kellogg (2000) prioritized U.S. watersheds in terms of vulnerability to manure nutrient contamination based on a number of factors, including soil percolation, soil runoff potential, soil erosion potential, and amount of animal nutrients applied to soils. Much of the North Carolina Coastal Plain, especially the Albemarle-Pamlico and Cape Fear watersheds, ranked highest in the nation in vulnerability. Many of the surface water supplies downstream of CAFO-dense areas on the North Carolina Coastal Plain (Figure 1) are sensitive to N and/or P loading, and will respond by formation of algal blooms (Rudek et al., 1991; Paerl et al., 1990; Glasgow & Burkholder, 2000). This is especially true in the Neuse, Pamlico, and New Rivers and their estuaries (Dame et al., 2000; Mallin et al., 2000). Algal blooms can build up high concentrations of biomass, and eventually die and become a source of labile organic material. Bacteria feed on this biomass and multiply, creating high biochemical oxygen demand (BOD) that will at times lower dissolved oxygen concentrations to levels that can kill sessile bottom organisms and create areas in which finfish cannot survive—a loss of usable habitat. Another impact of increased nutrient loading on estuaries is to stimulate growth of the toxic dinoflagellates *Pfiesteria piscicida* and *P. shumwayae*, which have bloomed downstream of CAFO areas in the Neuse, Pamlico, and New River Estuaries of North Carolina and the Chesapeake Bay in Maryland (Burkholder et al., 1995; Burkholder & Glasgow, 1997; Glasgow et al., 2001). Growth of *P. piscicida* is more stimulated by P loading whereas *P. shumwayae* appears to be more stimulated by N inputs (Glasgow et al., 2001). Both species of *Pfiesteria* have caused many fish kills in North Carolina and some in Maryland, as well as human health problems to researchers and watermen exposed to its toxins (Burkholder et al., 1995; Burkholder & Glasgow, 1997; Burkholder & Glasgow, 2001). Blooms of these organisms and consequent fish kills have led to closures of areas in the Chesapeake Bay region and the Albemarle-Pamlico estuarine region in North Carolina to commercial fishing, due to health concerns over the consumption of affected fish and exposure to airborne *Pfiesteria* toxins when on the water (Burkholder & Glasgow, 2001).

In the Cape Fear River basin, which produces 50% of North Carolina's swine and vast numbers of poultry, most of the CAFOs are in watersheds drained by blackwater streams. These are streams that drain lowland forests and riverine swamps, and in pristine condition are naturally nutrient poor. Recent experiments have been conducted on the response of blackwater streams to increased nutrient loading (Mallin et al., 2001). These experiments showed that N inputs of 1 mg/L led to spring and summer algal blooms in test waters, while P levels of 1 mg/L caused significant production of heterotrophic microbes and increased biochemical oxygen demand (Mallin, 2000; Mallin et al., 2000; Mallin et al., 2001). Since recent assessments (Figure 2) show a steady increase in ammonium in certain downstream locations in the Cape Fear basin, this loading has the potential for degrading water quality in areas receiving nutrient inputs.

Seagrass beds are an important coastal habitat for many species of finfish and shellfish. Historically, important seagrass habitat has been located downstream of CAFO-rich areas in the Albemarle-Pamlico estuarine system in North Carolina as well as the Chesapeake Bay. Much of that habitat disappeared in the mid-to-late 1900s. A number of factors can cause losses of seagrass, including reduced photosynthesis from increased turbidity (Dennison et al, 1993). However, the most important seagrass species on the mid-Atlantic seaboard (eelgrass—*Zostera marina*) has been shown to be sensitive to nitrate loading, and can die under prolonged exposure to nitrate concentrations of 50 to 100 μg N/L or higher (Burkholder et al., 1992; Burkholder et al., 1994). Some coastal North Carolina waters can periodically receive extended inputs of nitrate from upstream freshwater sources that exceed these critical levels (Mallin et al., 1993; Paerl et al., 1995; Mallin et al., 1999; Glasgow & Burkholder, 2000) thus providing a habitat stressful to eelgrass survival or re-establishment.

Animal Pathogens and Humans

Livestock are known to excrete many of the same pathogenic bacteria, viruses, and protozoans that can afflict humans. These organisms include pathogenic bacteria such as *Escherichia coli*, *Salmonella* spp., and *Streptococcus* spp., pathogenic protozoans such as *Giardia lamblia* and *Cryptosporidium parvum*, and a number of viruses (Mawdsley et al., 1995). The way animal waste is treated will affect pathogen survival and potential transmission to humans. Composting of manure raises temperatures high enough to kill most microbes, but animal waste slurries do not reach lethal temperatures (Mawdsley et al., 1995). Microbes in animal waste slurries such as lagoon liquid can survive for extended periods; *E. coli* has been known to survive up to 11 weeks in such an environment (Mawdsley et al., 1995). If waste is applied to the land surface survival time is cut to a matter of days, particularly under conditions of bright sunlight (Crane et al., 1983; Mawdsley et al., 1995). However, rain events occurring shortly after animal waste is surface-applied to fields cause vertical and horizontal movement of microbes to nearby water bodies (Crane et al., 1983; Mawdsley et al., 1995; Mallin, 2000). Large-scale microbial disease outbreaks have been traced to livestock vectors. In 1999 and 2000 the news media reported incidents in Albany, New York (MMWR 1999) and Walkerton, Ontario of mass illnesses and some deaths to humans that were exposed to pathogenic *E. coli* in water sources contaminated by runoff from cattle husbandry areas.

As indicated above, livestock on the Coastal Plain excrete large amounts of fecal bacteria in manure. Unlike human waste, microbes generated by CAFOs are not exposed to secondary treatment or chlorination to disinfect the material. When applied to fields in manure the vast majority of these microbes are likely deactivated by ultraviolet radiation, microbial competition and predation, or other means (Crane et al., 1983). However, because of the sheer volume of microbes deposited, there still remains a significant pollution potential from this material entering surface or groundwaters that humans will contact. If CAFO-generated microbes enter the sediments of water bodies, organisms such as *E. coli* can find a favorable environment where they can remain viable for over two months (Davies et al., 1995). For example, following a large swine waste lagoon spill in the New River, North Carolina, Burkholder et al. (1997) found fecal coliform bacterial counts ranging from 1,000,000 to 3,000,000 per 100 ml of river water several km downstream from the spill site. These very high concentrations declined to the range of 1,000 to 5,000 per 100 ml after 14 days, and to less than 1,000 per 100 ml in 61 days. However, further sampling indicated that the river sediments maintained concentrations of fecal bacteria up to 5,000 per 100 ml for 61 days. The risk of large quantities of fecal microbes entering the environment is thus high following acute CAFO mishaps; although the risk of human exposure to these microbes chronically through normal operations is yet undetermined.

Regulation

Point source discharges from municipal or industrial wastewater treatment plants are regulated under the National Pollution Discharge Elimination System (NPDES) enacted by the National Environmental Policy Act of 1971 (NEPA). This process authorizes the US Environmental Protection Agency or individual states to license and inspect dischargers, and set maximum pollutant discharge concentrations. However, CAFOs have been considered to be non-point source dischargers, and were thus exempt from this process. As such, regulation of pollutant discharges from them has been piecemeal and varies from state to state. Current legislated and regulatory controls on the environmental effects of CAFOs have generally followed demonstration of negative environmental impacts, rather than preventing them, e.g., Maryland's Water Quality Improvement Act of 1998. Laws and regulations in many states define CAFOs as farms and tacitly assume that CAFOs manage nutrients and other wastes as do conventional farms, when in fact CAFO operations depart significantly from the ecological relationships that control farm productivity (Jackson et al., 2000). Moreover, most laws and regulations address CAFOs as individual operations, thus neglecting the considerable effects of concentration of many CAFOs in relatively small regions.

Although some Federal legislators have shown concern for the environmental impacts of CAFOs (Harkin, 1997), comprehensive legislation designed to regulate CAFO-generated pollution has not yet occurred on the Federal level. Federal regulations have only recently recognized the need to limit P over-application in animal wastes; the U. S. Department of Agriculture's Natural Resource Conservation Service mandates soil P management in its most recent version of the Nutrient Management Standard 590 (Sharpley & Tunney, 2000). Implementation by the states is not uniform, however, as they utilize different soil test procedures, different risk assessment methods, and different remediation responses. North Carolina has just developed a Phosphorus Loss Assessment Tool (PLAT), which has not yet been fully implemented. However, these new regulations address only one aspect of the larger set of environmental challenges posed by CAFOs, and fail to address the consequences of regional concentration of CAFOs at all. Consequently, CAFOs present a major challenge to the current system of environmental law and regulations in the United States.

ACKNOWLEDGMENTS

This paper was in part an outgrowth of a presentation by the first author at the Politics and Life Sciences Conference held in Charleston, S.C. in October 2001. For funding support we thank the Lower Cape Fear River Program and the Water Resources Research Institute of the University of North Carolina (Project no. 70171). For assistance with data compilation we thank Virginia L. Johnson, Jill A. Mickucki, and Ellen J. Wambach. We thank Alice Clarke and two anonymous reviewers for helpful manuscript comments. This is contribution no. 291, Center for Marine Science, the University of North Carolina at Wilmington.

Waste from agricultural livestock operations has been a long-standing concern with respect to contamination of water resources, particularly in terms of nutrient pollution. However, the recent growth of concentrated animal feeding operations (CAFOs) presents a greater risk to water quality because of both the increased volume of waste and to contaminants that may be present (e.g., antibiotics and other veterinary drugs) that may have both environmental and public health importance. Based on available data, generally accepted livestock waste management practices do not adequately or effectively protect water resources from contamination with excessive nutrients, microbial pathogens, and pharmaceuticals present in the waste. Impacts on surface water sources and wildlife have been documented in many agricultural areas in the United States. Potential impacts on human and environmental health from long-term inadvertent exposure to water contaminated with pharmaceuticals and other compounds are a growing public concern. This workgroup, which is part of the Conference on Environmental Health Impacts of Concentrated Animal Feeding Operations: Anticipating Hazards—Searching for Solutions, identified needs for rigorous ecosystem monitoring in the vicinity of CAFOs and for improved characterization of major toxicants affecting the environment and human health. Last, there is a need to promote and enforce best practices to minimize inputs of nutrients and toxicants from CAFOs into freshwater and marine ecosystems. *Key words:* ecology, human health, poultry, swine, water contaminants, wildlife. *Environ Health Perspect* 115:308–312 (2007). doi:10.1289/ehp.8839 available via *http://dx.doi.org/* [Online 14 November 2006]

Background and Recent Developments

Concentrated animal feed operations and water quality. Animal cultivation in the United States produces 133 million tons of manure per year (on a dry weight basis) representing 13-fold more solid waste than human sanitary waste production [U.S. Environmental Protection Agency (U.S. EPA) 1998]. Since the 1950s (poultry) and the 1970s–1980s (cattle, swine), most animals are now produced for human consumption in concentrated animal feeding operations (CAFOs). In these industrialized operations, the animals are held throughout their lives at high densities in indoor stalls until they are transported to processing plants for slaughter. There is substantial documentation of major, ongoing impacts on aquatic resources from CAFOs, but many gaps in understanding remain.

Contaminants detected in waste and risk of water contamination. Contaminants from animal wastes can enter the environment through pathways such as through leakage from poorly constructed manure lagoons, or during major precipitation events resulting in either overflow of lagoons and runoff from recent applications of waste to farm fields, or atmospheric deposition followed by dry or wet fallout (Aneja 2003). The magnitude and direction of transport depend on factors such as soil properties, contaminant properties, hydraulic loading characteristics, and crop management practices (Huddleston 1996). Many contaminants are present in livestock wastes, including nutrients (Jongbloed and Lenis 1998), pathogens (Gerba and Smith 2005; Schets et al. 2005), veterinary pharmaceuticals (Boxall et al. 2003; Campagnolo et al. 2002; Meyer 2004), heavy metals [especially zinc and copper; e.g., Barker and Zublena (1995); University of Iowa and Iowa State Study Group (2002)], and naturally excreted hormones (Hanselman et al. 2003; Raman et al. 2004). Antibiotics are used extensively not only to treat or prevent microbial infection in animals (Kummerer 2004), but are also commonly used to promote more rapid growth in livestock (Cromwell 2002; Gaskins et al. 2002; Liu et al. 2005). In addition, pesticides such as dithiocarbamates are applied to sprayfields (Extension Toxicology Network 2003). Although anaerobic digestion of wastes in surface storage lagoons can effectively reduce or destroy many pathogens, substantial remaining densities of microbial pathogens in waste spills and seepage can contaminate receiving surface- and groundwaters (e.g., Burkholder et al. 1997; Mallin 2000). Pharmaceuticals can remain present as parent compounds or degradates in manure and leachates even during prolonged storage. Improper disposal of animal carcasses and abandoned livestock facilities can also contribute to water quality problems. Siting of livestock operations in areas prone to flooding or where there is a shallow water table increases the potential for environmental contamination.

The nutrient content of the wastes can be a desirable factor for land application as fertilizer for row crops, but overapplication of livestock wastes can overload soils with both macronutrients such as nitrogen (N) and phosphorous (P), and heavy metals added to feed as micronutrients (e.g., Barker and Zublena 1995). Overapplication of animal wastes or application of animal wastes to saturated soils can also cause contaminants to move into receiving waters through runoff and to leach through permeable soils to vulnerable aquifers. Importantly, this may happen even at recommended application rates. As examples, Westerman et al. (1995) found 3–6 mg nitrate (NO_3)/L in surface runoff from sprayfields that received swine effluent at recommended rates; Stone et al. (1995) measured 6–8 mg total inorganic N/L and 0.7–1.3 mg P/L in a stream adjacent to swine effluent sprayfields. Evans et al. (1984) reported 7–30 mg NO_3/L in subsurface flow draining a sprayfield for swine wastes, applied at recommended rates. Ham and DeSutter (2000) described export rates of up to 0.52 kg ammonium m^{-2} $year^{-1}$ from lagoon seepage; Huffman and Westerman (1995) reported that groundwater near swine waste lagoons averaged 143 mg inorganic N/L, and estimated export rates at 4.5 kg inorganic N/day. Thus, nutrient losses into receiving waters can be excessive relative to levels (~ 100–200 μg inorganic N or P/L)

known to support noxious algal blooms (Mallin 2000). In addition to contaminant chemical properties, soil properties and climatic conditions can affect transport of contaminants. For example, sandy, well-drained soils are most vulnerable to transport of nutrients to underlying groundwater (Mueller et al. 1995). Nutrients can also readily move through soils under wet conditions (McGechan et al. 2005).

Presence of contaminants in water sources. The presence of many contaminants from livestock waste has been documented in both surface water and groundwater supplies in agricultural areas within the United States (e.g., Campagnolo et al. 2002; Kolpin et al. 2002; Meyer 2004). Urban wastewater streams also contain these contaminants, and efforts to accurately determine sources of contamination are under way (Barnes et al. 2004; Cordy et al. 2004; Kolpin DW, unpublished data). The U.S. Geological Survey (USGS) began pilot surveillance programs for organic wastewater contaminants in 1999 and expanded that effort to a national scale over the past 5 years (Kolpin et al. 2002). Recent USGS efforts have focused specifically on water quality in agricultural locations (Kolpin DW, unpublished data). Nutrient levels have been detected in high parts per million (milligrams per liter) levels; pharmaceuticals and other compounds are generally measured in low levels (ppb [micrograms per liter]). In Europe, surveillance efforts conducted in Germany documented the presence of veterinary pharmaceuticals in water resources (Hirsch et al. 1999).

Animal wastes are also rich in organics and high in biochemical oxygen-demanding materials (BOD); for example, treated human sewage contains 20–60 mg BOD/L, raw sewage contains 300–400 mg BOD/L, and swine waste slurry contains 20,000–30,000 mg BOD/L (Webb and Archer 1994). Animal wastes also carry parasites, viruses, and bacteria as high as 1 billion/g (U.S. EPA 1998). Swine wastes contain > 100 microbial pathogens that can cause human illness and disease [see review in Burkholder et al. (1997)]. About one-third of the antibiotics used in the United States each year is routinely added to animal feed to increase growth (Mellon et al. 2001). This practice is promoting increased antibiotic resistance among the microbial populations present and, potentially, increased resistance of naturally occurring pathogens in surface waters that receive a portion of the wastes.

Contaminant impacts. Some contaminants pose risks for adverse health impacts in wildlife or humans. The effects of numerous waterborne pathogens on humans are well known, although little is known about potential impacts of such microorganisms on aquatic life. With respect to nutrients, excessive phosphorus levels can contribute to algal blooms and cyanobacterial growth in surface waters used for recreation and as sources of drinking water. Research is beginning to investigate the environmental effects, including endocrine disruption and antibiotic resistance issues (Burnison et al. 2003; Delepee et al. 2004; Fernandez et al. 2004; Halling-Sorensen et al. 2003; Sengelov et al. 2003; Soto et al. 2004; Wollenberger et al. 2000). However, knowledge is limited in several crucial areas. These areas include information on metabolites or environmental degradates of some parent compounds; the environmental persistence, fate, and transport and toxicity of metabolites or degradates (Boxall et al. 2004); the potential synergistic effects of various mixtures of contaminants on target organisms (Sumpter and Johnson 2005); and the potential transport and effects from natural and synthetic hormones (Hanselman et al. 2003; Soto et al. 2004). Further, limited monitoring has been conducted of ecosystem health in proximity to CAFOs, including monitoring the effects on habitats from lagoon spills during catastrophic flooding (Burkholder et al. 1997; Mallin et al. 1997; Mallin et al. 2000).

Ecologic and wildlife impacts. Anoxic conditions and extremely high concentrations of ammonium, total phosphorus, suspended solids, and fecal coliform bacteria throughout the water column for approximately 30 km downstream from the point of entry have been documented as impacts of waste effluent spills from CAFOs (Burkholder et al. 1997; Mallin et al. 2000). Pathogenic microorganisms such as *Clostridium perfringens* have been documented at high densities in receiving surface waters following CAFO waste spills (Burkholder et al. 1997). These degraded conditions, especially the associated hypoxia/anoxia and high ammonia, have caused major kills of freshwater fish of all species in the affected areas, from minnows and gar to largemouth bass, and estuarine fish, including striped bass and flounder (Burkholder et al. 1997). Waste effluent spills also stimulated blooms of toxic and noxious algae. In freshwaters, these blooms include toxic and noxious cyanobacteria while in estuaries, harmful haptophytes and toxic dinoflagellates arise. Most states monitor only water-column fecal coliform densities to assess whether waterways are safe for human contact. World Health Organization (WHO) guidelines for cyanobacteria in recreational water are 20,000 cyanobacterial cells/mL, which indicates low probability of adverse health effects, and 100,000 cyanobacterial cells/mL, which indicates moderate probability of adverse health effects (WHO 2003). Yet fecal bacteria and other pathogenic microorganisms typically settle out to the sediments where they can thrive at high densities for weeks to months following CAFO waste effluent spills (Burkholder et al. 1997).

The impacts from CAFO pollutant loadings to direct runoff are more substantial after such major effluent spills or when CAFOs are flooded and in direct contact with surface waters (Wing et al. 2002). Although the acute impacts are often clearly visible—dead fish floating on the water surface, or algal overgrowth and rotting biomass—the chronic, insidious, long-term impacts of commonly accepted practices of CAFO waste management on receiving aquatic ecosystems are also significant (U.S. EPA 1998). One purpose of manure storage basins is to reduce the N content of the manure through volatilization of ammonia and other N-containing molecules. Many studies have shown, for example, that high nutrient concentrations (e.g., ammonia from swine CAFOs, or ammonia oxidized to NO_3, or phosphorus from poultry CAFOs) commonly move off-site to contaminate the overlying air and/or adjacent surface and subsurface waters (Aneja et al. 2003; Evans et al. 1984; Sharpe and Harper 1997; Sharpley and Moyer 2000; Stone et al. 1995; U.S. EPA 1998; Webb and Archer 1994; Westerman et al. 1995; Zahn et al. 1997). Inorganic N forms are added to the atmosphere during spray practices, and both ammonia and phosphate can also adsorb to fine particles (dust) that can be airborne. The atmospheric depositions are noteworthy, considering that a significant proportion of the total ammonium from uncovered swine effluent lagoons and effluent spraying (an accepted practice in some states) reenters surface waters as local precipitation or through dry fallout (Aneja et al. 2003; U.S. EPA 1998, 2000). The contributed nutrient concentrations from the effluent greatly exceed the minimal levels that have been shown to promote noxious algal blooms (Mallin 2000) and depress the growth of desirable aquatic habitat species (Burkholder et al. 1992). The resulting chronically degraded conditions of nutrient overenrichment, while not as extreme as during a major waste spill, stimulate algal blooms and long-term shifts in phytoplankton community structure from desirable species (e.g., diatoms) to noxious species.

A summary of the findings from a national workshop on environmental impacts of CAFOs a decade ago stated that there was "a surprising lack of information about environmental impacts of CAFOs to adjacent lands and receiving waters" (Thu K, Donham K, unpublished data). Although the knowledge base has expanded since that time, especially regarding adverse effects of inorganic N and P overenrichment and anoxia, impacts of many CAFO pollutants on receiving aquatic ecosystems remain poorly understood. As examples, there is poor understanding of the impacts of fecal bacteria and other microbial pathogens from CAFO waste effluent contamination on aquatic communities; impacts of antibiotic-resistant bacteria created from CAFO wastes on aquatic life; impacts of organic nutrient forms preferred by certain noxious plankton; impacts from the contributed pesticides and heavy metals; and impacts from these pollutants acting in concert, additively or synergistically. This lack of information represents a critical gap in our present ability to assess the full extent of CAFO impacts on aquatic natural resources.

Despite their widespread use, antibiotics have only recently received attention as environmental contaminants. Most antibiotics are designed to be quickly excreted from the treated organism. Thus, it is not surprising that antibiotics are commonly found in human and animal waste (Christian et al. 2003; Dietze et al. 2005; Glassmeyer et al. 2005; Meyer 2004) and in water resources affected by sources of waste (Glassmeyer et al. 2005; Kolpin et al. 2002). Although some research has been conducted on the environmental effects from antibiotics (e.g., Brain et al. 2005; Jensen et al. 2003), much is yet to be understood pertaining to long-term exposures to low levels of antibiotics (both individually and as part of complex mixtures of organic contaminants in the environment). The greatest risks appear to be related to antibiotic resistance (Khachatourians 1998; Kummerer 2004) and natural ecosystem functions such as soil microbial activity and bacterial denitrification (Costanzo et al. 2005; Thiele-Bruhn and Beck 2005).

Human health impacts. Exposure to waterborne contaminants can result from both recreational use of affected surface water and from ingestion of drinking water derived from either contaminated surface water or groundwater. High-risk populations are generally the very young, the elderly, pregnant women, and immunocompromised individuals. Recreational exposures and illnesses include accidental ingestion of contaminated water that may result in diarrhea or other gastrointestinal tract distress from waterborne pathogens, and dermal contact during swimming that may cause skin, eye, or ear infections. Drinking water exposures to pathogens could occur in vulnerable private wells; under normal circumstances community water utilities disinfect water sufficiently before distribution to customers. Cyanobacteria (blue–green algae) in surface water can produce toxins (e.g., microcystins) that are known neurotoxins and hepatotoxins. Acute and chronic health impacts from these toxins can occur from exposures to both raw water and treated water (Carmichael et al. 2001; Rao et al. 2002). Removal of cyanotoxins during drinking water treatment is a high priority for the drinking water industry (Hitzfield et al. 2000; Rapala et al. 2002). The WHO has set a provisional drinking water guideline of 1 µg microcystin-LR/L (Chorus and Bartram 1999). While there are no drinking water standards in the United States for cyanobacteria, they are on the U.S. EPA Unregulated Contaminant Monitoring Rule List 3 (U.S. EPA 2006).

Exposure to chemical contaminants can occur in both private wells and community water supplies, and may present health risks. High nitrate levels in water used in mixing infant formula have been associated with risk for methemoglobinemia (blue-baby syndrome) in infants under 6 months of age, although other health factors such as diarrhea and respiratory disease have also been implicated (Ward et al. 2005). The U.S. EPA drinking water standard of 10 mg/L NO_3–N and the WHO guideline of 11 mg/L NO_3–N were set because of concerns about methemoglobinemia. (Note: "nitrate" refers to nitrate–nitrogen). Epidemiologic studies of noncancer health outcomes and high nitrate levels in drinking water have reported an increased risk of hyperthyroidism (Seffner 1995) from long-term exposure to levels between 11–61 mg/L (Tajtakova et al. 2006). Drinking water nitrate at levels < 10 mg/L has been associated with insulin-dependent diabetes (IDDM; Kostraba et al. 1992), whereas other studies have shown an association with IDDM at nitrate levels > 15 mg/L (Parslow et al. 1997) and > 25 mg/L (van Maanen et al. 2000). Increased risks for adverse reproductive outcomes, including central nervous system malformations (Arbuckle et al. 1988) and neural tube defects (Brender et al. 2004; Croen et al. 2001), have been reported for drinking water nitrate levels < 10 mg/L.

Anecdotal reports of reproductive effects of nitrate in drinking water include a case study of spontaneous abortions in women consuming high nitrate water (19–26 mg/L) from private wells (Morbidity and Mortality Weekly Report 1996).

While amassing experimental data suggest a role for nitrate in the formation of carcinogenic *N*-nitroso compounds, clear epidemiologic findings are lacking on the possible association of nitrate in drinking water with cancer risk. Ecologic studies have reported mixed results for cancers of the stomach, bladder, and esophagus (Barrett et al. 1998; Cantor 1997; Eicholzer and Gutzwiller 1990; Morales-Suarez-Varela et al. 1993, 1995) and non-Hodgkin lymphoma (Jensen 1982; Weisenburger 1993), positive findings for cancers of the nasopharynx (Cantor 1997), prostate (Cantor 1997), uterus (Jensen 1982; Thouez et al. 1981), and brain (Barrett et al. 1998), and negative findings for ovarian cancer (Jensen 1982; Thouez et al. 1981). Positive findings have generally been for long-term exposures at > 10 mg/L nitrate. Case–control studies have reported mixed results for stomach cancer (Cuello et al. 1976; Rademacher et al. 1992; Yang et al. 1998); positive results for non-Hodgkin lymphoma at > 4 mg/L nitrate (Ward et al. 1996) and colon cancer at > 5 mg/L (De Roos et al. 2003); and negative results for cancers of the brain (Mueller et al. 2001; Steindorf et al. 1994), bladder (Ward et al. 2003), and rectum (De Roos et al. 2003), all at < 10 mg/L. Cohort studies have reported no association between nitrate in drinking water and stomach cancer (Van Loon et al. 1998); positive associations with cancers of the bladder and ovary at long-term exposures > 2.5 mg/L (Weyer et al. 2001); and inverse associations with cancers of the rectum and uterus, again at > 2.5 mg/L (Weyer et al. 2001).

Exposure to low levels of antibiotics and other pharmaceuticals in drinking water (generally at micrograms per liter or nanograms per liter) represent unintentional doses of substances generally used for medical purposes to treat active disease or prevent disease. The concern is more related to possible cumulative effects of long-term low-dose exposures than on acute health effects (Daughton and Ternes 1999). A recent study conducted in Germany found that the margin between indirect daily exposure via drinking water and daily therapeutic dose was at least three orders of magnitude, concluding that exposure to pharmaceuticals via drinking water is not a major health concern (Webb et al. 2003). It should be noted that when prescribing medications, providers ensure patients are not taking incompatible drugs, but exposure via drinking water is beyond their control.

Endocrine-disrupting compounds are chemicals that exhibit biological hormonal activity, either by mimicking natural estrogens, by canceling or blocking hormonal actions, or by altering how natural hormones and their protein receptors are made (McLachlan and Korach 1995). Although very low levels of estrogenic compounds can stimulate cell activity, the potential for human health effects, such as breast and prostate cancers, and reproductive effects from exposure to endocrine disruptors, is in debate (Weyer and Riley 2001).

Workshop Recommendations

Priority research needs.

- Ecosystems monitoring: Systematic sustained studies of ecosystem health in proximity to large CAFOs are needed, including effects of input spikes during spills or flooding events.
- Toxicologic assessment of contaminants: Identification and prioritization of contaminants are needed to identify those that are most significant to environmental and public health. Toxicity studies need to be conducted to identify and quantify contaminants

(including metabolites), and to investigate interactions (synergistic, additive, and antagonistic effects).

- Fate and transport: Studies of parent compounds and metabolites in soil and water must be conducted, and the role of sediment as a carrier and reservoir of contaminants must be evaluated.
- Surveillance programs: Programs should be instituted to assess private well water quality in high-risk areas. Biomonitoring programs should be designed and implemented to assess actual dose from environmental exposures.

Translation of science to policy.

- Wastewater and drinking water treatment: Processes for water treatment must be monitored to ensure adequate removal or inactivation of emerging contaminants.
- Pollution prevention: Best management practices should be implemented to prevent or minimize release of contaminants into the environment.
- Education: Educational materials should be continued to be developed and distributed to agricultural producers.

Acknowledgments

The research described in this report was partially funded by the U.S. Environmental Protection Agency's 319 grant program that is administered by the North Carolina Department of Environment and Natural Resources, Division of Water Resources. The author thanks Keith Larick (former employee), Ted Bush, Rick Bolich, Michael Tutwiler, and Kim Nimmer of the North Carolina Department of Environment and Natural Resources for their help and support in this project. Appreciation is extended to the private landowners in eastern North Carolina who graciously allowed access to their property. This study would not have been possible without the help of U.S. Geological Survey personnel who assisted with sample collections and (or) data compilations, including Brian Pointer, Ryan Rasmussen, Sean Egen, Jessica Cain, Katharine Kolb, and Dominick Antolino. Finally, gratitude is extended to Thomas Cuffney, J.K. Böhlke, and Kristen McSwain, U.S. Geological Survey, for providing valuable technical discussions during the study, and to Judith Denver, Mary Giorgino, and Stephen Kalkhoff, U.S. Geological Survey, who provided many helpful review comments and suggestions on the report manuscript.

Surface-Water Quality in Agricultural Watersheds of the North Carolina Coastal Plain Associated with Concentrated Animal Feeding Operations

By Stephen L. Harden

Abstract

The effects of concentrated animal feeding operations (CAFOs) on water quality were investigated at 54 agricultural stream sites throughout the North Carolina Coastal Plain during 2012 and 2013. Three general watershed land-use types were examined during the study, including 18 background watersheds with no active CAFOs (BK sites), 18 watersheds with one or more active swine CAFOs but no poultry CAFOs (SW sites), and 18 watersheds with at least one active swine CAFO and one active dry-litter poultry CAFO (SP sites). The watershed drainage areas for these 54 stream sites ranged from 1.2 to 17.5 square miles. Conventional fertilizers used for crop production are the primary source of nutrients at the BK sites. Animal-waste manures represent an additional source of nutrients at the SW and SP study sites.

Land cover, soil drainage, and CAFO attributes were compiled for each watershed. Water-quality field measurements were made and samples were collected at the 54 primary sites during 6 bimonthly sampling periods from June 2012 to April 2013. An additional 23 secondary sites were sampled once during April 2013 to provide supplemental data at stream locations directly adjacent or in close proximity to swine CAFOs and (or) background agricultural areas within 9 of the primary watersheds. The watershed drainage areas for the 23 secondary sites ranged from 0.2 to 8.9 square miles. Water temperature, specific conductance, dissolved-oxygen concentration, and pH were measured directly in the streams. Water samples were analyzed for major ions, nutrients, and stable isotopes, including delta hydrogen-2 (δ^2H) and delta oxygen-18 (δ^{18}O) of water and delta nitrogen-15 (δ^{15}N) and δ^{18}O of dissolved nitrate plus nitrite.

Most of the water-quality properties and constituents varied significantly among the six sampling periods, changing both seasonally and in response to hydrologic conditions. The differences noted among the sampling periods indicate that the interactions between seasonal climatic differences, streamflow conditions, and instream biotic and abiotic processes are complex and their integrated effects can have varying degrees of influence on individual nutrients.

Water-quality differences were noted for the SW and SP land-use groups relative to the BK group. Median values of specific conductance, several major ions (magnesium, sodium, potassium, and chloride), and nitrogen fractions (ammonia plus organic nitrogen, ammonia, nitrate plus nitrite, total nitrogen, and δ^{15}N of nitrate plus nitrite) were higher for the SW and SP groups compared to the BK group. No significant differences in water temperature, dissolved oxygen, calcium, total organic nitrogen, orthophosphate, total phosphorus, or δ^{18}O of nitrate plus nitrite were noted among the land-use groups. When compared on the basis of land-use type, there was an overall measurable effect of CAFO waste manures on stream water quality for the SW and SP watershed groups.

Some individual sites within the SW and SP groups showed no measurable CAFO effects on water quality despite having CAFOs present upstream. An evaluation of sodium plus potassium concentrations coupled with δ^{15}N values of nitrate plus nitrite proved valuable for distinguishing which SW and SP sites had a water-quality signature indicative of CAFO waste manures. Sites with CAFO manure effects were characterized by higher sodium plus potassium concentrations (commonly between 11 and 33 milligrams per liter) and δ^{15}N values of nitrate plus nitrite (commonly between 11 and 26 parts per thousand) relative to sites reflecting background agricultural conditions, which commonly had sodium plus potassium concentrations between 6 and 14 milligrams per liter and δ^{15}N values of nitrate plus nitrite between 6 and 15 parts per thousand. On the basis of the results of this study, land applications of waste manure at swine CAFOs influenced ion and nutrient chemistry in many of the North Carolina Coastal Plain streams that were studied.

A classification tree model was developed to examine relations of watershed environmental attributes among the study sites with and without CAFO manure effects. Model results indicated that variations in swine barn density, percentage of wetlands, and total acres available for applying swine-waste manures had an important influence on those watersheds where CAFO effects on water quality were either evident or mitigated. Measurable effects of CAFO waste manures on stream water quality were most evident in those SW and SP watersheds having lower percentages of wetlands combined

with higher swine barn densities and (or) higher total acres available for applying waste manure at the swine CAFOs. Stream water quality was similar to background agricultural conditions in SW and SP watersheds with lower swine barn densities coupled with higher percentages of wetlands or lower acres available for swine manure applications. The model provides a useful tool for exploring and identifying similar, unmonitored watersheds in the North Carolina Coastal Plain with potential CAFO manure influences on water quality that might warrant further examination.

Introduction

The U.S. Environmental Protection Agency's (EPA) National Water Quality Inventory Report to Congress (U.S. Environmental Protection Agency, 2010) lists pathogens, sediment, organic enrichment and oxygen depletion, and nutrients as several leading causes of impairment of rivers and streams in the United States. Agriculture, including crop and animal production, was cited as the most probable source of impairments in the assessed rivers and streams. Nonpoint-source (NPS) pollution from agricultural activities is of particular concern in eastern North Carolina because nutrient over-enrichment in surface waters has contributed to water-quality problems in the Tar-Pamlico, Neuse, and Cape Fear River Basins, particularly in the estuaries (Spruill and others, 1998; Luettich and others, 2000; Burkholder and others, 2006). Excessive inputs of nitrogen (N) and phosphorus (P) to nutrient-sensitive waters can contribute to eutrophication, excess algal blooms, fish kills, and outbreaks of toxic dinoflagellates (Burkholder and others, 1995; Burkholder and Glasgow, 1997; Stow and others, 2001; Paerl and others, 2004). Animal feeding operations (AFOs) are recognized as important NPS contributors of N and P to streams in the North Carolina Coastal Plain physiographic province (Glasgow and Burkholder, 2000; Mallin and Cahoon, 2003; Burkholder and others, 2006; Rothenberger and others, 2009). Large amounts of land-applied animal manures in watersheds with high densities of AFOs can lead to nutrient surpluses that exceed the assimilative capacity of the watershed to absorb excess nutrients without having deleterious effects on water quality (Stone and others, 1998; Mallin and Cahoon, 2003; Hubbard and others, 2004; Sims and others, 2005; Copeland, 2010).

North Carolina is one of the Nation's leading animal producers, ranking second in the production of both swine and turkeys and fourth in the production of broiler chickens (North Carolina Department of Agriculture and Consumer Services, 2012). In North Carolina, AFOs are regulated and permitted as non-discharge facilities by the Animal Feeding Operations Program within the North Carolina Department of Environment and Natural Resources Division of Water Resources (DWR). As of January 2013, there were 2,356 individually permitted AFOs in North Carolina (North Carolina Division of Water Resources, 2013), with about 90 percent of the facilities consisting of swine AFOs (total of 2,132) and the remaining 10 percent consisting primarily of cattle (total of 199) and wet poultry (total of 21) AFOs. The majority of the swine AFOs (2,006) are located in the Coastal Plain (fig. 1). Most poultry AFOs in North Carolina consist of dry-litter operations that are exempt from permitting by the State. The number of dry-litter poultry AFOs in the Coastal Plain is likely similar to the number of swine AFOs (Keith Larick, North Carolina Division of Water Resources, oral commun., June 2013).

It is of note that the terms AFO and concentrated animal feeding operation (CAFO) often are used interchangeably within the literature; however, there are technical distinctions between them as defined by the EPA (40 CFR §122.23). The EPA generally defines AFOs as "operations where animals have been, are, or will be stabled or confined and fed or maintained for a total of 45 days or more in any 12-month period and where vegetation is not sustained in the confinement area during the normal growing season" (U.S. Environmental Protection Agency, 2012). An AFO may be further designated as a CAFO on the basis of the number of animals confined and specific criteria concerning the discharge of pollutants to adjacent surface waters, which if so designated makes the CAFO subject to National Pollutant Discharge Elimination Systems (NPDES) permitting requirements (40 CFR §122.23). In this report, swine and poultry feeding operations are collectively referred to as CAFOs even though they may not all technically meet the regulatory definitions.

At a typical swine CAFO, waste materials are flushed from the swine houses to one or more holding lagoons for temporary storage. Wastewater effluent from the lagoon(s) periodically is applied to nearby fields, commonly through surface spraying, in accordance with the permitted facility's Certified Animal Waste Management Plan such that the total N applied can be used during crop growth to avoid runoff or excessive leaching (Keith Larick, North Carolina Division of Water Resources, oral commun., June 2013); however, problems can result from adverse weather conditions or application rates that exceed crop uptake (Evans and others, 1984; Smith and Evans, 1998). At the poultry CAFOs, dry litter commonly is applied to cropland at the individual facilities if sufficient acreage is available, or the litter can be transported offsite and applied as a source of nutrients to other agricultural fields (Crouse and Shaffer, 2011).

Previous studies have examined the effects of swine and poultry CAFOs on groundwater and surface-water quality, especially regarding N and P, in the North Carolina Coastal Plain. Huffman (2004) found that seepage from swine-waste lagoons built before 1993, without clay liners, increased shallow groundwater concentrations of mineral N (ammonia N plus nitrate N) by 10 to 40 milligrams per liter (mg/L) as N at 11 sites and more than 40 mg/L as N at 16 sites. Various investigators have noted nitrate concentrations commonly between 10 and 30 mg/L, and in some cases between 50 and 150 mg/L, in groundwater collected beneath or adjacent to application fields receiving swine-lagoon effluent or

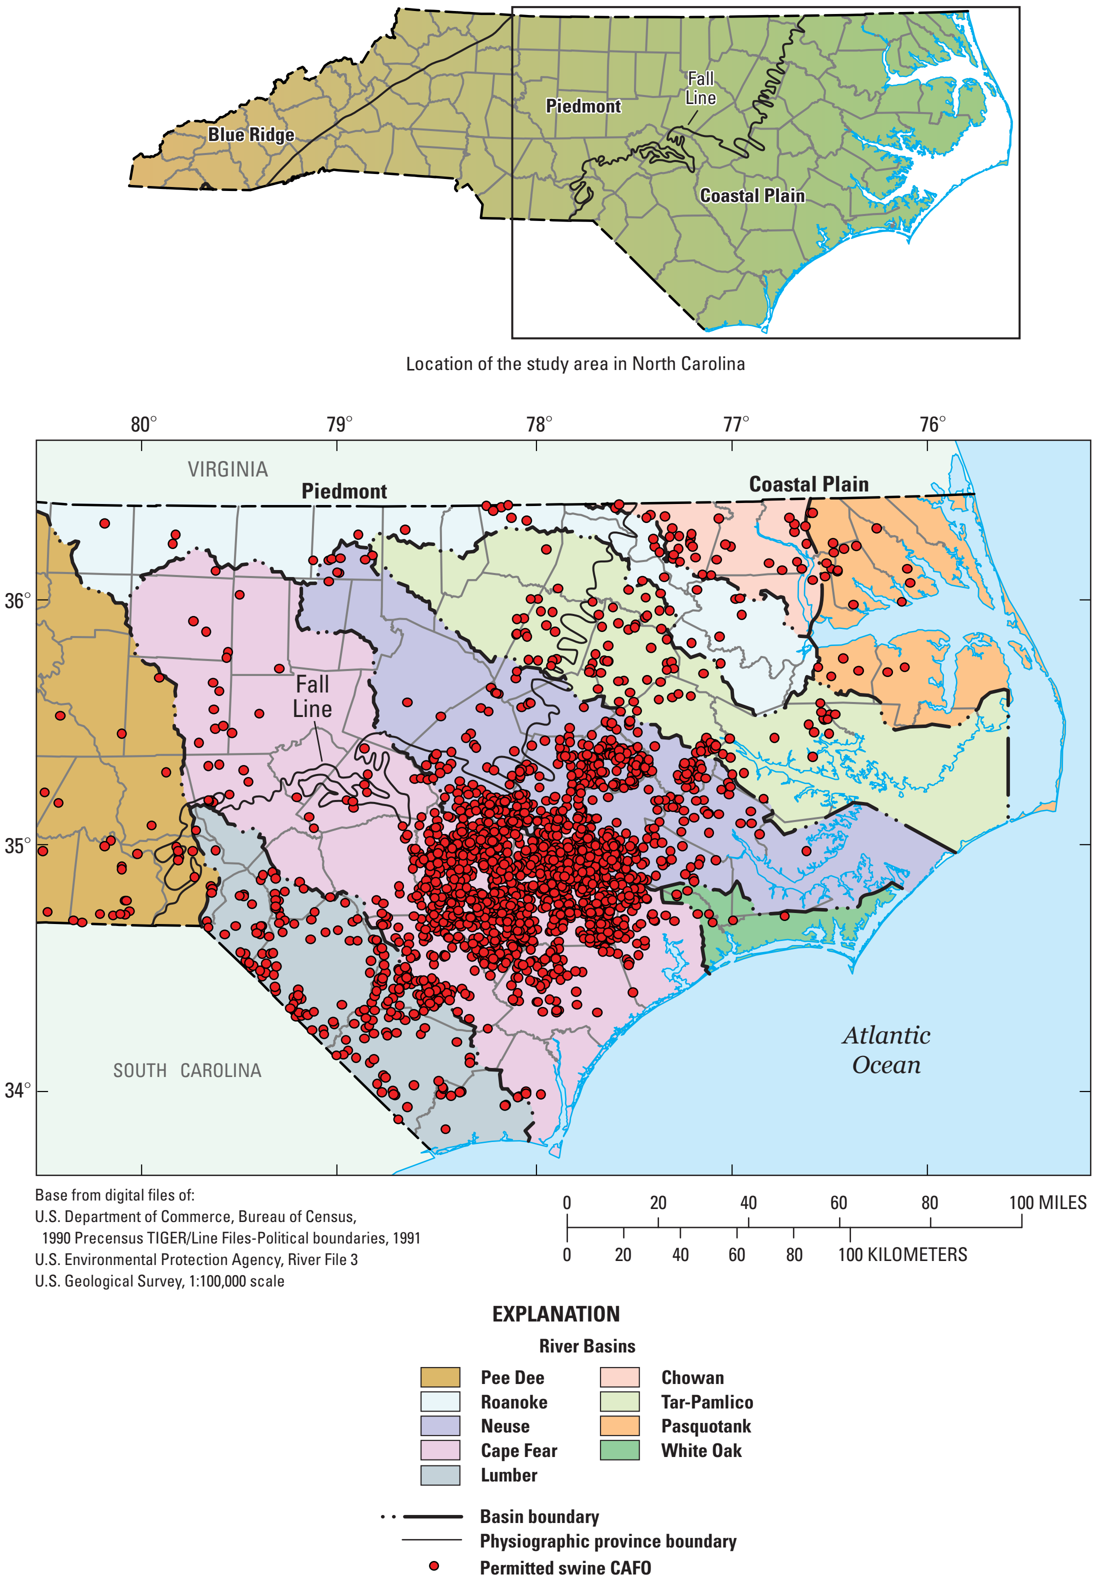

Figure 1. Locations of permitted swine concentrated animal feeding operations (CAFOs) in eastern North Carolina (swine CAFO locations obtained from North Carolina Division of Water Resources, 2013).

poultry litter (Hunt and others, 1995; Stone and others, 1998; Karr and others, 2001; Spruill and others, 2002; Israel and others, 2005; Dukes and Evans, 2006; Harden and Spruill, 2008). In addition to nitrate, increased concentrations of calcium, magnesium, sodium, potassium, and chloride have been observed in groundwater beneath swine CAFO spray fields (Karr and others, 2001; Spruill and others, 2005). The transport of P from agricultural fields to surface water typically occurs through overland runoff; however, repeated applications of swine-waste manure to fields can lead to excess accumulations of P in soil and subsequent leaching to groundwater for possible offsite transport to receiving streams (Novak and others, 2000; Nelson and others, 2005).

Elevated nutrient concentrations also have been observed in streams receiving overland runoff, groundwater discharge, and subsurface tile drainage derived from CAFOs (Stone and others, 1995; Karr and others, 2001; Spruill and others, 2005; Dukes and Evans, 2006; Harden and Spruill, 2008). Stone and others (1995) noted that a stream with intensive swine and poultry operations had nutrient concentrations during both stormflow and baseflow conditions that were several times higher than those in an adjacent background stream with no animal operations. In the stream influenced by the CAFOs, mean concentrations were 5.6 mg/L as N for nitrate, 0.74 mg/L as N for ammonia, and 0.68 mg/L for orthophosphate during baseflow conditions, and mean concentrations were 5.4 mg/L as N for nitrate, 2.28 mg/L as N for ammonia, and 1.3 mg/L for orthophosphate during stormflow conditions. Surface-water samples collected by Karr and others (2001) in a stream adjacent to two swine CAFOs had a median nitrate concentration of 6.7 mg/L as N. Harden and Spruill (2008) observed elevated levels of nitrate (median of 6.1 and range of 2.0 to 10.7 mg/L as N), ammonia (median of 0.76 and range of 0.09 to 2.38 mg/L as N), and dissolved P (median of 0.05 and range of 0.01 to 0.29 mg/L) in 28 surface-water samples collected in 2006 during stormflow and baseflow conditions from a stream next to waste-manure application fields at a swine CAFO. Elevated nitrate concentrations in this stream are considered to be strongly influenced by water discharged through a tile drain located in one of the adjacent spray fields (Spruill and others, 2005, Harden and Spruill, 2008). In 2006, water discharging from the tile drain to the stream had nitrate concentrations ranging from about 22 to 45 mg/L as N (Harden, 2008).

The practice of applying waste manure to fields at swine CAFOs is common in many watersheds throughout the Coastal Plain so there is substantial interest in understanding their influence on stream water quality. Many of the studies conducted to evaluate water-quality conditions related to CAFOs in the Coastal Plain have been limited in geographic extent, either focusing on individual farm sites or several streams within a particular watershed. The lack of stream water-quality data from a more representative number of watersheds makes it difficult for DWR to assess the extent to which effects of swine CAFOs on surface-water quality can be measured and how well existing CAFO regulations protect the waters of the State or to recommend effective changes to regulations or procedures. In 2011, DWR (formerly named the Division of Water Quality) and the U.S. Geological Survey (USGS) initiated a collaborative study to document whether swine CAFOs located in various Coastal Plain watersheds have a measurable effect on stream water quality. The study results presented in this report provide needed information from a large number of sites over a broader geographic area to better understand relations between swine CAFOs and stream water quality in eastern North Carolina.

Purpose and Scope

The primary purpose of this report is to summarize and synthesize chemical data collected from 54 agricultural watershed study sites throughout the North Carolina Coastal Plain to characterize water-quality conditions in streams receiving inputs from swine CAFOs compared to streams that receive inputs primarily from inorganic fertilizers. The scope of work included field measurements of water-quality properties and collection of surface-water samples for laboratory analysis of nutrients, major ions, and stable isotopes. Six rounds of bimonthly samples were collected from June 2012 to April 2013 at 54 primary watershed study sites. The last sampling round in April 2013 included collection and analysis of samples from 23 additional sites located within 9 of the 54 primary watersheds. Results were used to evaluate differences in stream water quality among watersheds with no CAFOs, watersheds with swine CAFOs, and watersheds with both swine and poultry CAFOs. Land cover, soil drainage class, and CAFO attributes (such as number of facilities, animal barns, swine animals, and total weight of swine) were used to examine potential relations between watershed environmental variables and water-quality conditions among the primary study sites. The main study objectives were to (1) assess water-quality differences among streams draining watersheds with and without land-applied CAFO waste manures, (2) examine the use of multiple chemical constituents for identifying effects of CAFOs on stream water quality, and (3) examine relations of environmental variables among watersheds with and without measurable CAFO manure effects. The study results are intended to assist water-resource managers and policy makers in their efforts to protect and improve stream water quality throughout North Carolina.

Description of the Study Area

The watershed sites examined in the Coastal Plain study area have drainage areas less than 20 square miles (mi^2) with land cover composed predominantly of cropland, forests, and wetlands. Most of the watersheds typically feature low-gradient blackwater streams and swamps with slow streamflow velocities. Varying degrees of submerged and floating aquatic vegetation and organic debris are present within and along the stream channels. These types of streams often have naturally low dissolved oxygen (DO) that can be depleted further as a result of nutrient and organic inputs from agricultural activities.

When examining stream water quality at the agricultural watershed sites in this study, it is important to understand that different processes influence fate and transport of nutrient inputs from agricultural fields to receiving streams. Nutrients applied to agricultural fields that percolate through the soils to the underlying surficial aquifer can be transported with groundwater as it discharges to receiving streams. Hydrograph separations performed on streamflow data during previous investigations indicate that groundwater, thought to be derived mostly from shallow aquifer systems, commonly contributes about 50 to 60 percent of the average annual streamflow to streams in the North Carolina Coastal Plain (McMahon and Lloyd, 1995; Spruill and others, 2005; Harden and others, 2013). Therefore, groundwater is potentially a major contributor of water and agriculturally derived chemical constituents to the stream study sites, particularly when there is minimal overland runoff from precipitation.

Various environmental, hydrogeologic, and geochemical factors that influence nitrate transport along groundwater flow paths beneath agricultural fields to receiving streams in the North Carolina Coastal Plain are discussed by Spruill and others (2005) and Harden and Spruill (2008). These factors include depth to water and saturated thickness of the surficial aquifer (Tesoriero and others, 2000; Tesoriero and others, 2005), groundwater residence times (Puckett, 2004; Tesoriero and others, 2005; Seitzinger and others, 2006), availability of organic carbon to drive denitrification reactions (Korom, 1992), and presence of riparian buffers (Speiran and others, 1998; Spruill, 2000; Puckett, 2004; Seitzinger and others, 2006). In evaluating changes in nitrate concentrations along groundwater flow paths at five study sites in the Coastal Plain, Harden and Spruill (2008) determined that denitrification was the most influential factor responsible for observed decreases in groundwater nitrate along the flow paths. Although some denitrification of groundwater nitrate occurred beneath the agricultural fields, nitrate reduction along the groundwater flow paths was most prevalent in the downgradient riparian buffer zone and hyporheic zone at the streams, where highly reduced conditions associated with organic-rich deposits enhanced the overall amount of denitrification.

The nitrate-reducing capacity of the buffer zone combined with that of the hyporheic zone can substantially lower the amount of groundwater nitrate discharged to streams in agricultural settings of the Coastal Plain (Spruill, 2000; Harden and Spruill, 2008). Depending on hydrogeologic and geochemical conditions, relatively young groundwater may move quickly along shallow flow paths beneath the riparian buffer and outpace the time needed for complete reduction of nitrate before discharging to a stream. Groundwater discharge along shallow flow paths may occur along seeps or channel walls that bypass the highly organic fluvial material in the hyporheic zone. If this water contains nitrate that has passed through the riparian buffer, the water can affect the nitrate concentration in the receiving stream.

In addition to groundwater transport, overland flow of water that occurs through field-drainage ditches is another important pathway that conveys nutrients from agricultural fields to receiving streams. Field-drainage ditches and subsurface tile drains commonly are used in the North Carolina Coastal Plain for improving drainage in agricultural fields with poorly drained soils (Evans and others, 1991; Gilliam and others, 1997). Water conveyed through the field ditches to the streams includes surface runoff from the fields, when rainfall amounts are greater than the infiltration capacity of soils, and subsurface inputs of shallow groundwater from beneath the fields. Lateral inflows of shallow groundwater through the banks and bottom of the ditches can occur during parts of the year when high water-table conditions are present beneath the fields. In fields with subsurface tile drains, shallow groundwater intercepted and collected by the tiles at the top of the water table is discharged through outlets directly to the ditches.

These drainage improvements lower the water table beneath agricultural fields, which increases the amount of land available for cultivation; however, the process of redirecting shallow groundwater beneath agricultural fields through tile drains and ditches can increase nutrient transport, particularly nitrate, in drainage water exiting the fields to receiving streams (David and others, 1997; Jaynes and others, 2001; Randall and Mulla, 2001; Harden and Spruill, 2004). As previously discussed, elevated nitrate concentrations in shallow groundwater beneath agricultural fields have commonly been observed in the Coastal Plain, especially at fields receiving land applications of animal-waste manures. A study by Harden and Spruill (2004) on the quality of drainage water from field ditches and tile drains in a North Carolina Coastal Plain watershed found that median concentrations of nitrate as N were significantly higher in water exiting field ditches (8.2 mg/L) and tile drains (32.0 mg/L) at fields receiving applications of swine-waste manures as compared to field ditches (2.7 mg/L) and tile drains (6.8 mg/L) at fields receiving applications of commercial fertilizers.

Because field ditches and tile drains are used to expedite the drawdown of the water table, they can allow groundwater with elevated nitrate levels in the upper part of the surficial aquifer beneath agricultural fields to bypass natural organic-rich aquifer sediments in the riparian buffer and hyporheic zones that normally would reduce the amount of nitrate in groundwater discharging to the streams (Spruill, 2000; Harden and Spruill, 2008). Considering that most watersheds examined for this study have substantial riparian buffer zones and organic-rich floodplain deposits and, hence, a high degree of denitrification potential prior to groundwater discharge, it is probable that overland inputs of water through field drainage ditches contribute much of the nitrate delivered to the stream sites. Overland transport through the field ditches can occur anytime there is excessive runoff from storm events but is most common during sustained periods of high water-table conditions, which typically occur during the colder winter and early spring months, generally from December to April, when evapotranspiration is lowest.

Methods

This section provides a discussion of the network design and watershed attributes compiled for the study sites, and the sampling and analytical methods used for generating the water-quality dataset. Statistical methods used during data analysis also are discussed.

Network Design and Watershed Attributes

An integrated approach was used for establishing the network of surface-water sampling sites for the study. Three general watershed land-use types, or groups, were included: watersheds with no active CAFOs (referred to as background (BK) sites); watersheds with one or more active swine CAFOs but no poultry CAFOs (referred to as SW sites); and watersheds with at least one active swine CAFO and one active poultry CAFO (referred to as SP sites). Although the initial study intent was to evaluate potential influences of swine CAFOs, it was difficult to find swine only watersheds across the study area that did not also contain poultry CAFOs. Therefore, the SP sites were included to provide data for additional watersheds containing swine CAFOs, as well as for examining potential differences between swine only sites and sites with both swine and poultry. Watersheds that contained only poultry CAFOs were not considered because it was outside the scope of work for this study.

The stream sites selected for study include an equal number (18) representing each of the BK, SW, and SP watershed land-use types (table 1; fig. 2) that also had similar distributions in watershed characteristics such as drainage areas and land cover. These 54 watershed sites are referred to as primary study sites because they were the primary focus of data-collection activities for the 6 bimonthly sampling periods from June 2012 to April 2013. The April 2013 sampling period included collection of surface-water samples from 23 additional sites, referred to as secondary sites, located within 9 of the primary watershed sites (table 1). One or more secondary sites were sampled upstream from the primary sites to provide additional water-quality data for stream sites located close or adjacent to swine CAFOs and (or) in subwatershed areas with no swine CAFOs. The study network spanned six river basins throughout the Coastal Plain in eastern North Carolina (table 1; fig. 2). Individual maps for the primary and secondary sites are provided in appendix A1 (figs. A1-1 through A1-54).

All study watersheds have than less than 10 percent developed (urban) lands, and none contain permitted NPDES wastewater-discharge facilities. Therefore, agricultural activities represent the most likely source of nutrients to the streams. The watersheds without CAFOs (BK sites) and with CAFOs (SW and SP sites) all contain agricultural lands where commercial fertilizers are used during the production of crops. The water-quality constituents analyzed in stream samples collected during the study include those essential primary nutrients (N, P, and potassium) and secondary nutrients (calcium, magnesium, and sulfur) found in commercial fertilizer materials commonly used in North Carolina for growing crops (Zublena and others, 1991; Tucker, 1999). These same essential plant nutrients, as well as sodium and chloride, are found in swine and poultry organic waste manures (Zublena and others, 1991, 1997a, 1997b; Barker and others, 1994; Osmond and Kang, 2008). Land applications of swine-waste manure and poultry litter represent an additional source of these constituents to agricultural fields in the SW and SP watersheds. Because watershed characteristics are similar among the three site groups, with the exception of the presence or absence of CAFOs, differences in stream concentrations of nutrients and (or) major ions observed at the SW and SP sites relative to the BK sites likely reflect inputs derived from swine and (or) poultry animal-waste manures.

Watershed boundaries and contributing drainage areas for the study sites were determined using the USGS StreamStats application developed for North Carolina (http://water.usgs.gov/osw/streamstats/north_carolina.html; Weaver and others, 2012). These features were calculated within StreamStats using a 30-foot (ft) by 30-ft lidar-derived digital elevation model (North Carolina Floodplain Mapping Program, 2012). Watershed drainage areas range from 1.2 to 17.5 mi^2 for the 54 primary sites and 0.2 to 8.9 mi^2 for the 23 secondary sites.

Data were compiled for selected watershed attributes to characterize environmental conditions at the study sites. Physical (land cover and soil drainage) and anthropogenic features (point-source dischargers, non-discharge land application sites, and CAFOs) were compiled using geographic information system (GIS) processes. The 54 primary sites were chosen to avoid or minimize potential influences of wastewater-discharge facilities, non-discharge facilities, and developed lands in order to facilitate water-quality interpretations between the watersheds with and without CAFOs.

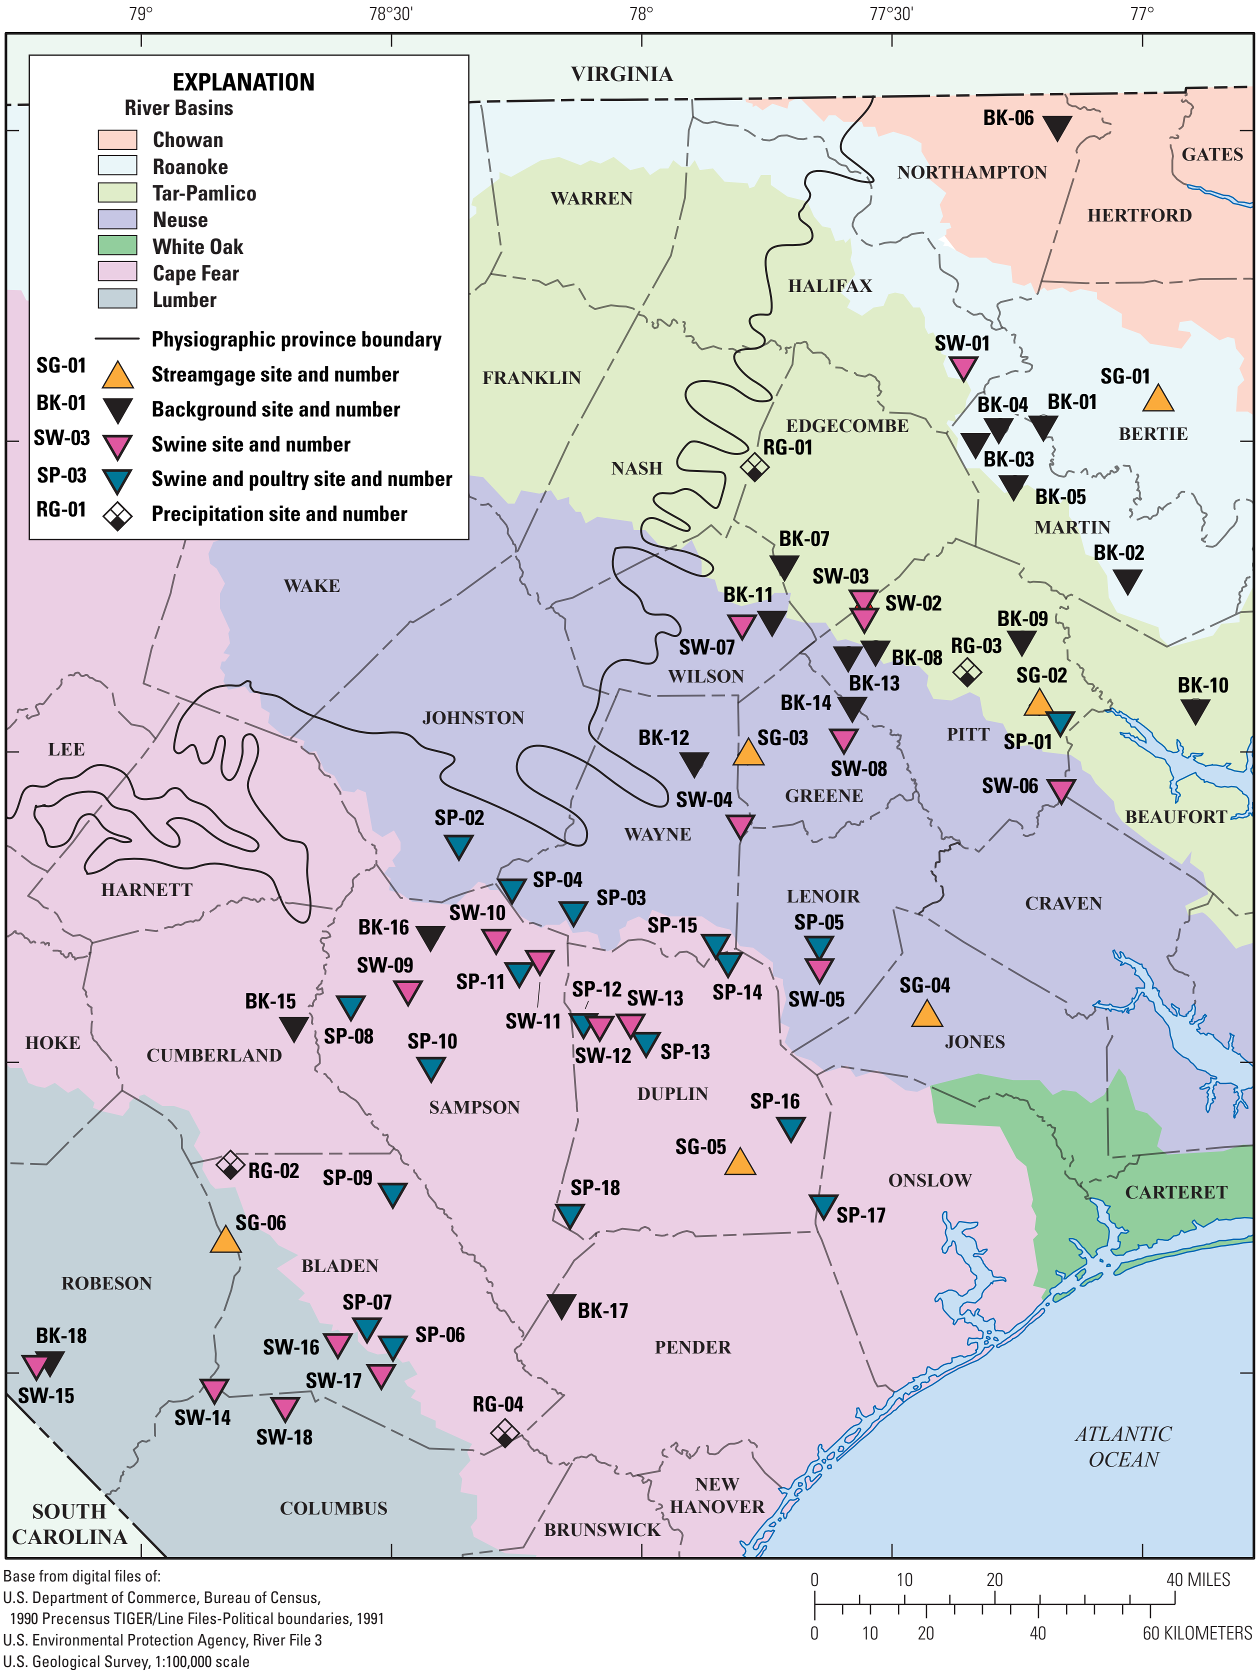

Figure 2. Locations of background, swine, and swine and poultry study sites, streamgage sites, and precipitation sites in the North Carolina Coastal Plain study area.

Land Cover and Hydrologic Soil Groups

Watershed attributes for land cover and hydrologic soil groups (HSGs) were compiled using StreamStats. Land-cover information was derived from the 2006 National Land Cover Database (NLCD) (Fry and others, 2011), which includes 15 individual land-cover classes. These 15 individual land-cover classes were aggregated into 8 principal land-cover categories (developed, forested, shrub, crops, grassland, wetlands, barren, and water), which were summarized for each watershed (appendix A2-1).

The study sites contain HSGs with varying degrees of soil drainage capacity. Data used to characterize the distribution of HSGs within the study sites were obtained through the U.S. Department of Agriculture Soil Survey Geographic Database (Soil Survey Staff, Natural Resources Conservation Service, n.d.). The areal extent and relative percentage for the four major HSGs (A, B, C, and D) and three dually classified HSGs (A/D, B/D, and C/D) were determined within the watershed of each site (appendix A2-2). Soils in HSGs A and B have low to moderately low runoff potential when thoroughly wet. Soils in HSGs C and D have moderately high to high runoff potential when thoroughly wet. Thus, soils in HSGs A and B have a higher degree of drainage, or water infiltration, as compared to soils in HSGs C and D, which are more poorly drained.

The dual hydrologic groups represent wet soils that were naturally classified as very poorly drained (HSG D) because of the presence of a water table within 2 ft of the land surface (U.S. Department of Agriculture, Natural Resources Conservation Service, 2009). If enhanced drainage measures, such as field ditches and subsurface tile drains, are used to maintain the seasonal high water table at least 2 ft below the surface, then the soils are characterized by the first letter of the dual groups (A/D, B/D, or C/D) on the basis of their saturated hydraulic conductivity and depth of the water table when drained (U.S. Department of Agriculture, Natural Resources Conservation Service, 2009). For this study, the data compiled for dual HSGs A/D, B/D, and C/D are assumed to represent drained soil conditions and were summed with their respective major HSGs to yield HSG total A, HSG total B, and HSG total C (appendix A2-2).

Wastewater Discharge Facilities and Non-Discharge Facilities

Information on NPDES-permitted wastewater-discharge facilities and permitted non-discharge facilities was provided by DWR (Michael Tutwiler, North Carolina Division of Water Resources, written commun., April 2012). Wastewater-discharge facilities that were considered included NPDES-permitted major municipal, minor municipal, major industrial/commercial, and 100 percent domestic discharge facilities. Harden and others (2013) previously indicated that point-source contributions of nutrients from wastewater-discharge facilities can have a significant influence on watershed nutrient yields in North Carolina. GIS analyses were used to map the locations of the discharge facilities in the Coastal Plain study area and to verify that none of the sites selected for study contained permitted dischargers.

GIS analyses also were performed to determine whether any permitted non-discharge facilities, which include wastewater irrigation, infiltration, or reclamation systems and land application of residual solids, were associated with the study sites. Only 2 of the 54 sites (SW-07 and SP-09) were found to have associated non-discharge facilities (appendix A3-1). Site SW-07 (appendix fig. A1-25) contains one residual solids land-application field, and site SP-09 (appendix fig. A1-45) contains two residual solids land-application fields. Any potential effects of these residual solids application fields on the water-quality results obtained at sites SW-07 and SP-09 are considered minimal and are not discussed in this report.

CAFOs

Available information on permitted CAFOs, including swine, cattle, and wet-poultry operations, was provided by DWR (Keith Larick, North Carolina Division of Water Resources, written commun., April 2012). All permitted CAFOs located in the 54 primary watersheds were mapped using GIS processes. The subgroups of the BK, SW, and SP study sites were operationally defined on the basis of the absence or presence of permitted active swine CAFOs located within the watersheds. None of the sites contained permitted cattle or wet-poultry CAFOs. Dry-litter poultry CAFOs, which are not required to have permits, were present in the SP watersheds.

Swine CAFO Attributes

Attribute data for the swine CAFOs were based on available information for facilities having either an active or inactive State of North Carolina permit. Swine CAFOs with active permits represent those facilities with ongoing swine production and field applications of swine-waste manure from the storage lagoons. Swine CAFOs with inactive permits represent former swine production facilities that are no longer operational. The inactive facilities currently have no swine animals or ongoing disposal of waste manure in application fields; however, remnant infrastructure, including barns and (or) inactive lagoons, may still be located at some of these facilities. The GIS analyses indicated that 10 of the study sites have 1 or 2 inactive-swine permits (appendix A3-2). Other than the permit numbers and locations, no other data were available for these inactive CAFOs. The active CAFOs, with ongoing waste-manure applications, are considered to have a more pronounced influence than the inactive CAFOs on water-quality conditions at the sites. Given the lack of information available for the inactive CAFOs, data evaluations conducted during the study focused on the permitted active swine CAFOs; the permitted inactive swine CAFOs were not considered further.

Several steps were taken in compiling attribute data for the active swine CAFOs. All active swine CAFOs within or along the boundaries of the 18 SW and 18 SP watershed sites were identified. Data provided by DWR for each active swine CAFO included information on the regulated swine activity, number of available acres for applying manure, amount of allowable plant available nitrogen (PAN), amount of generated PAN, and whether tile drains have been documented at the CAFO (appendix A3-3).

The regulated swine activity includes the type of swine production at the facility as well as the maximum annual average number of swine that can be produced. Seven types of swine production are associated with the CAFOs (Keith Larick, North Carolina Division of Water Resources, written commun., April 2012; table 2). Although multiple swine production activities are noted for some CAFOs, most produce only one type of swine. The average weight of swine produced and, consequently, the amount of waste manure generated by the swine population at a given CAFO depend on the type(s) of swine production at the facility. The maximum annual average number of swine (appendix A3-3) was multiplied by its respective average swine weight (table 2) to compute a total swine weight by production type. The number of swine and swine weights for all production types were summed to yield the total swine and total swine steady state live weight (SSLW) for each active CAFO.

The number of available acres listed for each active CAFO represents the total field acreage available at the facility for applying swine-waste manure (appendix A3-3). For a given facility, the amount of field acreage used for waste-manure applications during a given year may be lower than available. No information on the frequency and timing of applications or individual fields used was readily available for the CAFOs. The reported values for allowable PAN represent the maximum permitted amount of PAN that can be field applied annually at each CAFO. The reported values for generated PAN represent the calculated amount of PAN generated in waste manure that was field applied during 2012 at each CAFO (Keith Larick, North Carolina Division of Water Resources, written commun., July 2013). Ideally, the amount of generated PAN will be less than its allowable PAN on an annual basis such that the facility is not applying more PAN than allowed based on its permit.

Table 2. Swine production type and average swine weight associated with concentrated animal feeding operations in the study area.

Swine production type	Average weight of swine by production type (pounds)
Gilts	150
Wean to feeder	30
Wean to finish	115
Feeder to finish	135
Farrow to wean	433
Farrow to feeder	522
Farrow to finish	1,417

Qualitative information on the documented presence of tile drains at the CAFOs (appendix A3-3) was based on those either reported by the facility operator or identified by DWR facility inspectors; however, no specific information was available on the number or locations of documented tile drains at the facilities. Although there are no documented tile drains for some CAFOs, this may not be completely accurate because there are likely tile drains located at some facilities, the existence of which is unknown, and these would have gone unreported. The tile drain data are provided for informational purposes and are not considered to accurately reflect the extent to which subsurface tile drains may or may not be associated with the swine CAFO waste-manure application fields in the SW and SP study sites.

Available orthoimagery in Google Earth (http://www.google.com/earth/; accessed May 2012) was visually examined to identify the total number of lagoons and swine barns associated with each active swine CAFO and, of these, how many of the lagoons and barns were located within the watershed boundaries (appendix A3-3). Some of the CAFOs were located along the watershed drainage boundaries and, under these circumstances, overland runoff and groundwater flow from those facilities may be transported toward receiving streams both within and outside of the study watersheds. In these cases, the permit attribute data associated with CAFOs situated along the drainage boundaries were adjusted with a correction factor to allocate that fraction of the data deemed to be associated within the study sites (appendix A3-3). Where needed, the correction factor used to adjust the attribute data generally was taken as the ratio of swine barns located within the watershed to the total swine barns associated with the CAFO.

Attributes for the individual swine CAFOs, which reflect adjustments applied for total swine, total swine weight, available acres, PAN allowed, and PAN generated, are provided in appendix A3-4. This information was used to compute the total number of active swine CAFOs, lagoons, swine barns, swine animals and weight, available acres, allowable PAN, and generated PAN within each of the SW and SP watershed sites (appendix A3-5). Total watershed densities per square mile of swine barns, swine animals, swine weight (in tons), and available acres were determined as additional parameters for each site for use in evaluating the water-quality data.

Poultry CAFO Attributes

Available orthoimagery in Google Earth (http://www.google.com/earth/; accessed May 2012) was visually examined to identify apparent dry-litter poultry CAFOs and their associated number of poultry barns located within each watershed of the study sites. The SP sites were the only study sites determined to have one or more apparent dry-litter poultry CAFOs; these sites also contain one or more permitted active swine CAFOs. The apparent dry-litter poultry CAFOs were visually distinguished from the documented swine CAFOs on the basis of the presence of waste-storage lagoons at the permitted swine facilities and the absence of any waste-storage lagoons at the dry-litter poultry facilities. For verification purposes, a list of the apparent dry-litter poultry CAFOs identified for the 18 SP sites was provided to DWR for subsequent review by the North Carolina Department of Agriculture and Consumer Services, which indicated that the apparent dry-litter poultry CAFOs identified during this study were indeed active poultry facilities (Keith Larick, North Carolina Division of Water Resources, written commun., November 2012). No specific information on the operational characteristics (such as types and numbers of poultry raised, manure applications, or years of operation) for the dry-litter poultry CAFOs was publicly available for use in this study. Hereafter, the dry-litter poultry CAFOs at the study sites will be referred to as poultry CAFOs.

For this study, each cluster of poultry barns identified at the SP sites was considered to represent an individual poultry CAFO. Spatial coordinates and number of barns for the poultry CAFOs are provided in appendix A3-6. Each poultry CAFO was assigned a unique identifier, or field number, for use in this study. In some cases, adjacent poultry barn clusters may actually be part of the same operation. Similar to the process described previously for the swine CAFOs, in those cases where a poultry CAFO was located along the watershed drainage boundary, a prorated number of poultry barns was assigned to the CAFO to represent that fraction of the facility deemed to be within the watershed. The compiled information for the individual poultry CAFOs (appendix A3-6) was used to compute the total number of poultry CAFOs and poultry barns, as well as poultry barn density (barns per square mile), for each SP study site (appendix A3-7).

Data Collection

This section outlines procedures that were used to compile precipitation and streamflow monitoring data for examining hydrologic conditions in the study area. Sample collection procedures, laboratory analyses, and data quality-assurance practices are described for the water-quality data.

Precipitation and Streamflow

Precipitation data were obtained from four active USGS raingage monitoring stations (sites RG-01 through RG-04; table 3) in the Coastal Plain study area (fig. 2). Precipitation was measured at each site by using a tipping-bucket raingage that recorded precipitation at 15-minute intervals. Calibration checks were conducted semiannually on the raingages to ensure the accuracy of recorded data (U.S. Geological Survey, 2006). Precipitation data for sites RG-01, RG-02, RG-03, and RG-04 (table 3) are available from the USGS National Water Information System (NWIS) database (http://waterdata.usgs.gov/nc/nwis).

The precipitation data were used to better understand the extent to which each sampling date during the surface-water sampling periods was preceded by relatively wet or dry climatic conditions. For each raingage site, a cumulative total precipitation was computed for the 7-day period immediately preceding each date that samples were collected. Minimum, maximum, and mean values of the cumulative 7-day precipitation totals for the four raingage sites were determined for each sampling date for use in data analysis.

Ideally, instantaneous stream discharge would be measured to document streamflow conditions at the time water-quality samples are collected. However, the typical site conditions encountered during this study included low streamflow velocity coupled with varying degrees of submerged and floating aquatic vegetation within and along the stream channel. These conditions made it impractical to measure stream discharge during sample collections. Therefore, streamflow data were obtained from six active USGS streamgaging stations (sites SG-01 through SG-06; table 4) in the Coastal Plain study area (fig. 2) to describe regional hydrologic conditions during sampling periods. Streamflow data for the streamgage sites (table 4) are available from the USGS NWIS database (http://waterdata.usgs.gov/nc/nwis).

Water-Quality Samples

Water-quality data compiled for the study include the analytical results for precipitation samples and surface-water samples. Precipitation samples were collected at raingage monitoring sites RG-01 and RG-02 from late July 2012 to early April 2013 for laboratory analyses. In this study, separate USGS station numbers are used for the precipitation water-quality data and the continuous rainfall data collected at monitoring stations RG-01 and RG-02 (table 3). The precipitation collectors were deployed for periods ranging from 2 days to 2 weeks to capture one or more rainfall events. The length of each deployment was based on the frequency and magnitude of rainfall events and the overall amount of rain that could be captured without overfilling the collection container. Clean sampling equipment was used for each deployment. Samplers were not deployed during periods of extreme cold to avoid freezing, which could compromise the analytical results.

Surface-water samples were collected at the 54 primary and 23 secondary study sites (table 1) for laboratory analyses. Samples at the primary sites were collected during six rounds of bimonthly sampling, during June, August, October, and December 2012, and February and April 2013. Samples were collected at the secondary sites once during the April 2013 sampling round. The number of days needed to collect samples during each round ranged from 3 to 6.

Water temperature, specific conductance, pH, DO, and barometric pressure were measured in the field during sample collections using instruments that were calibrated daily prior to sampling. Established, documented protocols were followed for collecting and processing samples for chemical analyses (U.S. Geological Survey, variously dated). Non-isokinetic methods were used for collecting samples because streamflow velocities generally were low. Samples were collected at the mid-depth of the water column at one or more points across the stream, depending on the stream width and type of road crossing (bridge or culverts). Subsamples collected from multiple points were composited into a single sample, representing the stream cross section.

Field equipment was cleaned between sampling sites (U.S. Geological Survey, variously dated). Samples were filtered and preserved in the field. A disposable 0.45-micron (µm) pore size capsule filter was used to process samples for major ions and filtered nutrient fractions. Samples collected for the determination of nitrogen-15/nitrogen-14 ($^{15}N/^{14}N$) and oxygen-18/oxygen-16 ($^{18}O/^{16}O$) isotopic ratios of nitrate plus (+) nitrite were filtered twice, first with a 0.45 µm capsule filter followed by a 0.20 µm disc filter, and subsequently frozen to prevent microbial degradation prior to laboratory analysis.

Nutrients and Major Ions

Surface-water samples were shipped to the USGS National Water Quality Laboratory (NWQL) in Lakewood, Colorado, for chemical analysis of nutrients and major ions. Methods and reporting levels (RL) for each measured analyte (table 5) remained consistent for all samples analyzed during the study. Unfiltered samples were analyzed for concentrations of total ammonia+organic N and total P. Filtered samples were analyzed for concentrations of dissolved ammonia, dissolved nitrate+nitrite, and dissolved orthophosphate (ortho-P). Filtered samples also were analyzed to determine concentrations of dissolved calcium, chloride, magnesium, potassium, sodium, and sulfate.

The water-quality data for the surface-water samples are presented in appendix A4-1. One dataset includes water-quality results for all samples collected at the primary sites. The second dataset includes results for samples collected during the April 2013 sampling at the 9 primary sites and their 23 secondary sites. Analytical concentrations for the nitrogen species are reported in milligrams per liter as N and concentrations for ortho-P and total P are reported in milligrams per liter as P. The water-quality data also are available from the USGS NWIS database (http://waterdata.usgs.gov/nc/nwis).

Values for total organic N and total N (appendix A4-1) were computed from three directly measured nitrogen fractions (table 5). Total organic N was computed by subtracting dissolved ammonia from total ammonia+organic N. Total N was computed by summing total ammonia+organic N and dissolved nitrate+nitrite. If one of the underlying constituents used in computing total organic N or total N had a left-censored (<) value, then the < remark code was carried forward with the computed value. Although the < remark codes were carried forward with the total organic N and total N, they were ignored for the purpose of data evaluations in this study because the censoring levels associated with dissolved ammonia (RL = 0.010 mg/L) and dissolved nitrate+nitrite (0.04 mg/L) have minimal influence on the calculated values for total organic N and total N, respectively. Thus, examinations of the total organic N and total N data were based on the concentrations as reported in appendix A4-1 without regard to any < remark codes associated with the computed values. It is of note that, by default, total organic N and total N concentrations retrieved from the NWIS database retain the < remark code if one of the underlying constituents is left-censored. The handling of censored data is left to the discretion of data users.

Table 5. Nutrients and major ions measured in surface-water samples.

[N, nitrogen; P, phosphorus; mg/L, milligram per liter; EPA, U.S. Environmental Protection Agency; APHA, American Public Health Association]

Analyte	Reporting level, in mg/L	Analytical reference
Nutrients		
Ammonia as N, dissolved	0.010	Fishman (1993)
Ammonia + organic nitrogen as N, total	0.07	Patton and Truitt (2000)
Nitrate + nitrite as N, dissolved	0.04	Patton and Kryskalla (2011)
Orthophosphate as P, dissolved	0.004	Fishman (1993)
Phosphorus as P, total	0.004	USEPA (1993)
Major ions		
Calcium, dissolved	0.022	Fishman (1993)
Chloride, dissolved	0.06	Fishman and Friedman (1989)
Magnesium, dissolved	0.011	Fishman (1993)
Potassium, dissolved	0.03	APHA (1998)
Sodium, dissolved	0.06	Fishman (1993)
Sulfate, dissolved	0.09	Fishman and Friedman (1989)

Stable Isotopes

Surface-water and precipitation samples were shipped to the USGS Reston Stable Isotope Laboratory (RSIL) in Reston, Virginia, for analysis of stable isotopes by using a continuous flow isotope-ratio mass spectrometer. Surface-water samples were analyzed for stable isotope ratios of water (hydrogen-2/hydrogen-1 [$^2H/^1H$] and $^{18}O/^{16}O$) and (or) stable isotope ratios of dissolved nitrate+nitrite ($^{15}N/^{14}N$ and $^{18}O/^{16}O$). Precipitation samples were analyzed for stable isotope ratios of water ($^2H/^1H$ and $^{18}O/^{16}O$).

Stable isotope ratios are reported using the delta (δ) notation in units of parts per thousand (denoted as per mil or ‰) relative to a standard of known composition according to the following equation:

$$\delta\ (‰) = (R_{samp}/R_{stand} - 1) * 1{,}000 \qquad (1)$$

where R_{samp} and R_{stand} are the ratios of the heavy to light isotope ($^2H/^1H$, $^{18}O/^{16}O$, or $^{15}N/^{14}N$) in the sample and standard, respectively.

Stable isotopes of water (δ^2H and $\delta^{18}O$) were analyzed in surface-water samples collected at the primary sites (appendix A4-1) and in precipitation samples collected at sites RG-01 and RG-02 (appendix A4-2) following methods outlined in Révész and Coplen (2008a, b). Results for δ^2H and $\delta^{18}O$ of water are reported with a 2-sigma (σ) uncertainty of ±2 ‰ and ±0.2 ‰, respectively. Analysis of stable isotopes of dissolved nitrate+nitrite ($\delta^{15}N$ and $\delta^{18}O$) in surface-water samples was based on the microbial denitrifier method (Sigman and others, 2001; Casciotti and others, 2002; Coplen and others, 2012). Measurements of $\delta^{15}N$ and $\delta^{18}O$ of dissolved nitrate+nitrite generally were performed on samples for the primary and secondary study sites with nitrate+nitrite concentrations greater than or equal to the RL of 0.04 mg/L (appendix A4-1). The $\delta^{15}N$ and $\delta^{18}O$ results are reported with 2-σ uncertainties of ±0.5 ‰ and ±1.0 ‰, respectively, when analyzed samples had nitrate+nitrite concentrations greater than or equal to 0.06 mg/L as N; the uncertainties are doubled for samples with nitrate+nitrite concentrations less than 0.06 mg/L as N.

An important issue to note regarding $\delta^{18}O$ analyses with the denitrifier method is that the $\delta^{18}O$ values generated for combined nitrate+nitrite may be underestimated if samples contain appreciable amounts of nitrite, yet the nitrite contributions to the $\delta^{18}O$ results are not taken into account (Casciotti and others, 2007). When available, measured concentrations of nitrite are used to make applicable corrections to the $\delta^{18}O$ results (Casciotti and McIlvin, 2007; Casciotti and others, 2007). In this study, however, samples were analyzed for combined nitrate+nitrite concentrations rather than individual concentrations of nitrate and nitrite. Therefore, the $\delta^{18}O$ values of nitrate+nitrite reported in appendix A4-1 may underestimate actual values. The extent to which the results may have been biased by unaccounted-for nitrite in the samples is unknown.

Although nitrite concentrations were not determined for samples collected during this study, nitrite typically constitutes a relatively small amount (<10 percent) of the overall nitrate+nitrite observed in streams in the North Carolina Coastal Plain. With nitrite likely representing less than 10 percent of the measured nitrate+nitrite in the study samples, the potential low bias associated with the $\delta^{18}O$ values determined for nitrate+nitrite should be relatively muted. The presence of unrecognized nitrite in samples with the lowest concentrations of nitrate+nitrite (near the analytical RL of 0.04 mg/L) would likely have the most pronounced bias on the nitrate+nitrite $\delta^{18}O$ results. Therefore, evaluations of the stable isotope data ($\delta^{15}N$ and $\delta^{18}O$) for dissolved nitrate+nitrite in this study were focused on those samples having nitrate+nitrite concentrations greater than or equal to 0.100 mg/L in an effort to reduce the potential uncertainties associated with the nitrate+nitrite $\delta^{18}O$ results.

Quality Assurance

Quality-control samples, including field blanks and replicate samples, were collected to document potential bias and variability in data that may result during the collection, processing, shipping, and handling of environmental samples (U.S. Geological Survey, variously dated). Field blanks were collected using inorganic-free water processed in the field with the same equipment used for the environmental samples. Field blanks help to identify contamination resulting from improperly cleaned equipment, field sampling activities and exposure, and laboratory practices. Overall, the results of the field blanks did not indicate any systematic or substantial quality-assurance issues with the environmental data. Replicate samples were collected to help document the variability in data results associated with sample collection, processing, and laboratory analysis. No quality-assurance problems were identified for the environmental dataset based on the replicate samples.

A total of 26 field blanks (appendix A4-3) and 26 replicate samples (appendix A4-4) were collected during surface-water sampling. One replicate sample was obtained during the collection of precipitation samples at site RG-02. Approximately 13 percent of the total number of samples collected during the study were quality-control samples. All surface-water blank and replicate samples were analyzed for nutrients and major ions. Stable isotopes of water (δ^2H and $\delta^{18}O$) were measured in replicate samples collected at the primary study sites and in the one precipitation replicate. Stable isotopes of nitrate+nitrite ($\delta^{15}N$ and $\delta^{18}O$) were measured in most surface-water replicate samples having detectable concentrations of nitrate+nitrite above the RL of 0.04 mg/L.

Most constituents were below analytical RLs in the field blanks (appendix A4-3). Magnesium, sodium, potassium, and sulfate were not detected in any blank samples. Concentrations of calcium and chloride in one blank sample (0.037 and 0.11 mg/L, respectively) were an order of magnitude lower than calcium and chloride concentrations measured in environmental samples (appendix A4-1). For nutrients, ortho-P was not detected in any blanks. Nitrate+nitrite was detected in one blank sample at a concentration (0.070 mg/L) just above the RL of 0.040 mg/L. Total phosphorus was also detected in one blank sample at a concentration (0.005 mg/L) just above the RL of 0.004 mg/L. Ammonia+organic N was detected in about 12 percent of the blank samples (3 of 26) at concentrations of 0.08 to 0.14 mg/L; however, there was no indication of systematic bias that would affect the environmental results. All ammonia+organic N concentrations measured for the environmental samples (appendix A4-1) exceeded the greatest concentration of 0.14 mg/L detected in the blank samples (appendix A4-3).

Ammonia was detected in about 27 percent of the blank samples (7 of 26) at concentrations of 0.011 to 0.020 mg/L. Blank samples frequently may become contaminated with ammonia when exposed to the atmosphere—both in the field and laboratory (Fishman, 1993). This is especially apparent when blanks are analyzed using low-level techniques, as was done in this study. Although some low-level contamination of ammonia may have occurred, any effects on the environmental data are considered minimal. Of the 344 total environmental samples, 319 had concentrations of ammonia above the analytical RL of 0.010 mg/L (appendix A4-1). Approximately 89 percent of these samples (283 of 319) had ammonia concentrations that exceeded the highest ammonia concentration of 0.020 mg/L detected in the blank samples (appendix A4-3). In addition, 75 percent of the samples (241 of 319) had ammonia concentrations greater than 0.040 mg/L, more than twice the highest concentration of 0.020 mg/L detected in the blanks.

Replicate samples were used to assess the overall precision of the entire sample collection, handling, and analysis approach. A statistical summary of the relative percent difference (RPD) determined for each analyte for all paired environmental and replicate samples is provided in table 6. The RPDs in analyte concentrations rarely exceeded 15 percent. Exceedances above 15 percent were limited to one or two replicate sample pairs for sulfate, nitrate+nitrite, total P, and $\delta^{18}O$ of nitrate+nitrite. The mean and median RPDs were less than about 5 percent for all the measured constituents (table 6), which indicates very good agreement between the environmental and replicate samples.

Prior to data analysis, the water-quality data (appendix A4-1) were reviewed to identify any obvious outliers or potential issues in the sample results. Site SW-02 was noted to have the highest measured values for specific conductance and the major ions, by up to an order of magnitude, among any of the study sites (appendix A4-1). Nutrient results for site SW-02 were similar to the other study sites. Site SW-02 contains both one small swine CAFO (1 barn with 4,330 swine) and a granite quarry in the headwater area of the watershed (appendix fig. A1-20). The very high ion concentrations for site SW-02 are suspected of being influenced by mining activities associated with the quarry; therefore, the results for specific conductance, calcium, magnesium, sodium, potassium, chloride, and sulfate for this site were excluded from data analyses in this report. Results for the August 26, 2012, sample collected at site BK-01 (appendix A4-1) were excluded from data evaluations because they were considered to be influenced by backwater conditions from the adjacent Roanoke River (appendix fig. A1-1) when storm runoff increased river levels by about 8 ft between August 25–26, 2012. In addition, the $\delta^{2}H$ and $\delta^{18}O$ isotopic results for sites BK-17 (appendix fig. A1-17) and SW-11 (appendix fig. A1-29), which were influenced by upstream impoundments, were considered atypical and also were excluded from the data evaluations.

Table 6. Statistical summary of relative percent differences in analyte concentrations for the environmental and replicate sample sets.

[RPD, relative percent difference; %, percent; N, nitrogen; P, phosphorus; δ, delta]

Analyte	Number of paired replicate samples[1]	Statistical measure: Minimum RPD (%)	Maximum RPD (%)	Mean RPD (%)	Median RPD (%)
Calcium, dissolved	26	0.0	5.6	1.4	1.0
Magnesium, dissolved	26	0.0	5.7	1.3	1.2
Sodium, dissolved	26	0.0	4.6	2.0	1.9
Potassium, dissolved	26	0.0	8.3	2.7	2.2
Chloride, dissolved	26	0.0	1.8	0.3	0.0
Sulfate, dissolved	26	0.0	16.6	1.2	0.4
Ammonia + organic nitrogen as N, total	26	0.0	10.7	2.6	1.4
Ammonia as N, dissolved	22	0.0	5.6	1.8	1.1
Nitrate + nitrite as N, dissolved	19	0.0	18.6	5.3	1.9
Orthophosphate as P, dissolved	21	0.0	14.0	2.8	1.4
Phosphorus as P, total	26	0.0	35.0	4.1	1.4
δ Hydrogen-2 of water, dissolved	25	0.0	6.2	2.7	2.6
δ Oxygen-18 of water, dissolved	25	0.0	2.4	0.8	0.7
δ Nitrogen-15 of nitrate + nitrite, dissolved	18	0.2	10.8	1.6	0.7
δ Oxygen-18 of nitrate + nitrite, dissolved	18	0.0	28.8	3.8	1.5

[1]Relative percent differences were computed when both samples in a pair had concentrations above analytical reporting levels.

Statistical Analyses

Statistical evaluations of the study data included the use of analysis of variance (ANOVA) tests and pair-wise multiple-comparison tests (Helsel and Hirsch, 1992). One-way ANOVA tests were used to test for significant differences in watershed attributes, such as basin drainage area, among the three watershed land-use types (BK, SW, and SP). Two-way, or multifactor, ANOVA tests were used to test for significant differences in surface-water constituents on the basis of sampling period and (or) land-use type. Because most of the study data are non-normally distributed, a non-parametric approach was used in which the ANOVA tests were performed on rank-transformed data to assess differences between groups. The use of statistical analyses that rely on data ranks, rather than actual data values, also is appropriate for examining water-quality data containing left-censored "<" values when the < values for a given constituent are censored to the same analytical RL (Bonn, 2008). Left-censored values reported for ammonia, nitrate+nitrite, and ortho-P in surface-water samples (appendix A4-1) were set equal to their respective RLs prior to ranking the data for use in statistical analyses.

Constituent concentrations were ranked for all samples collected from the 54 primary study sites during the 6 sampling periods. A two-way ANOVA test was then performed on the ranks of the concentration data to test for differences based on the grouping (or explanatory) variables of sampling period (June, August, October, and December in 2012, and February and April in 2013) and land-use type (including the 18 BK, 18 SW, and 18 SP sites). By evaluating sampling period and land-use type simultaneously, the effect of one explanatory variable can be measured while compensating for the other. The test compares the mean ranks of the constituent concentrations in the treatment groups to the overall mean rank for the entire dataset and determines whether there is an influential effect based on sampling period, land-use type, and (or) the combined interaction between sampling period and land-use type.

The ANOVA results for a given constituent may indicate that a statistically significant difference in the mean ranks of the concentrations exists among a particular treatment group (such as land-use type); however, it does not specify which of the group treatments (such as BK, SW, and SP site types) are different. Those constituents with significant differences identified by the ANOVA tests were analyzed further with Tukey pair-wise multiple-comparison tests to identify which sampling period comparison pairs and (or) land-use type comparison pairs had statistically different means in their ranked values. The ANOVA and pair-wise multiple-comparison analyses, which were tested at the 95 percent confidence level ($P=0.05$), were conducted using the S-Plus software suite (by TIBCO Software Inc.).

Relations of environmental variables among study sites identified as either being influenced or not influenced by CAFO waste manures were modeled using classification tree analyses (Breiman and others, 1984). Classification tree-based modeling is an exploratory technique for uncovering structure in the data. The classification tree models evaluate the response variable, or defined category (such as sites without CAFO effects and sites with CAFO effects), and the associated predictor variables (such as environmental attributes) to identify the predictor variables that best partition, or split, the response variable into increasingly homogeneous subsets. The resulting classification tree is simplified (pruned) by removing splits that do not contribute to a reduction in model error. The classification tree analyses were conducted using the S-Plus software suite (by TIBCO Software Inc.).

Characterization of Watershed Settings and Hydrologic Conditions

Information compiled on land cover, hydrologic soil groups (HSGs), and CAFO attributes was used to examine watershed settings among the study sites. Regional information on precipitation and streamflows and measurements of stable isotopes of water in collected samples were used to characterize general hydrologic conditions during the six water-quality sampling periods.

Watershed Settings

Land cover, HSGs, and CAFO attributes (appendixes A2-1, A2-2, A3-5 and A3-7) for the primary study sites were evaluated to identify similarities or differences in watershed settings among the BK, SW, and SP site groups. Land cover and HSGs were examined among all three site groups. Attributes for swine CAFOs were examined only for the SW and SP groups. A statistical summary of watershed attributes in each site group is provided in table 7.

The overall results of the statistical analyses indicate that the general watershed settings of the study sites are comparable among the BK, SW, and SP site groups. The primary difference between the land-use groups is that the BK sites contain no CAFOs, the SW sites contain swine CAFOs, and the SP sites contain both swine and poultry CAFOs. ANOVA tests indicated few statistical differences in land cover and HSGs among the BK, SW, and SP site groups (table 8). Shrub land cover, HSG total A, and HSG D were the only watershed attributes that were significantly different ($P<0.05$) between some site groups. In addition, the ANOVA tests also did not identify any statistically significant differences ($P<0.05$) in any of the swine CAFO attributes examined between the SW and SP site groups (table 8). In other words, the SW and SP groups are similar with respect to swine CAFO attributes in the watersheds but differ in that poultry CAFOs also are present only in the SP watersheds (table 7).

Table 7. Statistical summary of watershed attributes by land-use type.

[n, number; mi^2, square mile; %, percent; CAFO, concentrated animal feeding operation; PAN, plant available nitrogen; SSLW, steady state live weight; na, not applicable]

Hydrologic Conditions During Sampling

Typical site conditions during sampling at most of the study sites included low streamflow velocity coupled with varying degrees of submerged and floating aquatic vegetation within and along the stream channel. Because of these conditions, it was not feasible to measure stream discharge at the study sites during sampling. Therefore, regional precipitation and streamflow data collected at active USGS monitoring stations (tables 3, 4; fig. 2), as well as δ^2H and $\delta^{18}O$ isotopic results for precipitation and stream samples, were used to assess general hydrologic conditions in the study area during the six sampling periods (June, August, October, and December in 2012, and February and April in 2013).

Precipitation

Regional precipitation measured during the study at the raingage monitoring sites (table 3; fig. 2) was slightly below normal levels. The annual precipitation recorded from May 1, 2012, through April 30, 2013, at raingage sites RG-01 (35.77 inches [in.]), RG-02 (40.49 in.), RG-03 (47.98 in.), and RG-04 (48.34 in.) has an average value of 43.14 in. Note that the annual values for RG-01 and RG-03 represent a lower limit because these sites had 17 days and 3 days, respectively, of missing data where precipitation was not recorded. The average annual precipitation is 45.60 in. if site RG-01 is excluded. Normal average annual precipitation in the study area, based on the 30-year period 1971–2000, ranges from about 46 to 52 in. (State Climate Office of North Carolina, n.d.).

Mean 7-day precipitation totals were used to document the differences in the amount of rainfall in the study area among the water-quality sampling periods (table 9; fig. 3). Overall, antecedent field conditions for the sampling periods were wetter for August and February, intermediate for June and April, and drier for October and December. It is important to note that for a given sampling event, there may have been considerable local differences in precipitation amounts among the study sites. For example, scattered thunderstorms occurred throughout the study area for the August period. The uneven distribution of precipitation is reflected by the higher standard deviations associated with the mean 7-day precipitation totals for August relative to the other sampling periods (table 9). The February sampling dates had mean 7-day precipitation totals similar to the August sampling dates, yet the lower standard deviations suggest that precipitation was more uniform across the study area during the February sampling event.

Table 9. Summary of the cumulative 7-day precipitation totals preceding each sample collection date based on raingage monitoring sites RG-01, RG-02, RG-03, and RG-04 (site locations in figure 2 and table 3).

Sample date	Number of primary study sites sampled	7-day precipitation total (inches)			
		Minimum	Maximum	Mean	Standard deviation
06/13/12	10	0.20	0.83	0.51	0.32
06/14/12	12	0.20	0.83	0.51	0.32
06/15/12	8	0.20	0.83	0.51	0.32
06/18/12	12	0.20	0.83	0.51	0.32
06/19/12	12	0.11	0.46	0.23	0.20

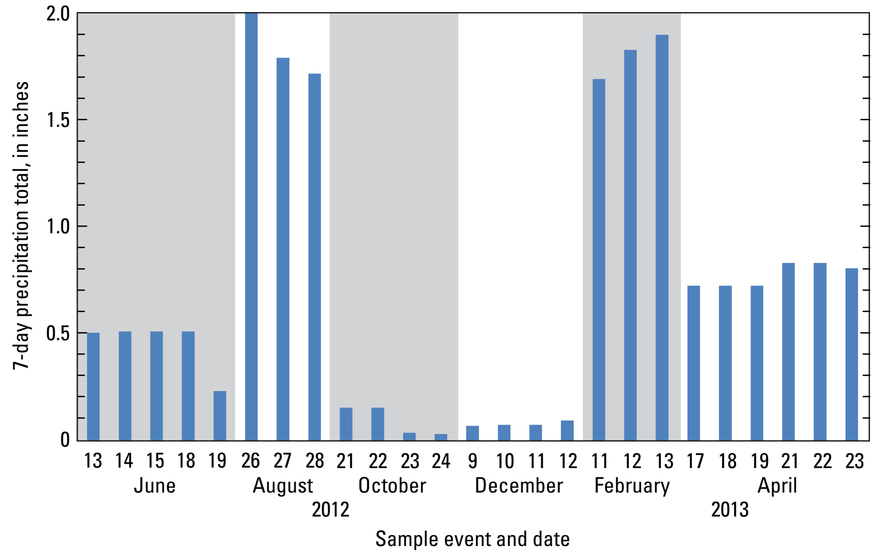

Figure 3. Mean cumulative 7-day precipitation totals preceding each sample collection date based on raingage monitoring sites RG-01, RG-02, RG-03, and RG-04 (site locations in figure 2 and table 3).

Streamflow

Relative differences in regional streamflow conditions during the water-quality sampling periods were inferred from streamflow records from six streamgage sites distributed throughout the study area (figs. 2, 4). The streamgage sites represent basin drainage areas ranging from 45 to 599 mi^2. Drainage areas for the primary study sites are considerably smaller, ranging from 1.2 to 17.5 mi^2. Although the magnitude of streamflow and the duration and timing of peak streamflows likely differ between the streamgage sites and the study sites, the hydrographs are useful indicators of relative streamflow trends throughout the study area during the sampling periods and the entire study period.

Streamflow conditions during most of the sampling periods were similar to or higher than historical streamflow conditions in the study area. Daily mean streamflows at the six streamgage sites during the study period (May 2012 through April 2013) are shown relative to long-term median daily mean streamflows for the 25-year period from May 1988 through April 2013 (fig. 4). In general, streamflows for the June, October, and April sampling periods were fairly similar to the long-term median values. Streamflows for the August and February periods tended to be substantially higher, and streamflows for the December period tended to be substantially lower relative to historical conditions.

Streamflow conditions varied among the six sampling periods (fig. 4). Compared to other sampling periods, streamflow conditions were relatively higher during the August and February sampling periods when precipitation amounts in the study area were higher (fig. 3) and overland transport of water to the streams was greater. The intermediate to lower streamflow conditions for the June, October, December, and April sampling periods reflect less precipitation and overland transport of water to the streams and a larger component of streamflow derived from groundwater compared to the August and February periods. The typically higher and more sustained stream-baseflow conditions (fig. 4) observed during the winter and early spring months (generally January to April) reflect greater groundwater discharge and likely higher inputs from field drainage ditches when the water table in the surficial aquifers is high. Variations in stream water quality at the study sites among sampling periods with higher versus lower relative streamflows may reflect relative differences in source contributions of water-quality constituents delivered through groundwater discharge and overland runoff.

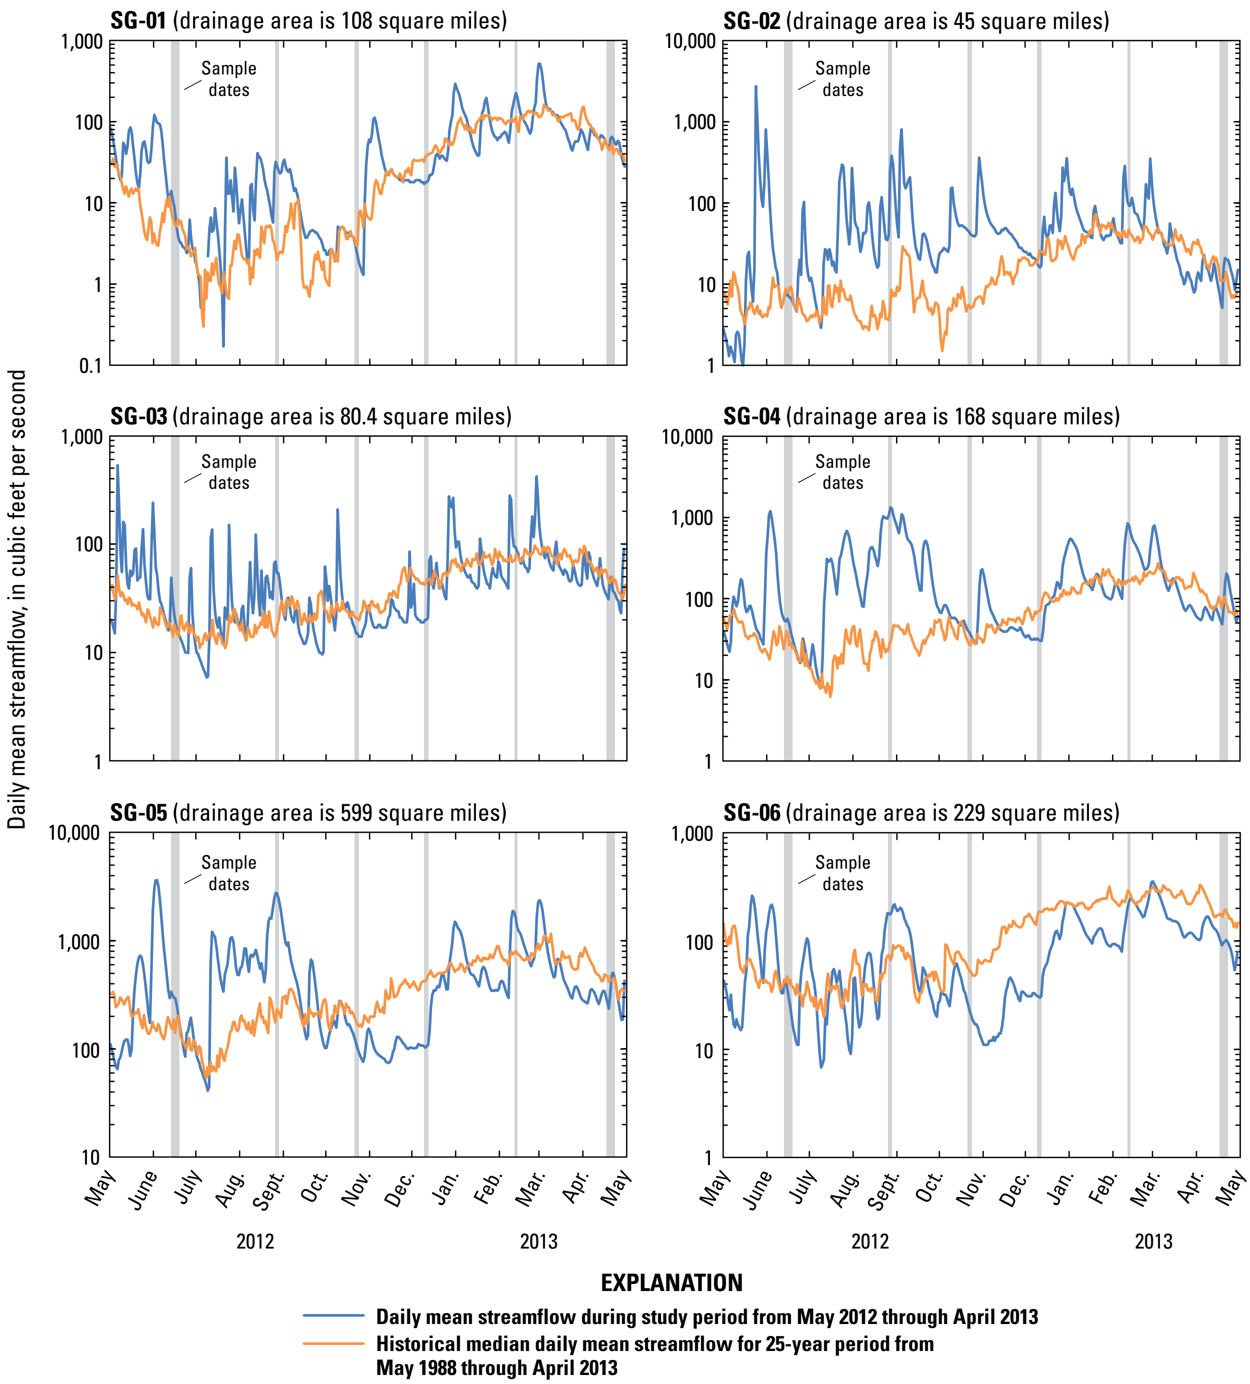

Figure 4. Streamflow hydrographs at sites SG-01, SG-02, SG-03, SG-04, SG-05, and SG-06 showing dates water-quality samples were collected during the study and historical median daily mean streamflows (site locations in figure 2 and table 4).

Water Stable Isotopes

Stable isotopes of water (δ^2H and $\delta^{18}O$) in precipitation and stream samples also were used to characterize general hydrologic conditions during the sampling periods. The δ^2H and $\delta^{18}O$ data for precipitation samples collected from July 2012 to April 2013 at rainfall monitoring sites RG-01 and RG-02 (fig. 2; appendix A4-2) were used to create a local meteoric water line (LMWL) for the Coastal Plain study area (fig. 5). The LMWL is represented by the linear relation between the δ^2H and $\delta^{18}O$ isotopic compositions in the precipitation samples:

$$\delta^2H = 8.33 * \delta^{18}O + 16.75 \quad (2)$$

The slope of 8.33 for the LMWL determined in this study is similar to the meteoric water line (MWL) equation ($\delta^2H = 8.29 * \delta^{18}O + 10.94$) determined by Kendall and Coplen (2001) using average values of surface-water samples obtained from 391 sites throughout the United States and Puerto Rico.

The δ^2H and $\delta^{18}O$ isotopic compositions of the samples collected at the primary sites (appendix A4-1) were compared to the LMWL to examine general differences in stream hydrologic conditions during the sampling periods (fig. 6). In general, surface-water samples with δ^2H and $\delta^{18}O$ values that correspond to the LMWL indicate that water in the streams reflects more recent inputs of precipitation to the land surface, which ultimately reaches the streams through runoff and groundwater discharge, that has undergone little fractionation. Samples with δ^2H and $\delta^{18}O$ values that plot along a line with a slope lower than the LMWL can be an indication that post-rainfall processes, commonly evaporation, altered the isotopic composition of the stream water prior to sample collection (Kendall and Coplen, 2001). As surface water evaporates, there is a preferential release of the lighter ^1H and ^{16}O isotopes to the atmosphere, which increases the δ^2H and $\delta^{18}O$ values of the remaining stream water; the values become increasingly more positive as evaporation proceeds.

During the six sampling periods, the δ^2H and $\delta^{18}O$ values for the February 2013 stream samples corresponded most closely to the LMWL (fig. 6*E*), reflecting the recent inputs of overland runoff when evaporation was least likely to have occurred (figs. 3, 4). The regression line for the February 2013 samples, with a slope of 6.97, almost paralleled the LMWL. For reference purposes, the regression line for the February 2013 data was superimposed on each of the δ^2H and $\delta^{18}O$ isotopic plots for the other five periods (fig. 6) to relate the isotopic compositions for those periods to the February period. The δ^2H and $\delta^{18}O$ values for the August 2012 samples plotted along a line with a slope of 6.08 (fig. 6*B*) that was just below the slope of 6.97 for the February 2013 period. The August samples had the largest observed range in δ^2H values (–12.3 to –37.3 ‰) and $\delta^{18}O$ values (–2.3 to –6.5 ‰). The August samples in the lower part of the regression line had isotopic signatures similar to the LMWL, indicating that stream water at some of the sites had received recent inputs of overland runoff and was minimally influenced by evaporation. August samples in the upper part of the regression line had more positive isotope δ^2H and $\delta^{18}O$ values that diverged to the right of the LMWL (fig. 6*B*), reflecting increased effects of evaporation and a lack of recent runoff at some of the sites sampled during August.

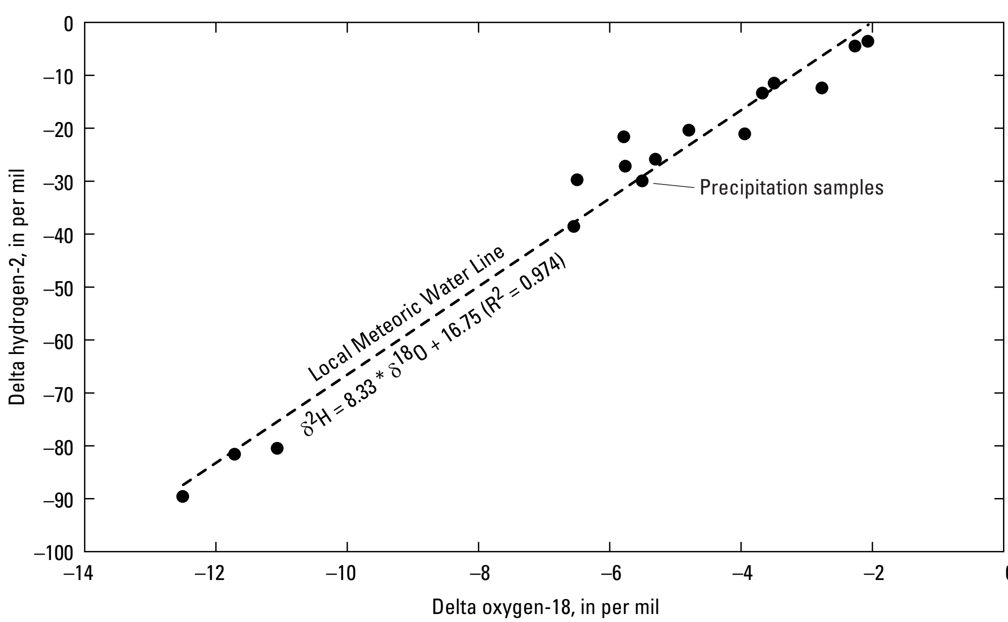

Figure 5. Comparison of delta oxygen-18 to delta hydrogen-2 isotope values in precipitation samples collected from July 2012 to April 2013 at raingage sites RG-01 and RG-02 in the Coastal Plain study area.

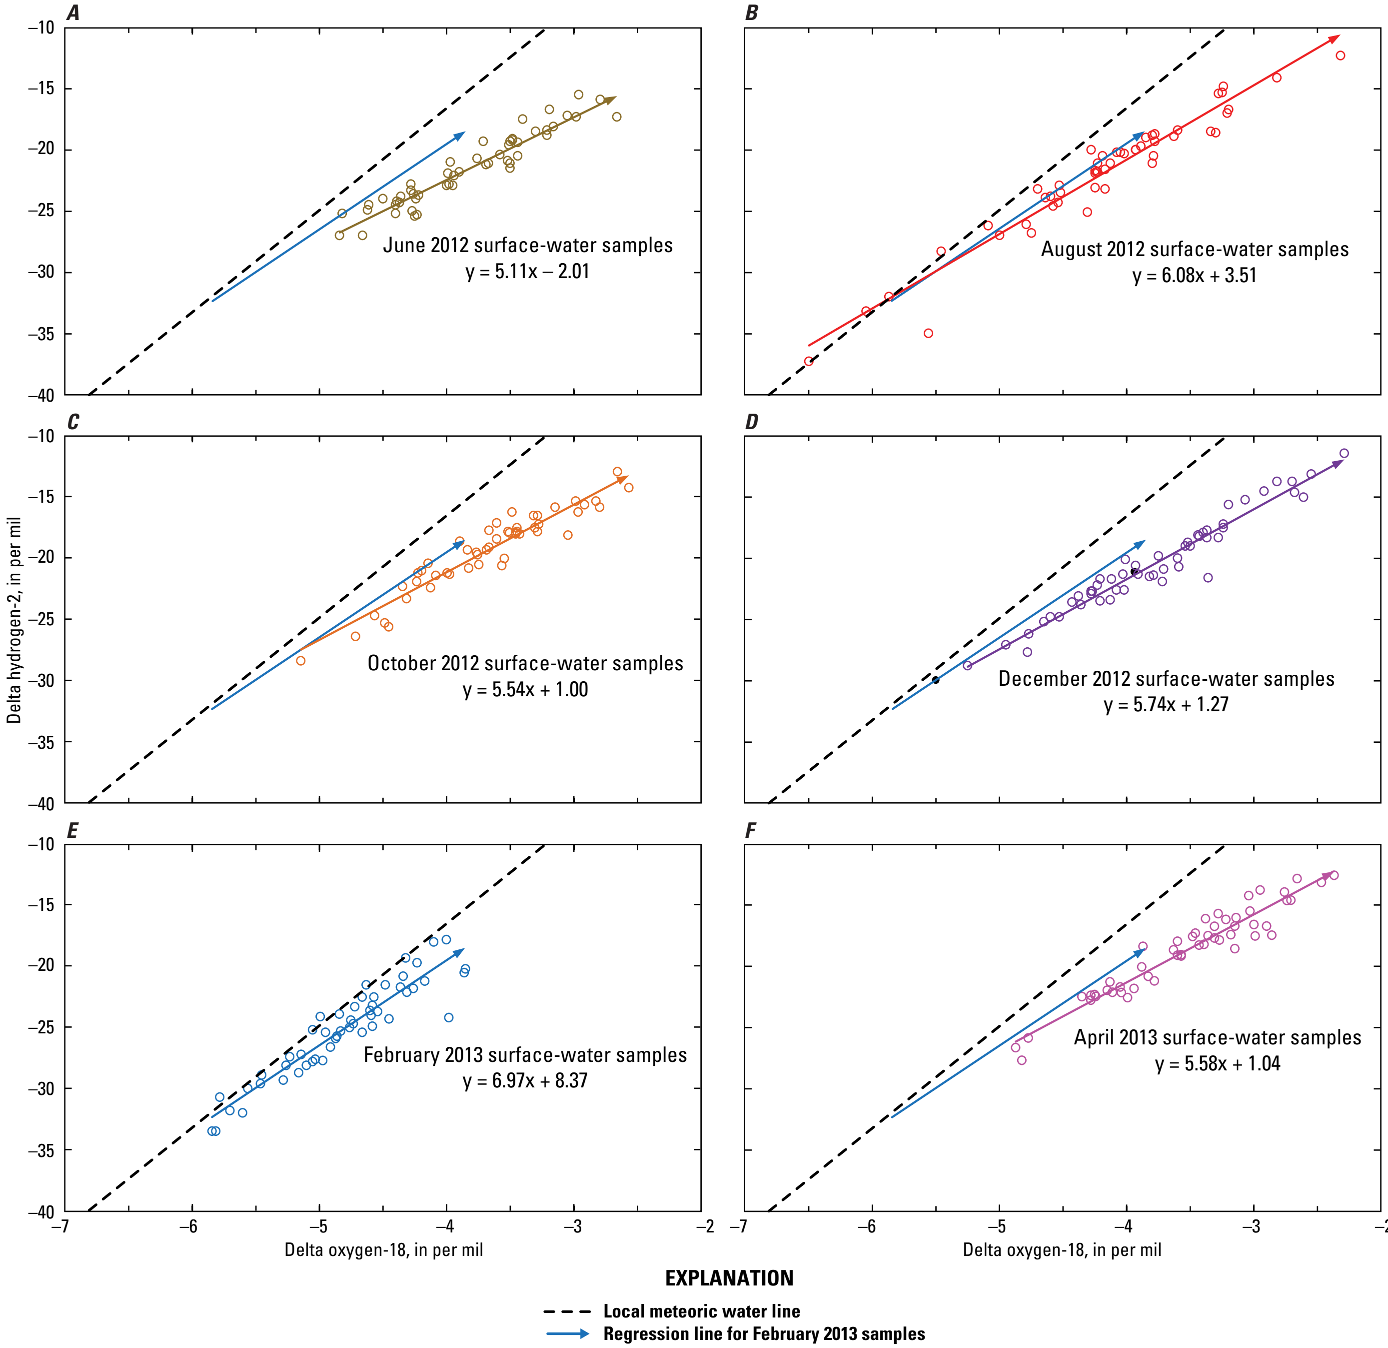

Figure 6. Comparisons of delta oxygen-18 to delta hydrogen-2 isotope values of surface-water samples for the (*A*) June 2012, (*B*) August 2012, (*C*) October 2012, (*D*) December 2012, (*E*) February 2013, and (*F*) April 2013 sampling periods relative to the local meteoric water line.

More pronounced effects of evaporation on the isotopic compositions at the stream sites were noted for the June, October, and December 2012 periods and the April 2013 period where the δ^2H and $\delta^{18}O$ values, with regression line slopes ranging from 5.11 to 5.74, plotted farthest away from the LMWL (fig. 6). These results support the previous discussion of the precipitation and streamflow data, which implied that streamflow conditions were relatively higher during the August and February periods as a result of increased rainfall and overland runoff (figs. 3, 4). Evaporation appeared to have a more influential effect on the surface-water δ^2H and $\delta^{18}O$ compositions during the June, October, December, and April periods. These periods were characterized by intermediate to lower streamflow conditions when there was less rainfall runoff to the streams and proportionally more input from discharging groundwater.

Comparison of Water-Quality Data by Sampling Period and Land-Use Type

Two-way ANOVA and multiple-comparison statistical tests were performed to characterize differences in stream water quality among the sampling periods (June, August, October, and December in 2012, and February and April in 2013) and watershed land-use types (BK, SW, and SP). Many of the water-quality properties and constituents were significantly influenced (ANOVA $P<0.05$) by one or both of the explanatory variables (sampling period and (or) land-use type) but there were no effects due to their combined interaction (sampling period:land-use type) (table 10). The lack of interaction indicates that the effects of sampling period and land-use type for a given constituent are independent; in other words, the effect of sampling period is the same across all land-use types and the effect of land-use type is the same across all sampling periods.

Seasonal and Flow-Related Water-Quality Differences

All of the water-quality properties and constituents, except calcium and the nitrate+nitrite isotopes ($\delta^{15}N$ and $\delta^{18}O$), had significant (ANOVA, $P<0.05$) differences among the sampling periods (table 10) based on data collected at the 54 primary sites. Differences reflected seasonal and hydrologic variations, as well as instream processes. Statistical summaries, by sampling period, of the original (non-ranked transformed) water-quality data are provided in tabular (table 11) and graphical formats (fig. 7) to aid the discussion. Figure 7 contains box plots for properties and constituents with significant differences (ANOVA $P<0.05$) among sampling periods; results of the multiple-comparison tests among the periods are denoted along the top of the plots. Rather than scrutinizing individual comparison pairs, the following discussion focuses on patterns among the sampling periods that reflect seasonal and hydrologic influences on water quality. Although ANOVA indicated a significant ($P=0.039$) difference for magnesium among sampling period (table 10), the multiple-comparison test did not identify any comparison pairs that were considered ($P<0.05$) different.

Water temperature followed an expected seasonal progression (fig. 7*A*). Specific conductance values were relatively lower during the August and February periods when rainfall was greatest, and higher for the October and December periods, when rainfall was least, although the difference was significant only for the December period (fig. 7*B*). Specific conductance in streams commonly is lower during high streamflows through dilution from overland runoff, and higher during low streamflows when baseflow, or groundwater discharge, is a larger component of the overall streamflow. Sodium (fig. 7*E*), potassium (fig. 7*F*), and chloride concentrations (fig. 7*G*) had distributions similar to specific conductance (fig. 7*B*) with highest concentrations during the drier December period.

In well-mixed, open flowing streams, DO concentrations typically are higher at cold temperatures and lower at warm temperatures. This is a result of higher solubility of dissolved gases in water at low temperatures. Although water temperatures (fig. 7*A*) followed expected seasonal patterns among the six sampling periods, there was no apparent relation between water temperature and DO (fig. 7*C*), with the exception of the February period. The streams examined in this study typically are slow moving and enriched with organic matter; low levels of DO are common in these stream settings. The variations in DO concentrations observed among the sampling periods likely reflect the integrated effects of hydrologic differences, such as the influx of oxygenated water from precipitation and overland runoff, and seasonal differences in the consumption of DO by microbial degradation of organic matter. The higher flow conditions for the February and August periods and intermediate flow conditions for the April period indicate more recent stream influxes of precipitation and runoff and, hence oxygenated water, were associated with these periods relative to the June, October, and December periods. The twofold difference in median DO concentrations between the February (8.0 mg/L) and August (3.6 mg/L) periods with the highest flow conditions appears to reflect seasonal differences in the microbial consumption of oxygen for degrading organic matter, which proceeds more quickly under warmer conditions and more slowly under cooler conditions. Although water temperatures were lower for October and December relative to August, the similarly low median DO concentrations for the drier October (2.4 mg/L) and December (2.1 mg/L) periods suggest that a substantial amount of microbial oxygen consumption occurred during the more sluggish streamflow conditions.

Concentrations of nutrients also differed among the sampling periods (table 10; fig. 7). Many biological, chemical, and physical processes can influence the forms and instream concentrations of the N and P constituents,

Table 10. Summary results of the two-way ANOVA tests on the ranked values of the water-quality properties and constituents based on sampling period and land-use type.

including assimilation and release by algae and aquatic plants; microbially mediated reactions like denitrification; adsorption and desorption processes; and exchange between streambed sediment and the overlying water column (Mulholland, 1992; McMahon and Böhlke, 1996; Mulholland and Hill, 1997; Mainstone and Parr, 2002; Dunne and Reddy, 2005). Interestingly, geochemically reducing conditions present in the buffer and hyporheic zones that help mitigate the amount of nitrate in groundwater discharged to the streams are the same conditions that can promote the mobilization and release of sorbed P from streambed deposits, including sediment derived from upland areas and decaying organic matter, into overlying stream water (Spruill, 2000; Spruill and others, 2005).

The results for nitrate+nitrite (fig. 7*L*) were notably different than the results for ammonia (fig. 7*J*) and organic N (fig. 7*K*). Nitrate+nitrite concentrations were substantially influenced by microbial denitrification, a process that reduces nitrate during anaerobic decomposition of organic matter. The median nitrate+nitrite concentration of 0.993 mg/L observed for February was substantially higher than the median concentrations for the other sampling periods, which ranged from <0.040 to 0.153 mg/L (table 11). The higher nitrate+nitrite concentrations for February coincided with higher streamflows and DO concentrations, and thus appear to reflect more overland contributions of nitrate in water from upstream field-drainage ditches to the streams, as well as less denitrification, for that period. These conditions are most likely to occur in the winter when the water table is high and the nitrate that is contributed to field ditches (from runoff, lateral groundwater inflows, and tile drainage) is likely to bypass the otherwise anoxic zones in near stream areas. Nitrate in the field ditches is rapidly carried to the main stem of the streams during high flows and is subject to less instream processing, including denitrification and uptake by plants and algae, when stream water temperatures are cold (fig. 7*A*) and DO concentrations are elevated (fig. 7*C*), as noted for the February sampling period. The lower nitrate+nitrite concentrations that occurred under the more reduced DO conditions during the June, August, October, and December sampling periods reflect a higher amount of denitrification. The highest median total N concentration of 1.6 mg/L also was observed for February (fig. 7*M*), reflecting the larger contribution from nitrate+nitrite compared to organic N, which constituted the more dominant fraction of total N among the other sampling periods.

Interestingly, sulfate (fig. 7*H*) had a similar distribution among the sampling periods as did both DO (fig. 7*C*) and nitrate+nitrite (fig. 7*L*). Sulfate concentrations were significantly higher during the February period. During the other periods with lower DO concentrations, sulfate apparently was reduced to other forms of sulfur.

In contrast to nitrate+nitrite, the median concentrations of ammonia (0.030 mg/L) and total organic N (0.56 mg/L) were lowest for the February period (fig. 7*J*, *K*; table 11). Similar to the seasonal pattern observed for water temperature (fig. 7*A*), median organic N concentrations were highest during the warm, growing-season months (June, August, and April) and steadily decreased through the fall and winter periods (October, December, and February). Organic N in streams occurs in both the dissolved form, such as urea, amino acids, and humic substances, and the particulate form, such as phytoplankton, zooplankton, microorganisms, and organic detritus. In this study, the dissolved organic N fraction was not measured. Therefore, the extent to which dissolved or particulate substances contributed to the organic nitrogen pool is not known. The observed pattern for total organic N is possibly influenced by algal and aquatic plant production, which likely would be higher during spring and summer and lower during the more dormant winter months.

Interesting differences among sampling periods also were noted for ortho-P (fig. 7*N*) and total P (fig. 7*O*). Overall concentrations for ortho-P (median of 0.009 mg/L) and total P (median 0.044 mg/L) were lowest in the February sampling period, the same period when the highest concentrations of nitrate+nitrite (fig. 7*L*) observed in the streams were attributed to increased overland transport of water through upstream field-drainage ditches. Concentrations of ortho-P and total P during the August period with higher flow conditions were not significantly different from the intermediate- or lower-flow sampling periods. In free-flowing streams with no point-source inputs, higher P concentrations in surface water tend to occur during higher streamflows in association with increased sediment inputs from overland runoff. In contrast, P patterns observed at the swampy, sluggish streams in this study area suggest that instream processes play a dominant role in P cycling. These processes may include adsorption/desorption processes and assimilation by aquatic plants, algae, and microbes in both the bed material and water column (Mainstone and Parr, 2002; Dunne and Reddy, 2005). The higher P concentrations observed during the more reduced DO conditions for the June, August, October, December, and April sampling periods possibly reflect higher amounts of algal biomass and (or) P releases into the water column from microbial degradation of organic matter and (or) desorption from organic substrates or anoxic bed sediments.

In summary, seasonal and hydrologic factors influenced water quality in these Coastal Plain agricultural watersheds. The differences noted among the sampling periods indicate that the interactions between seasonal climatic differences, streamflow conditions, and instream biotic and abiotic processes are complex and their integrated effects can have varying degrees of influence on individual nutrients. These findings are important to consider when developing studies to assess stream nutrient conditions in similar Coastal Plain settings and can inform the choice of specific objectives, nutrients to be examined, and overall timeline and frequency of sampling needed to capture seasonal and (or) hydrologic variability in the data.

Water-Quality Differences Related to Watershed Land-Use Type

Many of the water-quality properties and constituents were significantly influenced (ANOVA $P<0.05$) by watershed land-use type (table 10) on the basis of the results for all six sampling periods. Water-quality differences among the three land-use types, or groups (18 BK sites, 18 SW sites, and 18 SP sites), were examined to better understand potential CAFO influences. Statistical summaries, by land-use group, of the original (non-ranked transformed) water-quality data are provided in tabular (table 12) and graphical formats (fig. 8) to aid the discussion. Figure 8 includes box plots for properties and constituents with significant differences (ANOVA $P<0.05$) among land-use groups; results of the multiple-comparison tests among the groups are denoted along the top of the plots. No significant differences in water temperature, DO, calcium, total organic N, ortho-P, total P, and $\delta^{18}O$ of nitrate+nitrite were noted among the land-use types.

Significant differences were noted in specific conductance, pH, and all of the major ions, except calcium, among the land-use groups (table 10). Specific conductance, pH, magnesium, sodium, potassium, and chloride were significantly different between the BK and SW sites and the BK and SP sites, but not between the SW and SP sites (fig. 8*A–F*). Median specific conductance values for the SW and SP sites were higher than the BK sites, which reflects the higher median concentrations of dissolved magnesium, sodium, potassium, and chloride also noted at the SW and SP sites. Median pH values also were higher for the SW and SP sites relative to the BK sites. Sulfate (fig. 8*G*) for the SP sites was significantly different than both the BK and SW sites.

Median concentrations of ammonia+organic N, ammonia, and total N were higher at the SW and SP sites than at the BK sites (fig. 8*H*, *I*, and *K*; table 12). No significant difference in total organic N was noted among the land-use groups, suggesting that the differences in ammonia+organic N between the BK and SW sites and the BK and SP sites are associated with the ammonia fraction. Nitrate+nitrite was the only constituent found to be significantly different between all three land-use groups (fig. 8*J*). Median nitrate+nitrite concentrations progressively increase from the BK to the SW to the SP sites. Interestingly, no significant differences were identified for the P nutrients (ortho-P or total P) on the basis of land-use type (table 10).

Similar to the N constituents, median $\delta^{15}N$ values of nitrate+nitrite for the SW and SP sites were higher, or more positive, than the BK sites (fig. 8*L*), indicating that nitrate+nitrite at the SW and SP sites was more enriched in 15N. The higher median $\delta^{15}N$ values of nitrate+nitrite likely indicate that N inputs to streams at the SW and SP sites were more influenced by animal-manure sources; however, it is important to note that other processes, such as denitrification and assimilation by algae, also may have influenced the observed $\delta^{15}N$ values of nitrate+nitrite.

These results indicate that waste-manure storage and (or) field applications at the CAFOs have increased surface-water concentrations of selected constituents at the SW and SP sites above those noted for the BK sites, which do not contain any active CAFOs. Although the various types and amounts of commercial fertilizer products used in the watersheds of the individual study sites are unknown, it is considered unlikely that the significant differences noted in the water-quality constituents would only occur between the BK group of sites and both CAFO site groups (SW and SP) and not between the SW and SP site groups if related solely to differences in commercial fertilizer use. Most of the statistically significant differences for major ions (magnesium, sodium, potassium, and chloride) and nutrients (ammonia+organic N, ammonia, nitrate+nitrite, and total N) occurred between the BK and SW sites and the BK and SP sites (fig. 8). The median concentrations of these constituents were all higher at the SW and SP sites relative to the BK sites.

It is unclear whether the lack of detectable differences in P among the land-use groups indicates that stream inputs of P were the same among the study watersheds with and without animal-waste manure applications or whether other environmental processes (like sediment deposition, adsorption/desorption, and assimilation) have obscured differences in source inputs of P derived from commercial fertilizer and (or) animal-waste manure.

Phosphorus, which is relatively immobile in soil, typically is transported to streams in particulate form during overland runoff. The more soluble N constituents, such as ammonia and nitrate+nitrite, are prone to leaching in soils and may be transported to streams through both groundwater discharge and overland runoff. The disparity between N and P response among the sites may reflect differences in transport pathways or instream processing that influenced instream concentrations of these two classes of nutrients.

Multi-Analyte Approach for Differentiating Sites With Water-Quality Effects From CAFOs

The statistical evaluations discussed previously indicated that when all 54 primary study sites were examined collectively on the basis of their land-use type (BK, SW, and SP), several water-quality differences related to animal-waste manures were identified for the SW and SP site groups. Interestingly, some individual SW and SP sites did not appear to be affected by animal-waste manures. Data were further evaluated to better understand distinctions among selected water-quality constituents at sites with and without CAFOs to aid identification of those SW and SP watersheds with measurable CAFO manure effects on water quality.

Insights Based on Multi-Site Reconnaissance Sampling Within Selected Watersheds During April 2013

During April 2013, samples were collected once at 23 secondary sites within 9 of the primary watersheds to obtain water-quality data from upstream reaches. These secondary sites were located in proximity to either swine CAFOs and spray fields or to background agricultural fields. Nutrient and ion concentrations and the nitrate+nitrite stable isotope data were evaluated to distinguish sites where CAFO waste manures did or did not have a measurable effect on surface-water quality.

Stable isotopes ($\delta^{15}N$ and $\delta^{18}O$) of nitrate are often used in water-quality studies as environmental tracers for investigating anthropogenic sources of nitrogen (such as atmospheric deposition, commercial inorganic fertilizers, and organic animal manures and septic wastes). Kendall and others (2007) diagrammed common ranges, or fields, of nitrate $\delta^{15}N$ and $\delta^{18}O$ values derived or nitrified from various N sources (fig. 9). The $\delta^{18}O$ values tend to be more useful for separating nitrate derived from atmospheric deposition or synthetic nitrate fertilizers from other sources. The $\delta^{15}N$ values tend to be more useful for distinguishing nitrate derived from microbial nitrification of ammonium and (or) organic N in fertilizer, precipitation, soil, and animal manure or human septic waste because these sources have overlapping $\delta^{18}O$ values, commonly between –10 and +15 ‰ (Kendall and others, 2007; Xue and others, 2009).

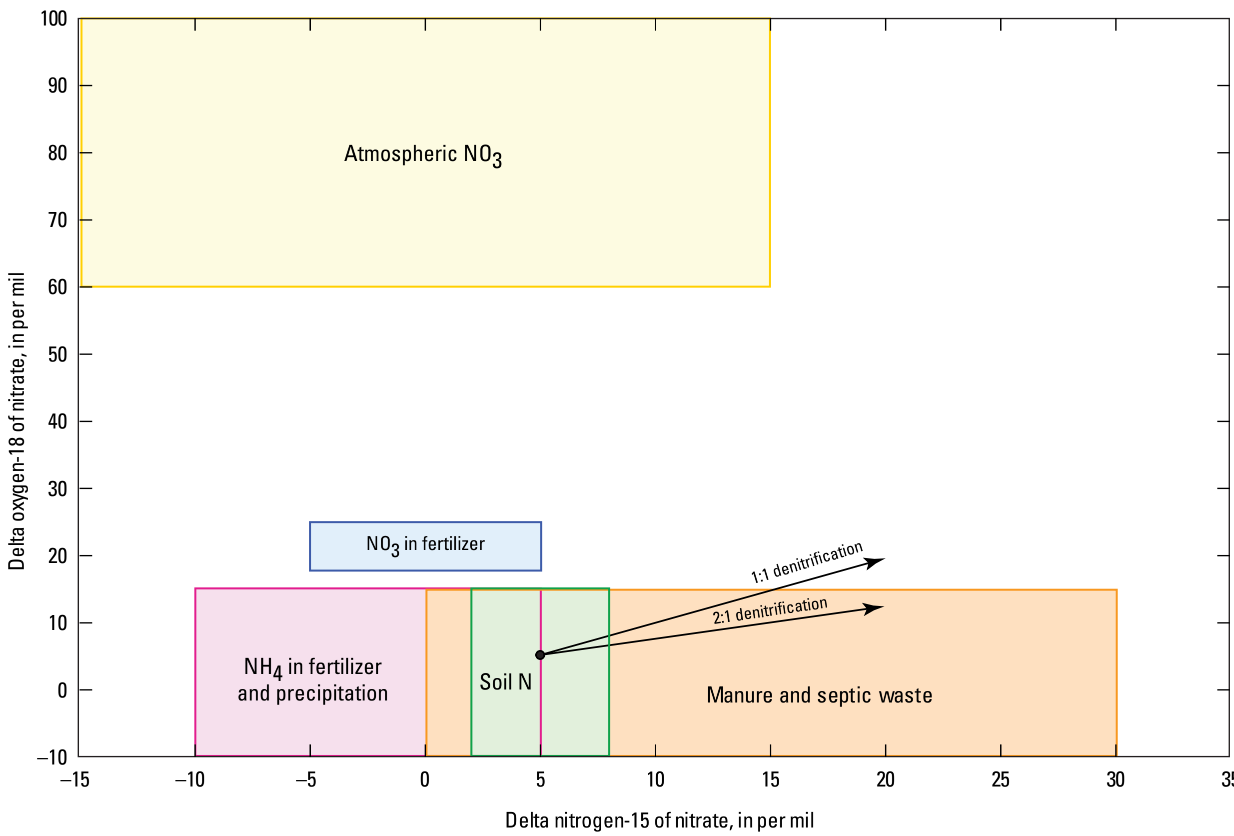

Figure 9. Common ranges in values of delta nitrogen-15 and delta oxygen-18 of nitrate derived from various nitrogen sources (modified from Kendall and others, 2007).

Inorganic fertilizers and animal-waste manures, which are the main sources of N in the agricultural watersheds in this study, generally have distinct $\delta^{15}N$ nitrate values (Kendall, 1998). The $\delta^{15}N$ values of nitrate originating from inorganic fertilizers typically are lower, about –5 to +5 ‰, than those from animal manures, which typically are higher and have a wider range of compositions, about 0 to +30 ‰ (Fogg and others, 1998; Kendall and others, 2007; Xue and others, 2009). Note that nitrate derived from human septic wastes generally has $\delta^{15}N$ values of about +5 to +20 ‰ that are indistinguishable from animal manures (Fogg and others, 1998; Xue and others, 2009); however, human-derived wastes are not considered to be a substantial contributor of N to streams in the study watersheds. Although the $\delta^{15}N$ values of soil nitrate derived from inorganic fertilizers tend to overlap those derived from the mineralization of natural soil organic N, about 0 to +8 ‰, they are often distinguishable from the higher nitrate $\delta^{15}N$ values associated with animal-waste manures (Fogg and others, 1998; Kendall and others, 2007; Xue and others, 2009).

Comparing measured nitrate $\delta^{15}N$ and $\delta^{18}O$ values in samples against the general source boxes depicted in figure 9 may be useful for assessing potential sources if the original source signal of the nitrate has not been substantially altered. Complications arise if the isotopic composition reflects a mixture of two or more nitrate sources and (or) has been influenced by biogeochemical processes, such as assimilation or denitrification, that transform N, which can cause the altered $\delta^{15}N$ and $\delta^{18}O$ values to resemble those of other sources (Kendall and others, 2007). During the process of denitrification, microbes preferentially use the lighter ^{14}N and ^{16}O isotopes, which enrich the remaining or residual nitrate pool with the heavier ^{15}N and ^{18}O isotopes, resulting in more positive nitrate $\delta^{15}N$ and $\delta^{18}O$ values. Denitrification causes coupled increases in the $\delta^{15}N$ and $\delta^{18}O$ values of the residual nitrate by an approximate 1:1 to 2:1 ratio (Böttcher and others, 1990; Kendall and others, 2007).

The effects of denitrification are illustrated using an example of assumed nitrate having an initial $\delta^{15}N$ value of 5 ‰ and $\delta^{18}O$ value of 5 ‰ similar to that derived from ammonium fertilizer or soil organic N (fig. 9). The two arrows indicate how the process of denitrification for nitrate with this initial isotopic signature produces residual nitrate $\delta^{15}N$ to $\delta^{18}O$ values that progressively increase along either a 1:1 denitrification line (having a slope of 1) or 2:1 denitrification line (having a slope of 0.5). As the $\delta^{15}N$ and $\delta^{18}O$ values of the initial nitrate reflecting an ammonium fertilizer or soil organic N source become increasingly more positive during denitrification, they become more similar to those expected for nitrate derived from animal-waste manures, thereby confounding interpretations of the nitrate sources.

These types of issues can make it complicated or impractical to identify nitrate sources solely on the basis of the nitrate isotopic compositions. It is beneficial to examine other chemical constituents in combination with the nitrate stable isotope data for differentiating sources of nitrate contamination in water (Spruill and others, 2002; Kendall and others, 2007; Xue and others, 2009). In the North Carolina Coastal Plain, Karr and others (2001) and Spruill and others (2002) used $\delta^{15}N$ data in combination with major ion data to examine sources of nitrate in groundwater. Karr and others (2001) used $\delta^{15}N$, potassium, and chloride data to examine swine-manure contamination in groundwater from a waste lagoon and spray field. Spruill and others (2002) evaluated the results of nitrate $\delta^{15}N$, nutrients (nitrate and ammonia) and major ions (calcium, magnesium, sodium, and potassium) with classification tree models to identify sources of groundwater nitrate derived from inorganic fertilizers, swine manure, poultry litter, and septic-system wastes. Ratios of selected ion concentrations (calcium to magnesium and sodium to potassium) and summed concentrations of sodium+potassium were found to be useful indicators for distinguishing the different nitrate sources.

The examination of the April 2013 water-quality data for the primary and secondary study sites primarily focused on evaluating nitrate+nitrite and sodium+potassium concentrations in combination with the nitrate+nitrite $\delta^{15}N$ values for differentiating those sites with measurable effects of CAFO manure on water quality (table 13). Comments on whether the surface-water samples that were collected had the potential to be influenced by one or more CAFOs upstream from the sites are noted in table 13. Detailed evaluations of the data for each group of associated sites are provided separately as appendix A5. Insights based on the evaluations of the April 2013 dataset (appendix A5) are discussed below.

In six of the nine watersheds that were examined, measured effects of swine CAFO manure on surface water at one or more upstream secondary sites also were noted further downstream at the primary site locations (table 13). The extent to which influences of CAFO manure may be identified in surface water at downstream watershed locations likely varies depending on the particular watershed setting, including such things as basin size, density of CAFOs and their locations, the presence or absence of tile drains and field ditches, stream morphology, and streamflow conditions. Many of the secondary sites that were located next to or downstream from swine CAFOs were found to be influenced by swine manure in terms of nitrate+nitrite and sodium+potassium concentrations and nitrate+nitrite $\delta^{15}N$ values. Conversely, no water-quality effect was noted at some of the sites (table 13), which suggests that all CAFOs do not necessarily have a measurable effect on these water-quality constituents in adjacent sections of streams.

The combined use of the nitrate+nitrite, sodium+potassium, and $\delta^{15}N$ of nitrate+nitrite data proved valuable for identifying those 9 primary and 23 secondary sites either having or not having a measurable water-quality effect associated with CAFO waste manures (appendix A5). Of the 32 sites, 18 had measurable manure influence, 11 had no measurable manure influence (including the 4 background agricultural sites), and 3 had unclear results (table 13). Distinctions among the results are illustrated in figure 10 for the sites with, without, or unclear CAFO manure influences. Boundaries delineating the general distribution in the

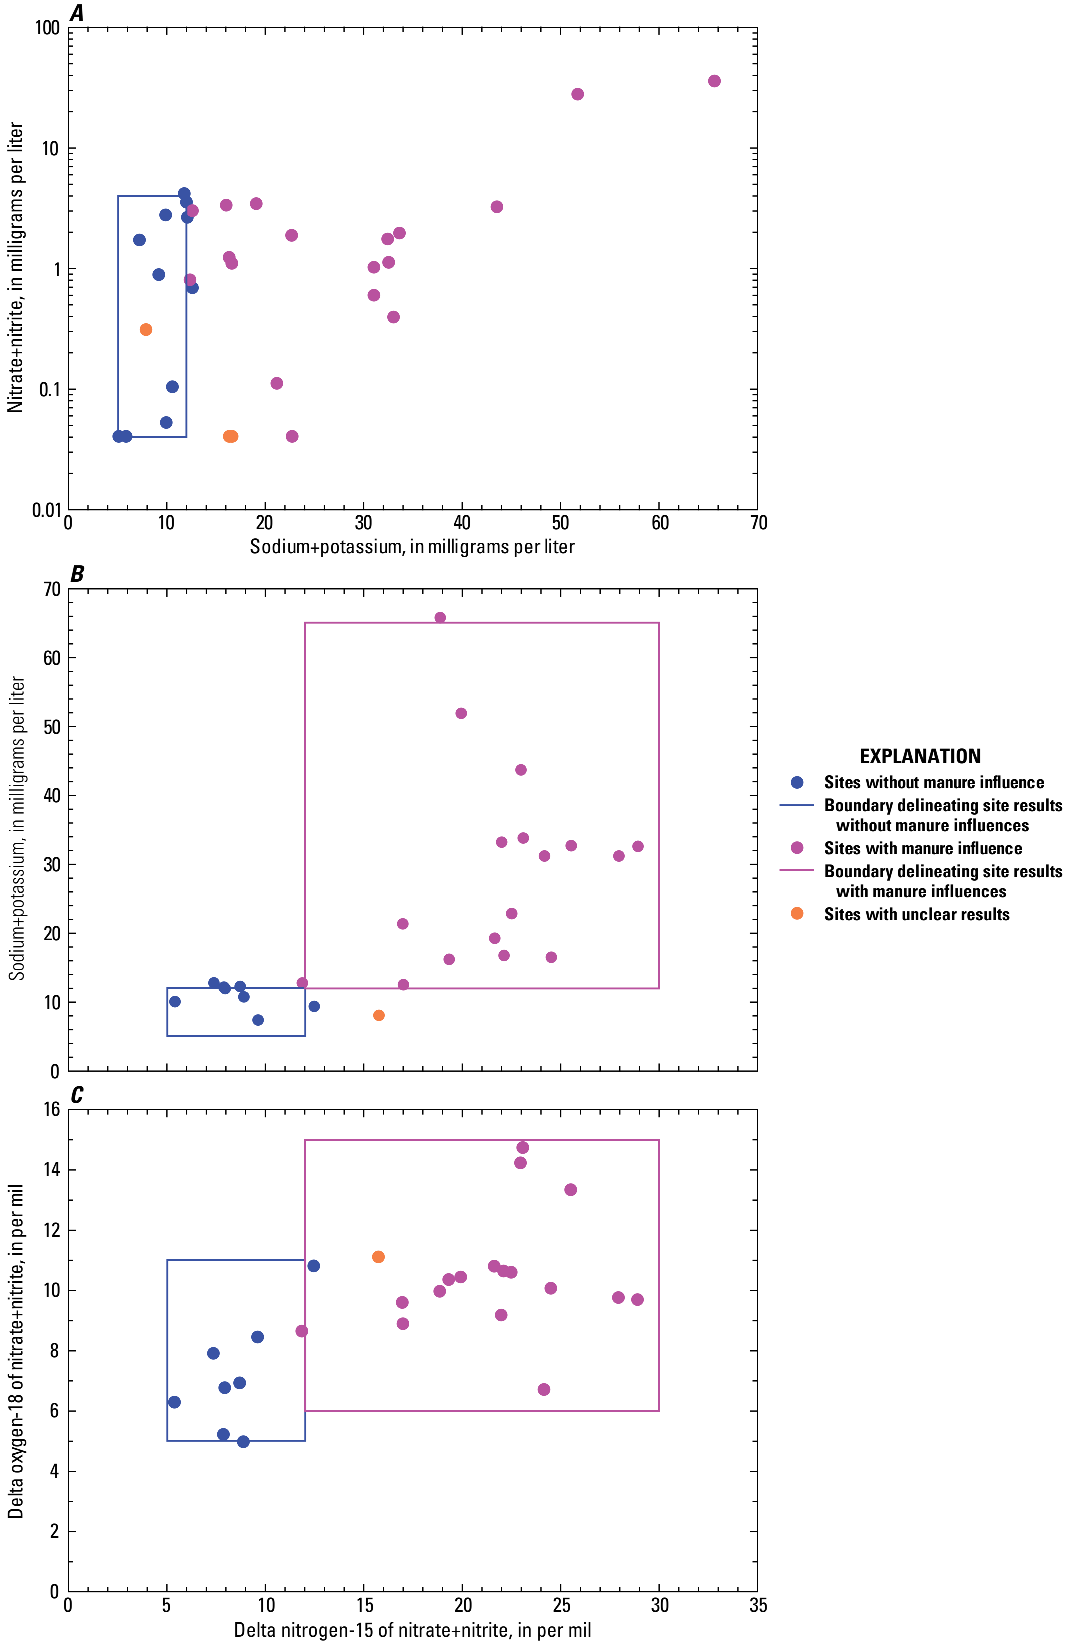

Figure 10. Graphs showing data comparisons of (*A*) sodium plus potassium to nitrate plus nitrite, (*B*) delta nitrogen-15 of nitrate plus nitrite to sodium plus potassium, and (*C*) delta nitrogen-15 to delta oxygen-18 of nitrate plus nitrite for sites with and without CAFO manure influences and sites with unclear results based on the April 2013 dataset.

sodium+potassium and nitrate+nitrite data for the sites without manure influences are shown in figure 10*A*. Boundaries delineating the general distributions in the nitrate+nitrite $\delta^{15}N$ and sodium+potassium data (fig. 10*B*) and the nitrate+nitrite $\delta^{15}N$ and $\delta^{18}O$ data (fig. 10*C*) are shown for both the sites without and with manure influences. The nitrate+nitrite $\delta^{15}N$ and $\delta^{18}O$ values for the sites without manure effects (fig. 10*C*) agree with the common $\delta^{15}N$ and $\delta^{18}O$ values of nitrate derived from ammonium fertilizer or natural soil organic N displayed in figure 9. The nitrate+nitrite $\delta^{15}N$ and $\delta^{18}O$ values for the sites with manure effects (fig. 10*C*) also agree with the $\delta^{15}N$ and $\delta^{18}O$ values of nitrate commonly derived from animal manure sources (fig. 9).

The overall range of nitrate+nitrite concentrations was fairly similar for the sites with and without manure influences; however, sodium+potassium concentrations were higher for the sites with a manure influence than those without an influence (fig. 10*A*). Better separation among the sites is noted in the nitrate+nitrite $\delta^{15}N$ and sodium+potassium data (fig. 10*B*). The sites without manure influences had lower $\delta^{15}N$ values (about 5 to 12 ‰) and sodium+potassium concentrations (about 5 to 12 mg/L) than the manure influenced sites, which are characterized by higher $\delta^{15}N$ values (about 12 to 30 ‰) and sodium+potassium concentrations (about 12 to 65 mg/L). Comparison of the nitrate+nitrite $\delta^{15}N$ to $\delta^{18}O$ data (fig. 10*C*) indicates that although the $\delta^{15}N$ values appear to segregate, the sites without and with manure influences tend to have overlapping $\delta^{18}O$ values of about 5 to 11 ‰ and 6 to 15 ‰, respectively. For several sites, limited or inconsistent results made it difficult to determine whether water quality reflected background agricultural conditions or waste-manure effects. For example, the unclear results shown for some sites included a sodium+potassium concentration within the range of sites without manure influences (fig. 10*A*, *B*) but the elevated $\delta^{15}N$ value (fig. 10*B*, *C*) could be indicative of either a manure signature or denitrification effects on soil nitrate derived from inorganic fertilizer or natural organic N.

Identification of Study Watersheds Having Measurable CAFO Effects on Water Quality

On the basis of the insights gained from the above evaluation of the April 2013 dataset, nitrate+nitrite and sodium+potassium concentrations and the nitrate+nitrite isotopic values ($\delta^{15}N$ and $\delta^{18}O$) for all 6 sampling periods at the 54 primary study sites (appendix A6) were evaluated to determine which of the 18 SW and 18 SP sites had apparent CAFO waste-manure effects on stream water quality. Results for the 18 BK study sites first were plotted to serve as a baseline, or background, dataset (fig. 11) against which the SW and SP site data could be compared. The reference boundaries determined for sites without and sites with measurable manure influences using the April 2013 dataset (fig. 10) also were included in figure 11 to aid examination of the results.

Overall, the baseline results for the BK sites fall within fairly well-defined clusters (fig. 11). Most of the nitrate+nitrite and sodium+potassium concentrations for the BK sites fall within the reference boundary for sites without waste-manure effects. Note that many of the BK sites had nitrate+nitrite concentrations less than the RL of 0.04 mg/L. As previously discussed, denitrification is one of the important factors known to influence nitrate+nitrite concentrations at the study sites. The effects of denitrification are evident in the background nitrate+nitrite $\delta^{15}N$ results. The BK sites had nitrate+nitrite $\delta^{15}N$ values, up to about 17 ‰, that extended beyond the upper limit of about 12 ‰ for the reference boundary for sites without manure influences (fig. 11*B*). The nitrate+nitrite $\delta^{15}N$ and $\delta^{18}O$ values for the BK sites plot along a best-fit regression line having a slope of 0.48 (fig. 11*C*), which is indicative of denitrification that causes coupled increases in the $\delta^{15}N$ to $\delta^{18}O$ values by a 2:1 ratio. Increased isotopic values resulting from denitrification explains why some of the BK sites, with no waste-manure influences, had nitrate+nitrite $\delta^{15}N$ and $\delta^{18}O$ values within the reference boundary reflecting manure influence.

Data for each of the SW and SP sites were plotted and compared against the figure 11 boundaries respresenting the BK site baseline data, as well as the sites without and with measurable manure influences, to categorize those SW and SP sites with results that (1) were similar to background conditions, or (2) had distinct differences indicating CAFO manure effects. It was impractical to include all of the comparison plots in the report. Therefore, for illustrative purposes, representative plots for selected sites with results similar to background conditions are shown in figure 12, and selected sites with results indicating manure influences are shown in figure 13.

Sites SW-14, SW-16, SP-05, and SP-15 had results similar to background conditions based on comparisons of their sodium+potassium to nitrate+nitrite concentrations (fig. 12*A*), nitrate+nitrite $\delta^{15}N$ values to sodium+potassium concentrations (fig. 12*B*), and nitrate+nitrite $\delta^{15}N$ to $\delta^{18}O$ values (fig. 12*C*). The effects of denitrification can also be seen in the $\delta^{15}N$ results for site SP-15.

The effects of CAFO waste manures are indicated in some or all of the results for sites SW-04, SW-05, SP-12, and SP-16 as compared to the reference boundaries (fig. 13). Sites SW-05 and SP-16 had samples with results overlapping background conditions as well as manure influences. These site results likely reflect different instream mixtures of groundwater and overland runoff from areas with and without CAFOs where at times manure influences on water quality were not always evident. CAFO manure effects were evident in all of the sample results for sites SW-04 and SP-12 (fig. 13). Site SP-12, located immediately downstream from multiple swine CAFO waste-manure lagoons and application fields (appendix fig. A1-48), had high nitrate+nitrite $\delta^{15}N$ and $\delta^{18}O$ values. The isotopic signatures of nitrate+nitrite derived from waste manures at this site possibly reflect the effects of different fractionation processes, such as ammonia volatilization and denitrification, that occurred before, during, and (or) after the applications of waste manures from the storage lagoons to the spray fields.

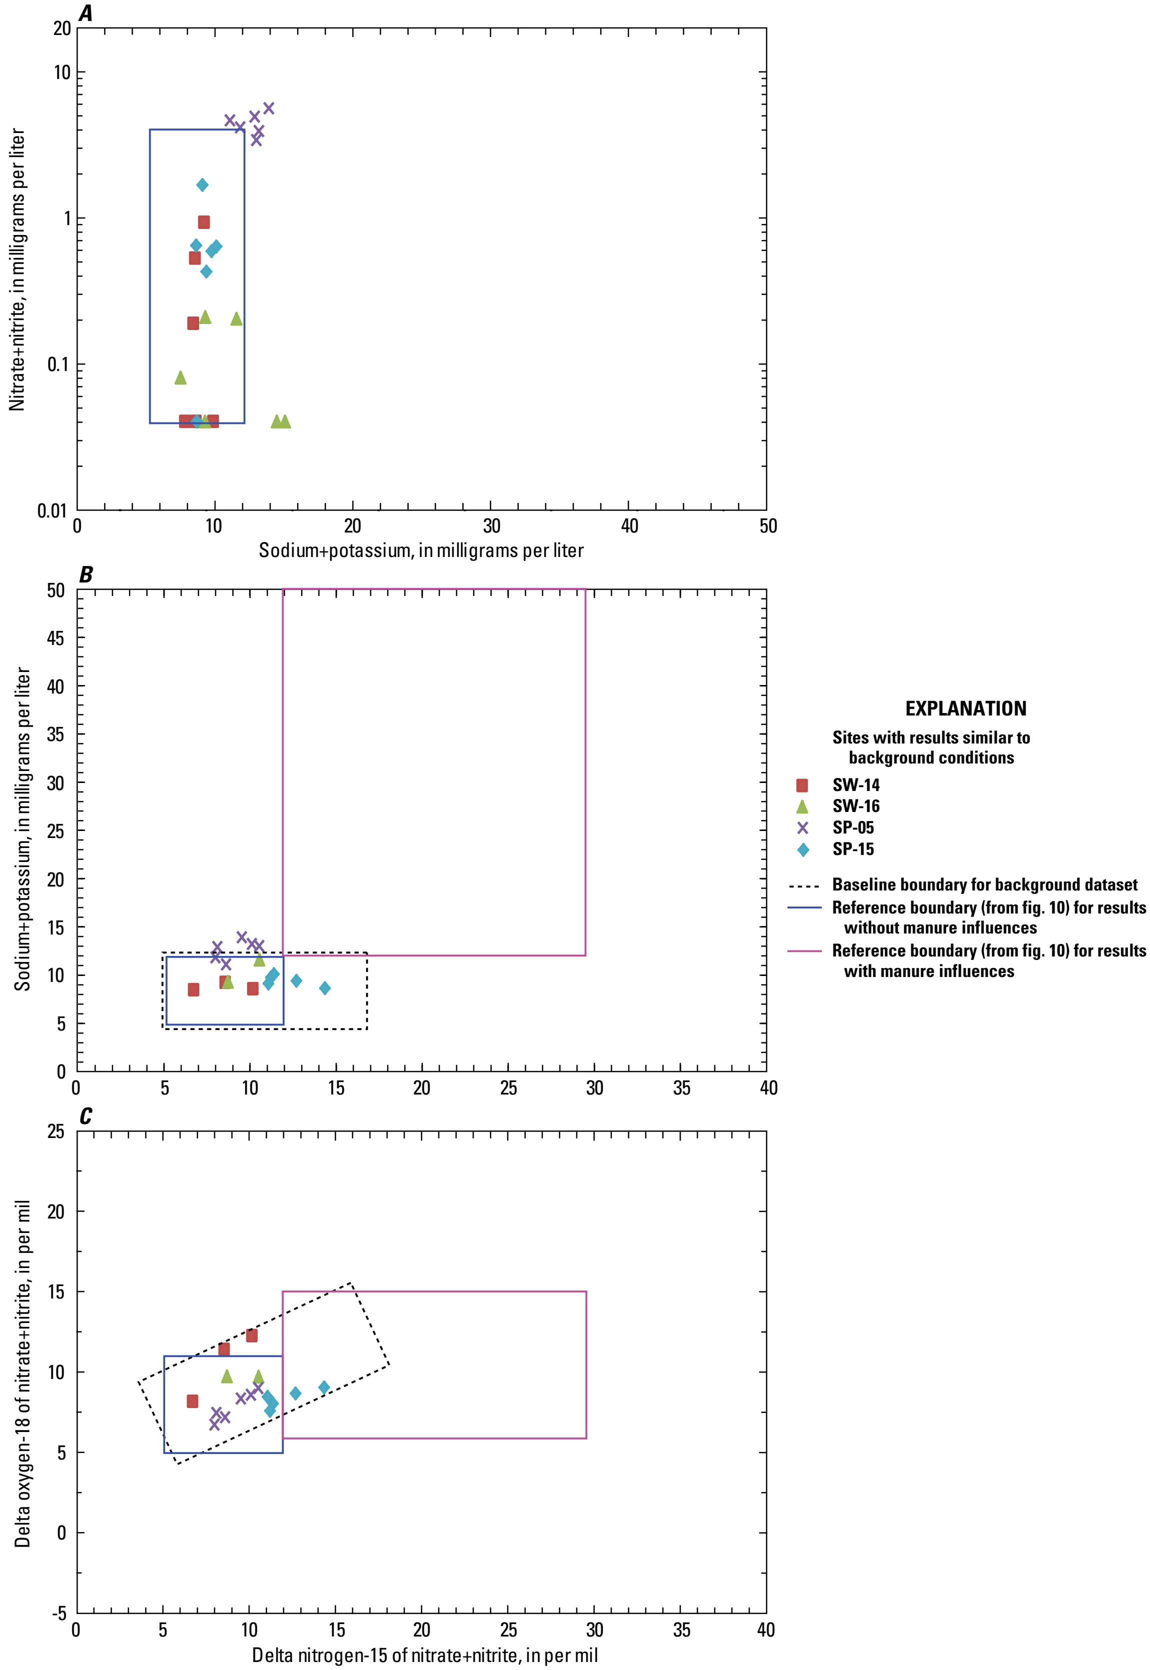

Figure 12. Graphs showing data comparisons of (*A*) sodium plus potassium to nitrate plus nitrite, (*B*) delta nitrogen-15 of nitrate plus nitrite to sodium plus potassium, and (*C*) delta nitrogen-15 to delta oxygen-18 of nitrate plus nitrite at four representative sites (SW-14, SW-16, SP-05, and SP-15) with results similar to background conditions.

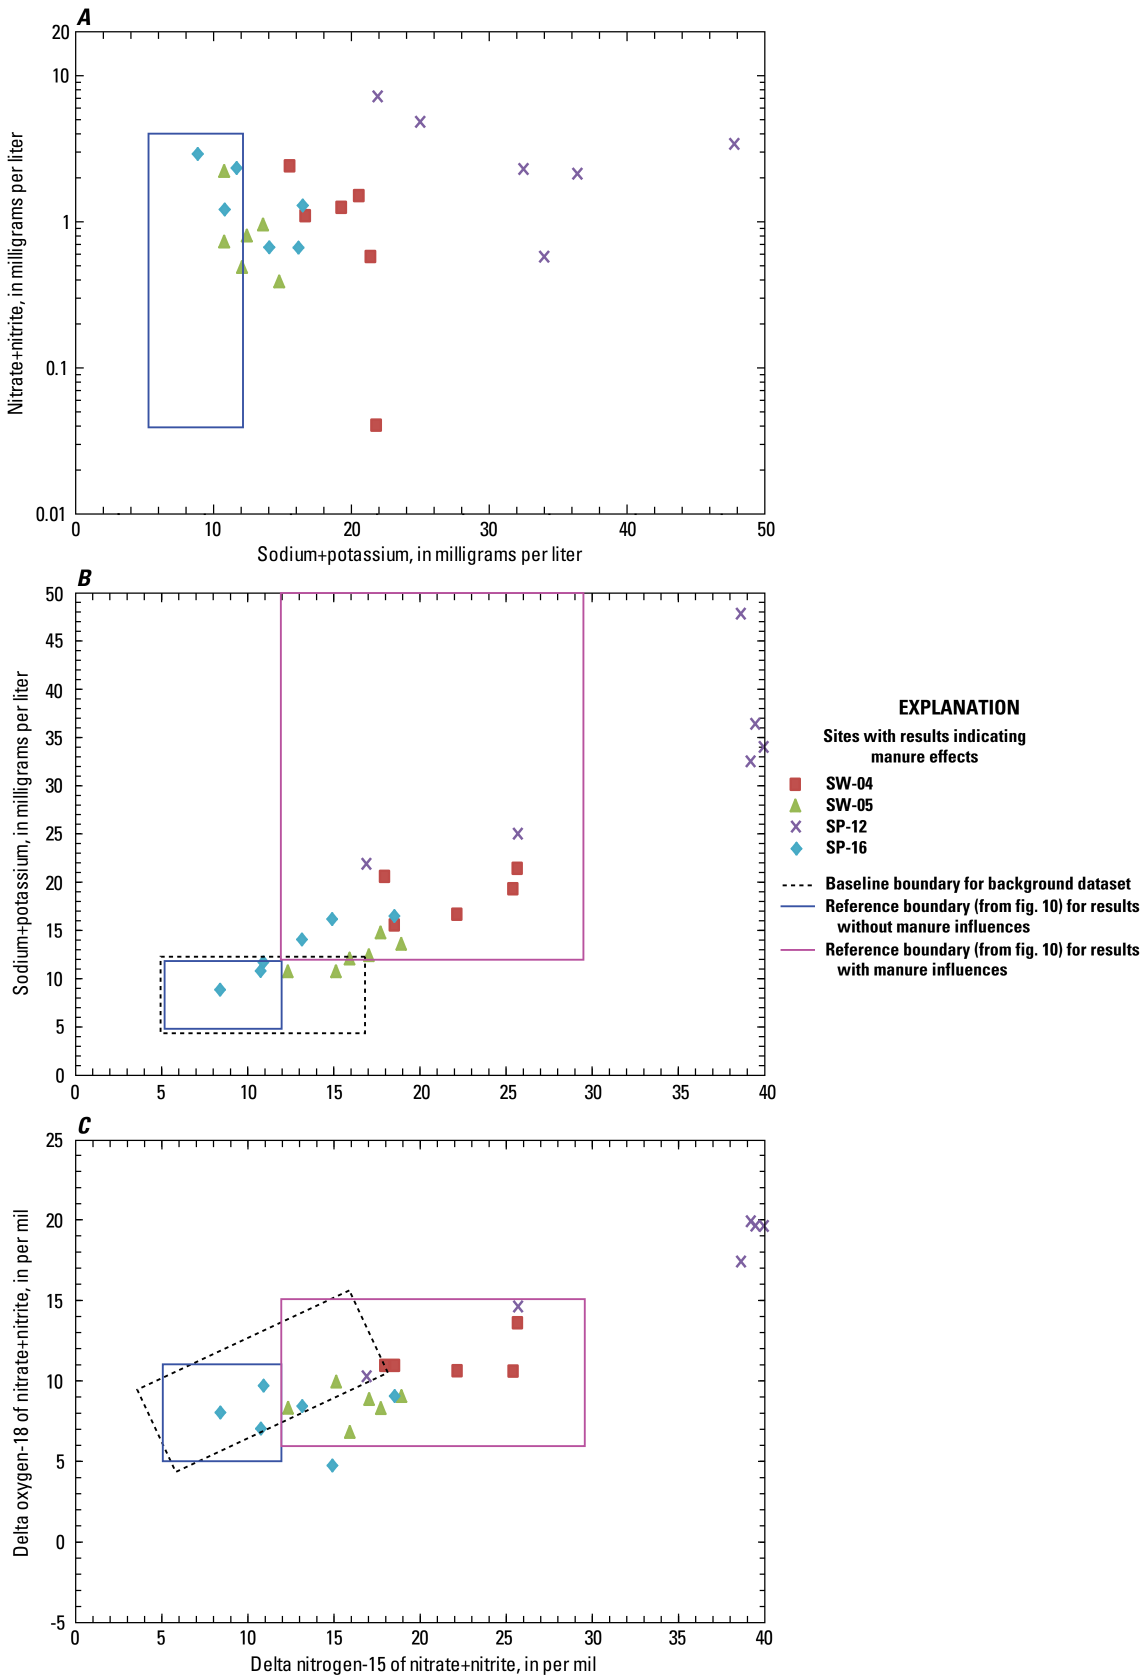

Figure 13. Graphs showing data comparisons of (*A*) sodium plus potassium to nitrate plus nitrite, (*B*) delta nitrogen-15 of nitrate plus nitrite to sodium plus potassium, and (*C*) delta nitrogen-15 to delta oxygen-18 of nitrate plus nitrite at four representative sites (SW-04, SW-05, SP-12, and SP-16) with results indicating manure effects.

On the basis of the comparisons of sodium+potassium concentrations, nitrate+nitrite concentrations, and the $\delta^{15}N$ and $\delta^{18}O$ of nitrate+nitrite values, 10 of the 36 CAFO sites (28 percent) had results similar to background conditions, and 21 of the sites (58 percent) had results with measurable CAFO manure effects (table 14). Note that the identification of those SW or SP watersheds as being similar to background conditions does not necessarily imply that CAFOs in those watersheds have no local influence on water quality, only that no distinction was noted at the watershed sampling location for the constituents that were examined. Three of the SW sites (SW-03, SW-08, and SW-15) and two of the SP sites (SP-03 and SP-08) had limited or indeterminate results for determining whether they were similar to background or manure influenced; these sites with unclear results were excluded from further evaluation.

The manure-influenced group of sites tended to have distinctly higher sodium+potassium concentrations (commonly between 11 and 33 mg/L) and $\delta^{15}N$ values of nitrate+nitrite (commonly between 11 and 26 ‰) relative to both the background and similar to background groups of sites, which commonly had sodium+potassium concentrations between 6 and 14 mg/L and $\delta^{15}N$ values of nitrate+nitrite between 6 and 15 ‰ (table 14; appendix A6). Based on the six sampling periods from June 2012 to April 2013, sodium+potassium concentrations and $\delta^{15}N$ values of nitrate+nitrite appear to be useful water-quality indicators for differentiating streams with measurable CAFO manure effects. It would be beneficial to base future similar analyses on a larger number of samples that more fully reflect hydrologic and seasonal variability in water-quality conditions among sites of interest.

Table 14. Statistical summary of selected water-quality constituents for the background sites, CAFO sites with results similar to background conditions, and CAFO sites with results reflecting manure influences.

[diss., dissolved; mg/L, milligrams per liter; N, nitrogen; O, oxygen; +, plus; <, less than; δ, delta; ‰, per mil]

Chemical constituent (unit)	Background sites[1]				Similar to background sites[2]				Manure-influenced sites[3]			
	Number of samples	10th percentile	Median	90th percentile	Number of samples	10th percentile	Median	90th percentile	Number of samples	10th percentile	Median	90th percentile
Sodium + potassium, diss. (mg/L)	106	6.35	9.23	12.9	54	6.48	9.57	14.5	124	10.8	16.66	32.7

[1]The background, or baseline, dataset includes the results of all 18 BK sites (BK-01 through BK-18).

[2]The sites with results deemed to be similar to background conditions include 6 SW sites (SW-02, 06, 07, 10, 14, and 16) and 4 SP sites (SP-01, 05, 15, and 17).

[3]The sites with results deemed to reflect manure influences include 9 SW sites (SW-01, 04, 05, 09, 11, 12, 13, 17, and 18) and 12 SP sites (SP-02, 04, 06, 07, 09, 10, 11, 12, 13, 14, 16, and 18).

Watershed Attributes Associated With CAFO Water-Quality Effects

Watershed environmental attributes were compared among the study sites with and without CAFO manure influences (see previous section). The five sites (SW-03, 08 and 15, and SP-03 and 08) with indeterminate results were not included in this analysis. The remaining 49 sites were grouped into three response categories: 18 background sites; 10 similar to background CAFO sites, and 21 manure-influenced CAFO sites. A classification tree model was developed to examine relations between selected watershed environmental variables and the three response categories (appendix A7).

The main intent in this analysis was to identify key differences in watershed characteristics associated with sites either having or not having measurable CAFO manure effects. Watershed characteristics analyzed as predictor (independent) variables in the model included drainage area size, land cover (percentages of forested land, cropland, grassland, and wetlands), soil drainage (percentages of HSGs total A, total B, total C, and D), swine CAFO attributes, and poultry CAFO attributes (appendix A7). The swine CAFO attributes included the total number of permitted active swine CAFOs, total swine barns and barn density, total swine and swine density, total swine weight and weight density, total acres available for applying swine-waste manure and acre density, and total generated PAN for each watershed site. The poultry CAFO attributes available for examination with the classification tree analysis were limited to the total number of identified poultry CAFOs, total poultry barns, and poultry barn density for each site. Results of the classification tree analysis, including the splits in the tree model, the selected environmental variable and value defining each split, and the response category with the number of sites classified in each category, are illustrated in figure 14 and summarized in table 15.

Table 15. Classification tree model results for the 49 study sites.

[#, number; <, less than; ≥, greater than or equal to; >, greater than; mi^2, square mile; %, percent; na; not applicable]

Split	Predictor variable and split value	Response category (# of sites)	Number of misclassified sites	Identity of misclassified sites (actual category)
1	Total active swine CAFOs < 1	Background group (18)	0 of 18	na
1 2	Total active swine CAFOs ≥ 1 Swine barn density > 2.9 barns/mi^2	Manure-influenced group 1 (15)	0 of 15	na
1 2 3	Total active swine CAFOs ≥ 1 Swine barn density < 2.9 barns/mi^2 Wetlands > 14.4 %	Similar to background group 1 (7)	0 of 7	na
1 2 3 4	Total active swine CAFOs ≥ 1 Swine barn density < 2.9 barns/mi^2 Wetlands < 14.4 % Total acres available for applying swine-waste manure > 52.4	Manure-influenced group 2 (5)	0 of 5	na
1 2 3 4	Total active swine CAFOs ≥ 1 Swine barn density < 2.9 barns/mi^2 Wetlands < 14.4 % Total acres available for applying swine-waste manure < 52.4	Similar to background group 2 (4)	1 of 4	SP-10 (Manure influenced)

The tree model selected the presence/absence of active swine CAFOs, swine barn density, percentage of wetlands, and acres available for applying swine-waste manure as the best discriminators, or predictor variables, for classifying the study sites among the background, similar to background, and manure-influenced response categories or groups (fig. 14; table 15). The model was highly successful in accurately classifying the sites into the appropriate response categories. Only 1 of the 49 sites was misclassified (table 15). The first, or primary, split in the tree model was based on the presence/absence of active swine CAFOs in the watersheds (fig. 14). All 18 of the BK sites were placed in the background group because none of the BK sites contain any active swine CAFOs.

Interestingly, the 15 SW sites and 16 SP sites, which all had at least 1 active swine CAFO, were further differentiated into two groups for the manure-influenced category (referred to as manure-influenced groups 1 and 2) and two groups for the similar to background category (referred to as similar to background groups 1 and 2) on the basis of subsequent splits in swine barn density, percentage of wetlands, and total acres available for applying swine-waste manure (fig. 14; table 15). The splits among these four groups indicate how variations in these particular swine CAFO and land-cover variables may inhibit or promote the ability of the watersheds to mitigate manure effects on water quality in streams receiving inputs from swine CAFO application fields.

When swine barn density in the watersheds was greater than 2.9 barns/mi^2, 15 sites (7 SW and 8 SP sites) with measurable CAFO manure effects on water quality were correctly placed in manure-influenced group 1 (fig. 14). The SW and SP sites in manure-influenced group 2 and similar to background groups 1 and 2 all had swine barn densities that were less than 2.9 barns/mi^2 (fig. 14; table 15). Seven sites (4 SW and 3 SP sites) without measurable CAFO manure effects on water quality were correctly placed in similar to background group 1 when the amount of wetlands in the watershed was greater than 14.4 percent. In comparing manure-influenced group 1 to similar to background group 1 (fig. 14), the SW and SP sites with measurable CAFO manure effects had higher swine barn densities (median of 4.8 barns/mi^2), more acres available for applying swine manure (median of 243.7 acres), and less wetlands (median of 12.1 percent) relative to the SW and SP sites without measurable CAFO manure effects. Similar to background group 1 had lower swine barn densities (median of 1.2 barns/mi^2), fewer acres available for applying swine manure (median of 66.9 acres), and more wetlands (median of 20.8 percent).

When both swine barn density was less than 2.9 barns/mi^2 and wetlands was less than 14.4 percent, the SW and SP sites with or without measurable CAFO manure effects were separated on the basis of the total acres available for applying swine-waste manure in the watersheds (fig. 14; table 15). Five sites (2 SW and 3 SP sites) were correctly placed in manure-influenced group 2 when total acres available were greater than 52.4; four sites (2 SW and 2 SP sites) were placed in similar to background group 2 when total acres available were less than 52.4 (fig. 14). Similar to background group 2 contained misclassified site SP-10, which actually belongs to the manure-influenced category (table 15). Site SP-10 had a swine barn density of 2.7 barns/mi^2, just below the split value of 2.9 barns/mi^2, wetlands of 8.7 percent, and total available acres of 39.2, which resulted in its placement in similar to background group 2. The sites in manure-influenced group 2 and similar to background group 2 had comparable median values of swine barn density (2.2 and 2.5 barns/mi^2, respectively) and wetlands (11.7 and 8.4 percent, respectively). The primary distinction between these groups is that the total available acres for applying swine manure for the sites in manure-influenced group 2 (median of 164.1 acres) were about 5 times higher than the total available acres for the sites in similar to background group 2 (median of 34.0 acres).

The classification tree analysis, as well as the other data evaluations in this report, indicate that land-applications of waste manure at swine CAFOs had an effect on water-quality conditions in streams at many, but not all, of the SW and SP study sites. Measurable effects of CAFO waste manures on stream water quality were most evident in those SW and SP watershed study sites having lower percentages of wetlands combined with higher swine barn densities and (or) higher total acres available for applying waste manure at the swine CAFOs. Conversely, the SW and SP watersheds with stream water quality similar to background agricultural conditions were associated with lower swine barn densities combined with higher percentages of wetlands or lower total acres available for applying waste manure at the swine CAFOs.

None of the poultry CAFO attributes examined with the tree model were selected as predictor variables for identifying differences between the sites with and without CAFO manure effects. This should not be misconstrued to indicate that poultry CAFO manures do not have an influence on stream water quality but rather may be a function of the limited poultry CAFO attribute data that were available for examination, as well as the nature of the watershed sites selected for this study, which had a primary emphasis on swine CAFOs. Thirteen of the 16 SP study sites included in the classification tree analysis (appendix A7) had substantially more swine barns (ranging from 4 to 59) than poultry barns (ranging from 1 to 8) in the watersheds. These watersheds likely received larger proportions of land-applied swine manure relative to poultry litter. Additional water-quality data, as well as more detailed information on poultry CAFO attributes (such as the types and numbers of poultry raised), from watersheds only containing poultry CAFOs would allow further comparisons to swine-only watersheds to better understand whether swine manure and poultry litter have similar or different effects on water quality.

The classification tree model provides a useful approach for exploring potential CAFO manure effects in similar, small (1 to 18 mi^2) Coastal Plain watersheds where water-quality data are lacking. Potential sites could be screened on the basis of the influential watershed attributes (swine barn density, acres available for applying swine manure, and percentage of wetlands) identified by the model. Results could help water-resource managers and researchers identify streams with high potential for manure influences on water quality in order to prioritize them for further investigation and (or) targeted best management practices. The classification tree model can be refined as additional CAFO attribute information and water-quality data become available, both for existing study sites as well as new locations. The inclusion of data on specific manure-disposal practices at both swine and poultry CAFOs (including specific application fields and the frequency, timing, and amounts of applied manures) would enhance understanding of the effects of swine and poultry waste manures on stream water quality in different agricultural settings of the North Carolina Coastal Plain.

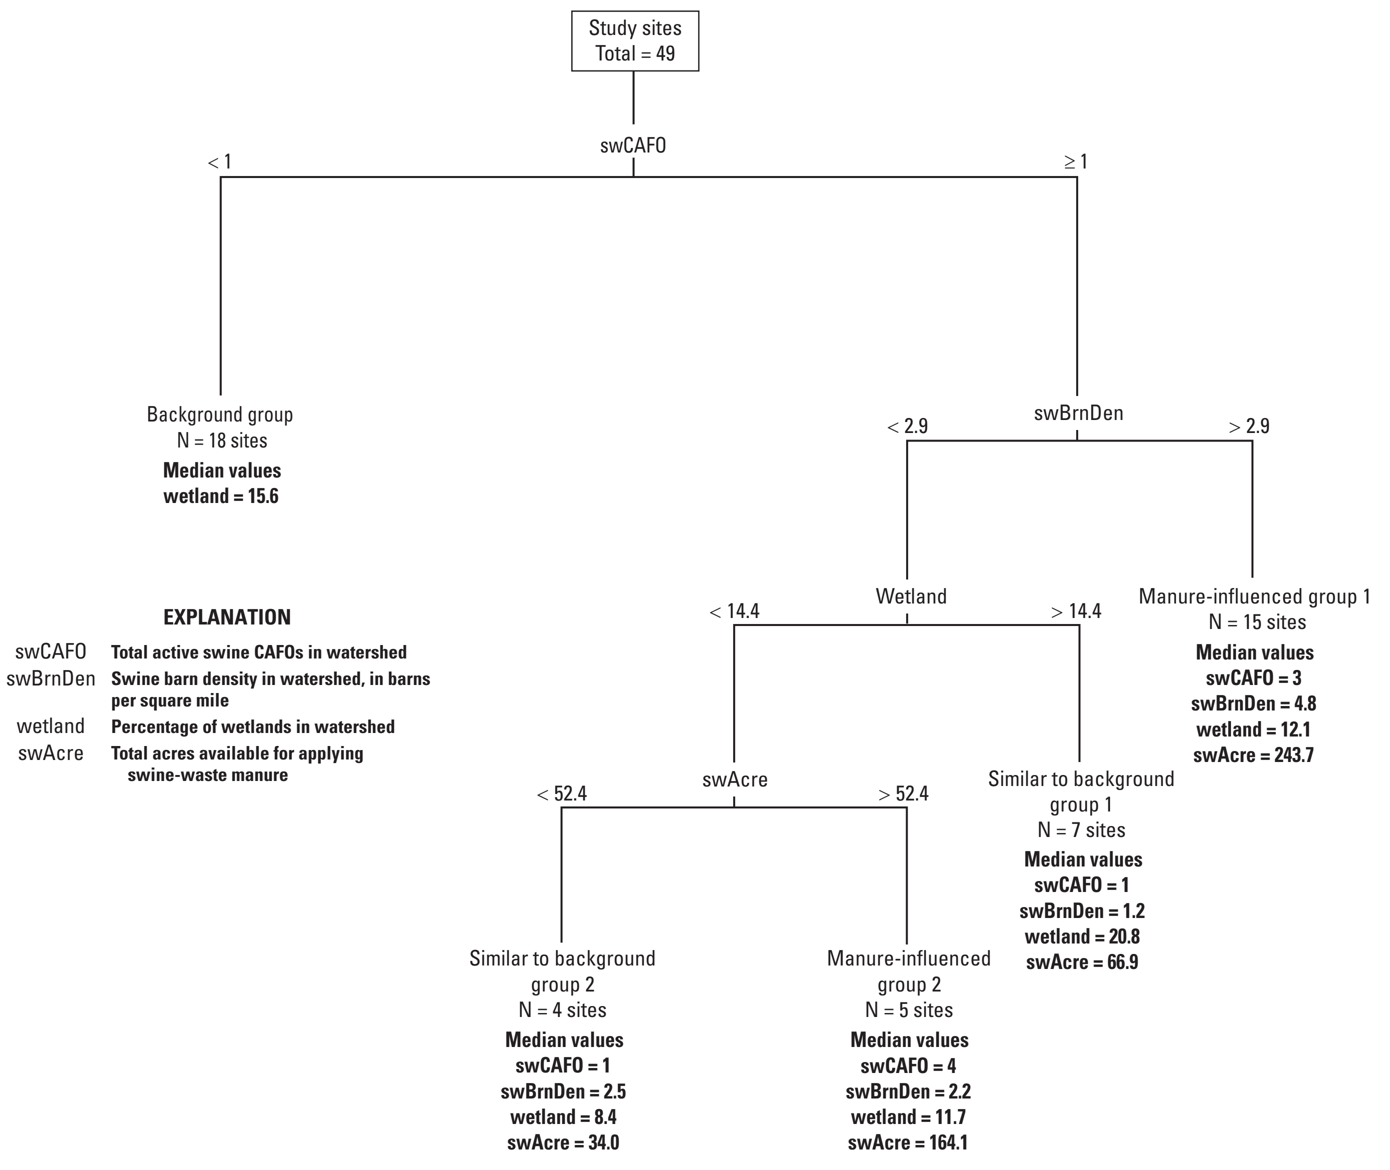

Figure 14. Classification tree model identifying the environmental predictor variables that best classified the 49 examined sites among the background, similar to background, and manure-influenced response categories.

Summary and Conclusions

Water quality was evaluated at 54 agricultural stream sites in the North Carolina Coastal Plain for the period June 2012 through April 2013. Water-quality data and detailed watershed attributes were collected, compiled, and statistically analyzed to determine differences among streams draining watersheds with and without land-applied CAFO waste manures. Three general watershed land-use types, or groups, were examined during the study, including 18 background watersheds with no active CAFOs (BK sites), 18 watersheds with one or more active swine CAFOs but no poultry CAFOs (SW sites), and 18 watersheds with at least one active swine CAFO and one active dry-litter poultry CAFO (SP sites). The watersheds had drainage areas ranging from 1.2 to 17.5 mi^2 and land cover was composed predominantly of cropland, forests, and wetlands. Most watersheds had low gradient, swampy floodplain streams that were typically characterized by slow velocities, high organic matter, and relatively low dissolved oxygen. None of the watersheds contained permitted point-source discharge facilities, cattle CAFOs, or wet-poultry CAFOs. Conventional fertilizers used for crop production were the primary source of nutrients at the BK sites. Animal-waste manures applied to agricultural fields associated with the swine or poultry CAFOs represented additional sources of nutrients at the SW and SP study sites.

Water-quality data included field measurements of water temperature, specific conductance, pH, and dissolved oxygen, and laboratory analyses of major ions, nutrients, and stable isotopes. Samples were collected at the 54 primary sites during 6 bimonthly sampling periods from June 2012 to April 2013. An additional 23 secondary sites within 9 of the primary watershed sites were sampled once during April 2013 to provide additional data at stream sites directly adjacent or in close proximity to swine CAFOs and (or) background agricultural areas. Regional precipitation and streamflow data, along with δ^2H and $\delta^{18}O$ isotopic results for precipitation and stream samples, were used to assess general hydrologic conditions during the sampling periods.

ANOVA and multiple-comparison statistical tests were performed to characterize differences in stream water quality among the six sampling periods and the three (BK, SW, and SP) watershed land-use types. Most of the water-quality properties and constituents varied significantly among sampling periods, changing both seasonally and in response to hydrologic conditions. Nutrient differences among the sampling periods indicate that the relations between seasonal climatic differences, streamflow conditions, and instream biotic and abiotic processes are complex, and their integrated effects can have varying degrees of influence on individual nutrients in different watersheds. These findings are important to consider when developing approaches to assess stream nutrient conditions in similar Coastal Plain settings and can inform the development of sampling strategies that capture seasonal and (or) hydrologic variability. For example, the highest median concentrations of dissolved oxygen and nitrate+nitrite were observed during February 2013, when higher streamflows appeared to reflect more overland contributions of nitrate from upstream field-drainage ditches. Nitrate in the field ditches is carried to the main stem of the streams during higher flows and is subject to less instream processing, including denitrification and assimilation, when stream water temperatures are colder and dissolved oxygen concentrations are elevated. Nitrate+nitrite tended to be lowest during warm and dry sampling periods, when conditions were favorable for denitrification. In contrast, median concentrations of ammonia, total organic N, ortho-P, and total P were lowest during February. Environmental factors that likely influenced the various forms and instream concentrations of the N and P constituents include assimilation and release by algae and aquatic plants, redox conditions, microbially mediated reactions, adsorption and desorption processes, and biogeochemical exchange between streambed sediment and the overlying water column.

Water quality also varied significantly among the three watershed land-use types. Median values of specific conductance, several major ions (magnesium, sodium, potassium, and chloride), and nitrogen fractions (ammonia+organic N, ammonia, nitrate+nitrite, total N, and $\delta^{15}N$ of nitrate+nitrite) were higher for the SW and SP land-use groups as compared to the BK group, which have no active CAFOs. The higher concentrations of these constituents reflect the influence of swine-waste manure storage or applications at the SW sites and swine- and (or) poultry-waste manure storage or applications at the SP sites. No significant differences in water temperature, dissolved oxygen, calcium, total organic N, ortho-P, total P, or $\delta^{18}O$ of nitrate+nitrite were noted among the land-use groups. The disparity observed between N and P response among the site groups may reflect differences in transport pathways or instream processing that influenced instream concentrations of these two classes of nutrients. When comparing the land-use groups, there was an overall measurable effect of animal-waste manures on stream water quality for the SW and SP watersheds relative to the BK watersheds; however, this does not mean that CAFO waste manures had an observable effect on water-quality conditions at every SW and SP site. Additional evaluations were performed on the water-quality data to distinguish those SW and SP sites where effects of CAFO waste manures were evident.

At the majority of individual SW and SP watersheds, measurable CAFO effects on water quality were clearly distinguished. At other sites, effects were less evident. Elevated concentrations of nitrate+nitrite did not necessarily indicate a CAFO effect; conversely, low nitrate+nitrite concentrations did not necessarily indicate the absence of a CAFO effect. An integrated evaluation of nitrate+nitrite concentrations, sodium+potassium concentrations, and stable isotopes ($\delta^{15}N$ and $\delta^{18}O$) of nitrate+nitrite was used to differentiate which SW and SP sites did or did not have a CAFO waste-manure signature.

Streams with CAFO manure effects typically had higher sodium+potassium concentrations (commonly between 11 and 33 mg/L) and $\delta^{15}N$ values of nitrate+nitrite (commonly between 11 and 26 ‰) relative to streams reflecting background agricultural conditions, which commonly had sodium+potassium concentrations between 6 and 14 mg/L and $\delta^{15}N$ values of nitrate+nitrite between 6 and 15 ‰. Denitrification affected the $\delta^{15}N$ and $\delta^{18}O$ signatures of nitrate+nitrite at some sites and must be accounted for during interpretations of nutrient sources.

As part of the evaluation, individual SW and SP sites were differentiated into two groups, including (1) those with results that were similar to background conditions, and (2) those with results reflecting CAFO waste-manure effects. Ten of the 36 SW and SP sites (28 percent) had water quality similar to background conditions. Twenty-one of the SW and SP sites (58 percent) had distinct water-quality differences, reflecting swine- and (or) poultry CAFO manure effects. Five of the SW and SP sites (14 percent) had limited or indeterminate results for determining whether they were similar to background or manure influenced; these sites were omitted from further evaluation. On the basis of the results of this study, it is apparent that land-applications of waste manure at swine CAFOs influenced ion and nutrient chemistry in many of the North Carolina Coastal Plain streams that were studied. In particular, sodium+potassium concentrations coupled with $\delta^{15}N$ values of nitrate+nitrite were useful water-quality indicators for distinguishing sites with measurable CAFO manure effects.

Relations in watershed environmental attributes among the similar to background and manure-influenced site groups were examined through classification tree analysis. The classification tree model identified swine barn density, percentage of wetlands, and total acres available for applying swine-waste manures as the best discriminators, or predictor variables, for classifying sites among the similar to background and manure-influenced groups. Variations in these particular attributes appeared to influence those watersheds where CAFO effects on water quality were either evident or mitigated. Measurable effects of CAFO waste manures on stream water quality were most evident in those SW and SP watersheds having lower percentages of wetlands combined with higher swine barn densities and (or) higher total acres available for applying waste manure at the swine CAFOs. Stream water quality was similar to background agricultural conditions in SW and SP watersheds with lower swine barn densities coupled with higher percentages of wetlands or lower acres available for swine manure applications.

The classification tree model provides a useful approach for examining potential CAFO manure effects on stream water quality among similar Coastal Plain watersheds, including those where water-quality data are lacking. The model can serve as an exploratory tool to identify watersheds that might warrant further examination and (or) targeted best management practices. The study model can be refined as additional watershed attribute information and water-quality data become available. Additional water-quality data, poultry CAFO attribute data, and information on manure disposal practices at both swine and poultry CAFOs would enhance scientific understanding of the effects of swine and poultry waste manures on stream water quality under different agricultural settings.

SEEPAGE EVALUATION OF OLDER SWINE LAGOONS IN NORTH CAROLINA

R. L. Huffman

ABSTRACT. *Thirty−four swine waste lagoon systems in North Carolina were examined for evidence of seepage losses to the shallow groundwater. All were constructed prior to the state's January 1993 adoption of stricter construction standards. Mineral nitrogen concentrations (ammoniacal plus nitrate nitrogen) were used as the primary indicators of seepage impacts. Total mineral concentrations were compared to the U.S. EPA drinking water standard for nitrate−N of 10 mg/L. The shallow groundwater on approximately one−third of the 34 systems met the EPA standard at a distance of 38 m (125 ft) downgradient from the lagoon(s).*

Keywords. *Groundwater, Lagoons, Seepage, Water quality.*

Swine production in North Carolina grew dramatically in the late 1980s and early 1990s, nearly quadrupling during that period. Virtually all of the growth involved intensive confinement systems that use wet waste handling and anaerobic lagoons. As of the beginning of 1993, state regulation required lagoon construction to meet the design standards recommended by the USDA Soil Conservation Service (SCS, changed in 1994 to Natural Resources Conservation Service, NRCS) in Appendix 10D of the *Agricultural Waste Management Field Handbook* (SCS, 1992). As of that date, well over 2000 swine waste lagoons were already in service in North Carolina (NCDENR, 1997). Many of those were sited and designed with NRCS assistance, but did not specifically include clay (or equivalent) liners as specified in the 1993 regulations.

Waste lagoons were expected to develop a seal at the liquid−soil interface that would impede seepage. Mechanisms for the phenomenon include physical clogging of pores by particulates or microbial gums and sludge (Chang et al., 1974; Barrington et al., 1987; Barrington and Madramootoo, 1989; Davis et al., 1973; Maulé et al., 2000). Many early studies concluded that the sealing effect would limit seepage to rates that would not significantly contaminate the shallow groundwater, even with sandy soils (e.g., Hills, 1976; Ritter et al., 1984; Miller et al., 1985; Rowsell et al., 1985). Some later studies found that self−sealing did not adequately control seepage on coarser materials (Ritter and Chirnside, 1990; Korom and Jeppson, 1994). Recent investigations of older, unlined lagoons in North Carolina found that about half of the lagoons studied had seepage losses high enough to exceed the drinking water standard for nitrate−nitrogen (Huffman and Westerman, 1995; Westerman et al., 1995). Those studies found that seepage problems were often localized, suggesting problems in construction where sandy lenses were not properly excavated and replaced with better materials. They reported concentrations of mineral nitrogen (nitrogen as both nitrate and ammonia) as high as 470 mg/L. Ham (2002) reported on ammonia and organic nitrogen distributions under lagoons in Kansas, showing concentrations in excess of 1000 mg/kg within the first meter and tapering off with depth. He attributed this to adsorption of the ammonia onto clays. In the stratified systems of the Atlantic Coastal Plain, where most North Carolina swine production is concentrated, nitrate from fertilizers and waste applications is very rarely observed below the first significant clay layer (Gilliam et al., 1996).

Concern for the environmental impacts of seepage have centered on excessive concentrations of nitrate−nitrogen in the groundwater. Although lagoon wastewater contains very little nitrate, the nitrogen present in seepage as ammonia, ammonium, or organic nitrogen can be converted to nitrate in the groundwater. The concern for possible groundwater contamination from lagoons prompted the North Carolina General Assembly to fund a large−scale survey of the older swine waste lagoons in the state. The survey was to extend the knowledge base by investigating a relatively large number of lagoons to see what contaminant concentrations were present in the shallow groundwater. The survey was to focus on systems built before the regulatory adoption of construction standards in 1993.

The primary objective of this survey was to determine the proportion of older (i.e., pre−1993) swine waste lagoons that pose a threat to local groundwater quality. A secondary objective was to determine whether soil textures of the upper profile (like those reported in soil surveys) could predict lagoon performance with respect to seepage losses.

Article was submitted for review in November 2003; approved for publication by the Soil & Water Division of ASAE in July 2004.

The author is **Rodney L. Huffman, ASAE Member Engineer,** Associate Professor, Department of Biological and Agricultural Engineering, North Carolina State University, P.O. Box 7625, Raleigh, North Carolina 27695−7625; phone: 919−515−6740; fax: 919−515−7760; e−mail: rod_huffman@ncsu.edu.

METHODS

The project was planned in consultation with the Groundwater Section of the Division of Water Quality of the North Carolina Department of Environment and Natural Resources. Since the focus was on systems that had been in operation for at least five years, it was assumed that seepage

  ISSN 0001−2351

plumes within the area of interest would be well developed. It was therefore agreed that a one−time snapshot, as opposed to monitoring over some period of time, would be sufficient to indicate the presence and approximate severity of seepage contamination. Estimates of time and cost per site led to choosing a target of 40 sites. With the intent of providing a statistically valid sampling of lagoons within the state, a goal was set to identify 100 candidate sites from which 40 could be randomly selected.

Site Selection

Over 2600 letters were mailed to North Carolina swine producers to solicit cooperation in this project. To be included in the project, the lagoons had to predate 1993 and have reasonable access to a distance of at least 38 m (125 ft) from the lagoon to permit sampling operations. Only 136 responses were received. Fifty−two of those volunteered to cooperate in the study. Each of those sites was visited to assess its usability. The primary considerations were accessibility for sampling operations and absence of confounding factors such as mortality burial pits. Of the 52 sites, 22 had clear access, 8 had somewhat limited access, 9 had more limited access but could be used, 5 had very limited access, and 8 had no access. Limitations to access included buildings, fences, property boundaries, and woods.

In general, owners were not able to provide information regarding the specifics of lagoon construction, so it could not be determined whether the lagoons had clay liners. Common practice during that period did not include use of clay liners, so it is reasonable to assume that the construction materials were the soils on site.

The 40 candidate sites deemed most usable were scheduled for inclusion in the study. As the work progressed, some of those sites were lost for various reasons, such as changes in ownership. Two others were volunteered that had not responded to the original solicitation. The final number of sites included in the study was 36. Most of these sites were located in the Coastal Plain physiographic province of North Carolina. Three of the sites were in the Piedmont province. At each site, a topographic survey was conducted to determine the relative positions of the lagoons, buildings, nearby surface waters, and the general shape of the land.

Groundwater Sampling

Many of the sites had systems of two or more lagoons. For sites where the sampling procedure could not isolate a particular lagoon within a system, the lagoon complex was treated as a single unit. Where one or more of the lagoons on a site was constructed under the new regulations, the study focused only on the pre−1993 lagoon(s).

In North Carolina, standard permits for industrial waste sites define a review boundary at 38 m (125 ft) from a containment structure and a compliance boundary at 76 m (250 ft). Prior to 1993, lagoons were not individually permitted, but rather deemed “permitted by regulation” if the systems met the operational criteria in the North Carolina Administrative Code (NCAC, 2004). Although review and compliance boundaries were not defined under that arrangement, 38 m (125 ft) was selected, in consultation with the Groundwater Section, as a standard distance from the lagoons for groundwater sampling.

Three or more exploratory borings were made with 114 mm (4.5 in.) augers at approximately 38 m (125 ft) from

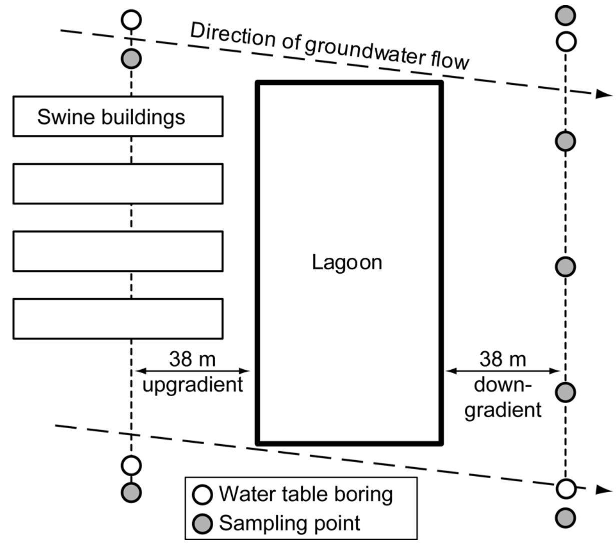

Figure 1. Layout of sampling points on a typical lagoon site.

the lagoon. Distances were measured from the interior top of the bank. The textures of cuttings were determined in the field, by feel, and recorded. Relative elevations of the water table in the boreholes were used to determine the most likely direction of groundwater flow. Once the direction of the local gradient was determined, sampling points were selected 38 m (125 ft) upgradient and 38 m (125 ft) downgradient of the lagoon. If the gradient was not well defined and the area was accessible, sample points were selected all around the lagoon(s). Buildings or other obstructions sometimes made it impossible to sample completely around the lagoons. In general, at least two sampling points were selected in upgradient positions, and four or more were selected in downgradient positions. Figure 1 shows a typical layout and how the points were chosen. Most systems were constructed on sloping land with the buildings situated upslope from the lagoon(s) to allow wastes to flow by gravity from the buildings into the lagoon(s). Since shallow groundwater generally flows in the direction of the surface slope, the gradients were usually similar to those shown in figure 1.

One of two methods was used for collecting groundwater samples, depending on the penetrability of the soils on the site. On most sites, it was possible to drive direct−push sampling probes (Diedrich Drill, Inc., La Porte, Ind.) into the

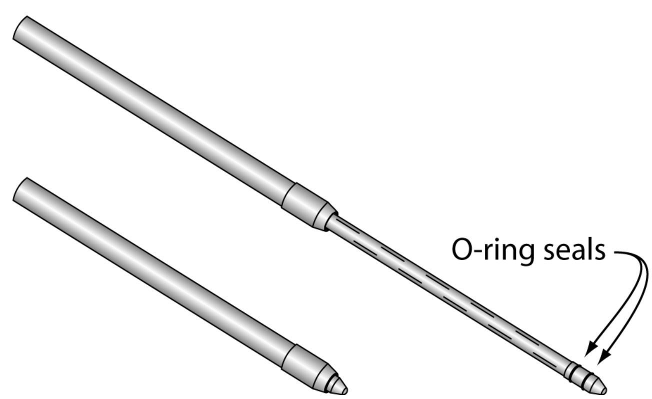

Figure 2. Direct−push tooling used for groundwater sampling. Top: slotted inner rod extended for water collection. Bottom: slotted inner rod retracted for driving to sampling depth.

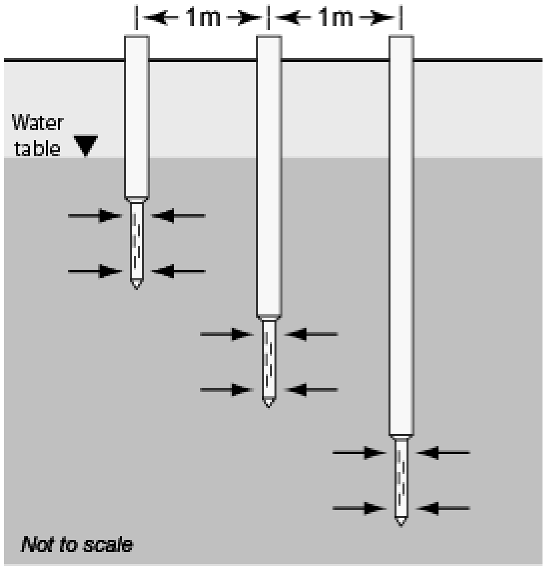

Figure 3. Profile sampling using direct−push tooling. Sample is bailed from slotted inner rod.

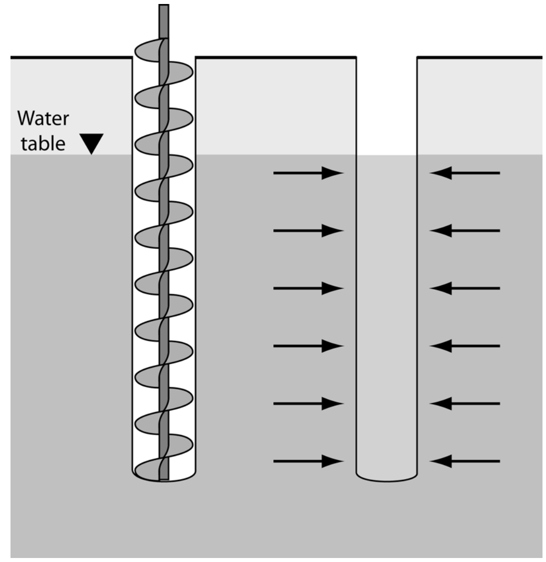

Figure 4. Auger−hole method for water sampling. Sample is bailed from open auger hole.

soil. The probes consist of a 51 mm (2.0 in.) diameter outer casing and a 29 mm (1.125 in.) diameter inner rod in 1.22 m (4 ft) sections, with drive points, shoes, and adapters. The probe assembly is illustrated in figure 2. Figure 3 illustrates sampling at multiple depths with the direct−push tooling. To avoid disturbance or interference between probes, multiple probes at one location were spaced approximately 1 m apart. The inner rod and outer casing were sealed together by two O−rings while the probe was driven to the desired depth. The inner rod was then pushed an additional 0.6 m (2 ft) to expose the slotted inner rod section. The slots were 51 mm (2.0 in.) long and 0.25 mm (0.010 in.) wide. A 250 mL sample was collected using a 12.7 mm (0.50 in.) diameter stainless steel bailer. The first flows into the sampler were collected for analysis. Tooling was cleaned between uses. The shallowest sample at a location was collected just below the water table. Additional samples were taken at 2.4 m (8.0 ft) intervals until either a restrictive layer was encountered or the capability of the drill rig was reached.

Table 1. Analytical methods.

	Method
TKN	Persulfate digestion and ammonia−salicylate method for automated analysis. Method 351.2 (EPA, 1979) with slight modifications including dialysis.
NH_3−N (ammonia)	Ammonia−salicylate method for automated analysis. Method 351.2 (EPA, 1979) or Standard Methods 418.F (APHA, 1981) with slight modifications including dialysis.
NO_3−N + NO_2−N (nitrate + nitrite nitrogen)	Cadmium reduction method for automated analysis. Method 353.2 (EPA, 1979), Technicon Industrial Method No. 100−70W (1973), or Standard Methods 418.F (APHA, 1981) with slight modification including dialysis.
Cl (chloride)	Ferricyanide method for automated analysis. Method 325.2 (EPA, 1979) or Standard Methods 407 D (APHA, 1981) with slight modifications including dialysis.
pH	Electrometric method. Method 150.1 (EPA, 1979) or Standard Methods 205 Conductivity (APHA, 1981).

The second method was used at eight sites because the resistance of the soil to the probes was so great that they could not be driven to the desired depths. In those cases, a hole was augered to about 1.5 m (5 ft) below the water table and a water sample was bailed from the open hole (fig. 4). This method limited sampling to only one sample for each location rather than the vertical profiles possible with the direct−push probes. Samples were collected as soon as there was sufficient water in the holes to permit bailing. Although it was less informative, sampling from auger holes was sufficient to indicate whether seepage was present in the shallow groundwater.

All samples were immediately placed on ice and delivered to the Environmental Analysis Laboratory in the Department of Biological and Agricultural Engineering at North Carolina State University. The analytical methods used are listed in table 1.

Seepage Classification

Anaerobic swine lagoons are strong sources of ammoniacal nitrogen. Most of the nitrogen present in the wastewater is in an ammoniacal form (NH_3 or NH_4^+). A minor fraction (typically about 20%) is in organic forms. Nitrate−N is not present in anaerobic lagoons in significant concentrations (Westerman et al., 1990; Barker et al., 2001). Where seepage rates were high, ammoniacal nitrogen was usually present in the shallow groundwater at concentrations well above the typical background concentrations, which are less than 1 mg/L (Spruill et al., 1996). Where ammoniacal nitrogen dominates, conditions are not conducive to complete conver−

sion to nitrate (NO_3^-). This is probably due to a combination of high seepage and limited oxygen availability in the saturated sediments. High ammonia concentrations may also be toxic to nitrifying bacteria (Westerman et al., 1995). Where nitrate is the dominant form, the oxygen supply is sufficient to permit nitrification of the ammoniacal nitrogen in the seepage.

Assessments of seepage were based on the sum of ammoniacal nitrogen and nitrate nitrogen concentrations. These two forms represent the major forms of mineral nitrogen present in the groundwater. Samples were also analyzed for total Kjeldahl nitrogen (TKN), which represents the sum of ammoniacal nitrogen and organic nitrogen. In anaerobic decomposition, such as occurs in lagoons, organic nitrogen is converted to ammoniacal nitrogen. In the presence of sufficient oxygen, ammoniacal nitrogen can be converted to nitrate nitrogen, which is the form that is most mobile in groundwater. Concentrations of either mineral form of nitrogen in natural groundwater are typically less than 1 mg/L. Most of the mineral nitrogen applied to agricultural fields, whether by manure, wastewater, or commercial fertilizers, appears in the nitrate form after a short period of time. Concentrations of 5 to 15 mg/L nitrate−N are common in the shallow groundwater under agricultural fields (Krider, 1986). Chloride (Cl^-) concentration is sometimes used as a seepage indicator (Ritter et al., 1984; Westerman et al., 1995; Ham, 2002) and was also evaluated. Since the chloride−based indications were very similar to the nitrogen−based indications, only the nitrogen−based results are presented here.

The U.S. Environmental Protection Agency’s drinking water standard for nitrate−N is 10 mg/L. There is no standard for ammoniacal nitrogen, but since it is readily converted to nitrate−N under favorable conditions, it was included with nitrate−N in these assessments.

Each site rating was based on the difference between the minimum upgradient concentration and the maximum downgradient concentration of mineral−N. This method gives the most severe rating because it does not average in samples that may have been taken above, below, or to the side of a seepage plume. Concentration differences were used to isolate the nitrogen contributed by lagoon systems from nitrogen contributed by upgradient sources, such as agricultural fields. The concentration ranges for the various classes for seepage evidence are given in table 2.

Results

The goal of randomly selecting 40 study sites from a large pool of candidates could not be met because the number of volunteered sites was too small. However, the 36 sites included in the study provide a reasonable representation of the types of conditions and performance of older lagoons in the state. The conditions and performance observed in this study were very similar to those found in earlier work (Huffman and Westerman, 1995; Westerman et al., 1995).

Shallow rock was encountered at two of the 36 sites, both of which were located in the Piedmont. Attempts to drill into the rock with the available equipment were unsuccessful. Since groundwater samples could not be collected, it was not possible to assess the seepage characteristics of those lagoons. Seepage assessments were therefore completed on only 34 sites.

Table 3 presents physical and operational characteristics of the sites, along with the results of the groundwater analyses. For each of the 34 sites, the means and ranges of mineral nitrogen concentrations are shown for both upgradient and downgradient locations. On 16 sites, the maximum upgradient nitrogen concentration exceeded 10 mg/L. One of those had a mixture of woods and fields upgradient. The remaining 15 had agricultural fields upgradient.

A statistical analysis of the results shown in table 3, using the maximum difference between upgradient and downgradient mineral nitrogen concentrations as the response variable, did not find any significant predictors among the variables Type of Operation, Size of Operation, Age of Operation, Lagoon Surface Area, or Average Water Table Depth.

The seepage classes at 38 m (125 ft) downgradient are summarized in table 4. Seven of 34 sites (21%) ranked as None or Weak. Eleven of 34 (32%) ranked as Moderate. Sixteen of 34 (47%) ranked as Strong or Very Strong.

County soil surveys provide descriptions of the upper 1.5 to 2.4 m (5 to 8 ft) of the soil profile. It would be useful if the appropriateness of a site for lagoon construction could be predicted on the basis of the soil type. To examine the relationship between soil texture and seepage classes, textures in the upper 1.5 m (5 ft) of the soil profile and seepage classes at 38 m (125 ft) downgradient were compared, as presented in table 5. As can be seen from the wide ranges of textures in the various classes, the textures in the upper 1.5 m of the soil profile do not provide a good indication of seepage containment.

Table 4. Summary of seepage classes at 38 m (125 ft).

Seepage Class	Number of Lagoons	Percent
None	5	15
Weak	2	6
Moderate	11	32
Strong	7	21
Very Strong	9	26
Total	34	100

Discussion

Sites ranked as either None or Weak were judged very unlikely to present any contamination problem. They contributed less than 10 mg/L mineral−N to the shallow groundwater. Sites ranked Moderate or higher could present problems if the shallow groundwater was extracted for use.

While sites ranked Moderate or higher would not meet EPA drinking water standards, they do not necessarily require corrective action. All of the lagoons in this survey were positioned on the landscape such that the seepage plumes moved toward areas where direct use of the shallow groundwater was very unlikely. Many are positioned immediately upgradient from woodlands or swamps that can assimilate modest nutrient loads. In some cases, there were streams nearby where the plumes would discharge with the natural flow of the shallow groundwater and be greatly diluted. Before requiring remedial action, consideration should be given to the affected area and whether adverse impacts actually exist. In a case where seepage losses are excessive and the plume has an actual adverse impact, corrective action should be taken. If a plume does not have an actual adverse impact at present, but the owner can foresee the possibility of future problems, corrective action would be prudent.

While inspection of tables 3 and 5 suggests a general trend toward higher mineral nitrogen concentrations on sites where sandy soils (s, sl, ls) were observed (1410, 1954, 4551, 4589, 6726, and 7225), there were lagoon systems on locations with sandy soils (fsl, sl) that showed little evidence of seepage (1116, 2757, and 3914). Conversely, some systems on locations with clayey soils (scl, cl, sc, c) had strong indications of seepage (3200, 3933, 4547, 4649, 5827, 7286, 7940, and 8971). The weakness of the relationship between seepage performance and textures in the upper profile can be explained in part by the fact that lagoons were often constructed in and with soil materials that were deeper than those that would be described in soil surveys. Clayey horizons that typically underlay sandy surface horizons in the Coastal Plain could have been used in lagoon construction. Soil textures may also vary dramatically, both vertically and horizontally, within the range of distances that are typical of lagoon dimensions.

On some sites, high concentrations were observed across much of the downgradient area, giving evidence of a broad plume. On other sites, high concentrations were found in only a few samples, suggesting a narrow plume that may have been the result of transport through sandy lenses that were not properly excavated and patched during lagoon construction.

Table 5. Soil textures observed in upper 1.5 m (5 ft) on sites in each seepage class.

Seepage Class	Soil Textures in Upper 1.5 m of the Soil Profile
None	Fine sandy loam, sandy clay loam, clay loam, silty clay loam, silty clay.
Weak	Sandy clay, clay loam.
Moderate	Sand, loamy sand, sandy loam, loam, clay loam, sandy clay, silty clay, clay.
Strong	Sandy loam, sandy clay loam, clay loam, sandy clay, clay.
Very strong	Sand, loamy sand, sandy loam, loam, sandy clay loam, clay loam, sandy clay.

Detailed reports for all sites, including site layout, sample locations, and analytical results, are in Huffman (1999).

CONCLUSIONS

Approximately one−fifth of pre−1993 swine waste lagoon systems in this survey contributed less than 10 mg/L mineral−N to the shallow groundwater at a distance of 38 m (125 ft) downgradient from the lagoons. Although four−fifths of the systems showed heavier loadings to the shallow groundwater, none of the systems in this survey were positioned in the landscape such that the seepage plumes represented an immediate hazard to groundwater users.

Lagoons constructed on sites with coarse−textured soils were expected to have higher seepage losses than those constructed on sites with fine−textured soils. Although the data suggest a very weak correlation between soil texture in the upper 1.5 m and seepage losses, soil textures in the upper 1.5 m of the profile were not good predictors of lagoon seepage performance.

A follow−up study was initiated to examine the variability of plume strength with distance from the source. It will be reported in a later article.

Introduction

The swine population in North Carolina increased from approximately 2.5 million in 1990 to 10 million in 1998 and went from being raised on small independent farms to large intensive livestock contract operations. More hog intensive livestock operations (ILOs) result in more hog waste concentrated in a specific area. The waste is first stored in a confinement or growing house and then flushed and pumped into a nearby lagoon. The wastewater is periodically sprayed onto fields. Odors from such operations emanate from the confinement houses, the lagoons, and the spraying fields. Generally, the odors coming from the confinement houses and some phases of the spraying operations are the most intense. The growth of the hog population is concentrated in the southeastern part of the state. Two counties, Duplin and Sampson, account for approximately four million hogs or forty percent of the state's hog population and rank as the number one and two hog producing counties in the United States. The sudden growth of swine intensive livestock operations (ILOs) resulted in increased community complaints particularly about the problems associated with hog waste. Citizens were concerned with the industry's impact on the health of nearby residents, the environment, and the overall quality of life in the community.

Neighbors of hog intensive livestock operations, especially those affected by the odors, have been especially vociferous at public meetings (Schiffman, 1998). Concerns about human health include exposure to odors; waste; resulting flies; poor air quality; and the contamination of drinking water supplies. Environmental concerns include groundwater and surface water contamination, air pollution, and the overloading of nutrients and heavy metals on soils where hog waste is applied. Citizens comment before boards of health that their health is negatively impacted and their quality of life is degraded. Dr. Hervy B. Kornegay, Sr., MD, who serves as Chair of the Duplin County Board of Health, reports, "Such a correlation is medically difficult to prove and document, but it is certainly perceived." (Kornegay, 1998) Citizen concerns in the counties with major swine livestock operations, such as Duplin and Sampson counties, and major processing plants, as in Bladen County, include increased truck traffic especially at night, dead animals sitting in the hot sun awaiting pick-up and then exploding when dumped in the hauling truck, and resulting animal waste on the road from alive and dead hogs. Community health issues associated with the hog industry embody concerns about the workforce, and pre-existing health problems they have, who are drawn to the area due to employment opportunities at the operations and the slaughterhouses. There is a high turnover rate of the workforce (Cooper, 1997). Many who work at such facilities are immigrant workers who suffer high rates of tuberculosis and HIV infection, especially among young Hispanics (Kornegay, 1998).

Researchers are challenged to determine what the impacts of the hog industry are, especially as it pertains to human health. Few studies have been conducted to determine the health effects for residents living near swine intensive livestock operations (ILOs). Most research has focused on the more direct consequences that workers face in the confinement houses and processing plants. Two recent preliminary studies have looked at the impact on the physical and mental health of nearby residents. These studies need to be conducted with larger study populations to validate their preliminary findings. Additionally, research is needed to see if some of the anecdotal findings as reported in the media, such as the effect of hog odors on asthmatics, can be substantiated through rigorous health studies. This paper summarizes the issues pertinent to human health that are raised by people and pigs living in proximity to each other. Section One includes research findings and information related to air issues. This section contains specific concerns for the health of workers employed in the hog industry; the effect on the physical and mental health of neighbors to hog ILOs; and some preliminary concerns for asthmatics living in proximity to such operations. Section Two covers the groundwater issues associated with hog ILOs and the related health concerns of consuming water contaminated with nitrates. Section Three includes some of the surface water issues that appear to be related to high nutrient waters. Section Four contains information about infectious disease concerns for workers and neighbors to such hog operations. In Section Five the findings are summarized and recommendations made.

Section One: Air Quality

Livestock air emissions and the resulting odors are not new to eastern North Carolina. The countryside is dotted with hog, turkey, and poultry operations. In 1998, the state ranked number 2 in the nation in hog production, number 1 in turkeys, and number 4 in poultry. The number 1 and 2 hog producing counties in the nation, Duplin and Sampson counties, are also number 1 and 2 in the nation in turkey production. The two counties have a combined hog population of 4 million and 22.4 million turkeys (NC Dept. of Agri., 1998). Although all livestock operations generate smell, odors are most intense from the large hog intensive livestock operations. These operations are wet-based waste management systems with water used to flush the waste periodically from the growing houses. Poultry and turkey are dry-based waste management systems. The dry litter helps absorb some of the volatile organic compounds (VOCs) which result in less VOCs transported to the atmosphere.

1.1 Physical Health Effects for Workers in Swine Intensive Livestock Operations

Thousands of gases and/or particles are emitted from swine intensive livestock operations. These gaseous emissions are of particular concern for workers at such facilities. The health issues are well-documented (Donham, et al., '84, '85, '90, '93). They include: scratchy throat, morning phlegm, cough, burning eyes, wheezing, shortness of breath and chronic bronchitis. Additionally, workers in swine confinement houses are found to experience increased organic dust syndrome (Rylander et al., 1990). The primary gases and particles emitted by such operations are: ammonia, carbon monoxide and dioxide, hydrogen sulfide, methane, dust, organic dust, and endotoxins (Donham et al., 1985). Bacteria are present in the hog dust that consists mostly of hog epithelium. Endotoxins are the primary lipid component of the outer membrane of Gram-negative bacteria (Donham, 1986) and are the cause of chronic respiratory symptoms of workers employed in swine containment facilities. The odors are generated by a mixture of fresh and decomposing feces, urine, feed, the animals themselves, and dead hog carcasses.

Worker health issues have become more pronounced as hog production has increased in scale and moved to large, closed confinement growing houses, a trend which started in the 1960s in the United States (Donham, 1993). Compared with the older conventional livestock houses, confinement buildings are more enclosed and tightly constructed, which results in the trapping and recirculation of air. The ILOs house a larger number of animals per house than in the older hog houses and typically confine from 800-1200 in each house in North Carolina. New operations constructed in the West, such as Utah, by North Carolina integrators can house from 3000-4000 hogs in one structure. The animals are grown in small tightly packed areas within the house, where they are in constant contact with each other. One of the reasons for housing the hogs in multiple structures is when there is a disease outbreak, it can hopefully be contained in the one structure and not spread to all the animals at the ILO.

Hogs are kept in such structures 24 hours a day for the duration of their life, approximately six months, until they are ready for shipment to a slaughterhouse. Such buildings are usually heated and ventilated and animal waste is disposed of through a mechanized system. Animals stand on cement floors with openings. The excrement of the animal is pushed through the openings after the animal lays on top of it. The waste sits in storage areas below the animals and is emptied periodically- sometimes only every few days. The air environments of such closed hog growing structures with up to 1200 animals located in a single house are more contaminated than in houses which are more open and where less animals are kept.

Poor air quality in the confinement structures is of concern to worker exposure, but likewise to animal health and productivity. Some growers may be more inclined to make structural changes to the houses knowing that their hogs will produce more efficiently. Swine grow faster and are therefor more productive in confinement structures with better quality air (Donham, 1990, 1993). Dr. Donham stated, "Advising this fact to a swine producer may be the most expedient way to create environmental improvement that would help the person as well as the animals in the building."(Donham, 1993)

The first study of worker health issues resulting from employment in hog confinement houses was published in 1977 by a team of Iowa researchers (Rylander et al., 1989). Workers employed in such hog growing structures are exposed to both dust and gases which can be harmful to human health (Donham, 1990). Of the off gases in such facilities, ammonia is most likely to exceed the Threshold Limit Value. Most gases emitted are in small amounts, well below Threshold Limit Values. The mixture of over 400 gaseous compounds (Schiffman, 1996) represents a potential health threat for the 400,000 workers employed in swine confinement buildings. The gases can on occasion reach acutely toxic levels during manure agitation, ventilation failure, or the malfunction of heating units.

The nature of the gases and their intensity depend on multiple factors: the age of the animals, time of year, management practices, ventilation, how and what animals are fed, how well the facility is managed, and most importantly how the animal waste is handled including frequency of wash (Donham, 1993). William Smith, the Health Director in Robeson County, North Carolina, described the importance of the waste options available to hog producers and the consequent impact on workers who spend hours a day in such structures but also the odor impact on nearby residents living downwind. Mr. Smith said a facility that does not frequently flush the waste out of the building is like a large family where everyone uses the same toilet that is only flushed once a day, or even every few days. He compared this to a family whose members flush the toilet after each use. An equivalent swine waste management system, developed by such companies as Awash, involves a continuous flush of hog feces and urine into a waste lagoon and thereby cuts down on odors and gases that might build up in the confinement houses.

When studying worker health response to employment in hog ILOs, it was found that cough and phlegm were the most common symptoms and were experienced by 12-55% of the workers (Donham, 1990) depending on the particular ILO facility studied. Chest tightness, coughing, nasal and eye symptoms can occur within 30 minutes of entering the confinement structures but typically require two or more hours of exposure. Symptoms usually disappear after one to two days, however, they can persist for long-term employees. Worker symptoms in response to employment in swine growing houses are more frequent and severe among smokers and by those who work in the larger swine operations. Health effects are also greater among those with pre-existing respiratory problems, such as hay fever and bronchitis, and among those with heart trouble or allergies.

A small percentage of the cases of workers experiencing symptoms are thought to be specific allergic-mediated illnesses, such as asthma, and the rest fall into chronic inflammatory reactions. In a Swedish study, hog farmers indicated reported symptoms that included throat irritation (28%), eye irritation (25%), and nose irritation (25%) (Rylander et al., 1990). Of particular concern is worker exposure in the confinement houses to hydrogen sulfide. At high concentrations the gas has toxic properties and can result in sudden collapse and associated respiratory paralysis and pulmonary edema and even death. Research conducted by an international team of scientists involved in clinical and epidemiological investigations of 2000 workers in five countries found symptoms of acute and chronic airway inflammation were common in addition to organic dust toxic syndrome.

In addition to immediate symptoms, workers can experience delayed reactions up to six-hours after working in the confinement buildings. This is true after exposure to especially dusty operations, involving the handling, moving or sorting of animals. Called organic dust toxic syndrome (ODTS), symptoms can include fever, malaise, muscle aches and pains, headache, cough, and tightness of chest. Some moderate pulmonary function changes were found. (Rylander et al., 1989)

Chronic health effects, such as bronchitis, is experienced by 25% of all swine confinement workers (Donham, 1993). Chronic bronchitis is found more than twice as frequently in workers in confinement buildings as those who work in conventional swine growing units. Symptoms related to chronic bronchitis include chronic cough, excess production of phlegm, and sometimes chronic wheezing.

Some workers, once removed from working in the confinement buildings, are still symptomatic two or more years later. However, most, especially nonsmokers, become asymptomatic after a few months. Long-term lung damage may be occurring as seen in lower flow rates. Pulmonary function decreases during the workday. The severity of chronic bronchitis increases with workers with a longer history in confinement units. The air in the confinement units does not cause asthma, however, exposure to the dust particles exacerbates asthmatic symptoms. Although the health effects for workers in swine ILOs has been well documented, the impact on neighbors has only been studied recently and so is less well understood.

1.2 Physical Health Effects for Neighbors to Hog ILOs

Neighbors of hog intensive operations have reacted to the noxious and unaesthetic air quality generated by the ammonia and hydrogen sulfide associated with the waste. Given the low concentrations of the gases, some believed that there was no significant risk to health and the odors represented more of a degradation of quality of life (Swinker, 1998) than a present health threat, even though those two can be hard to separate out. Swinker points out that it is difficult to distinguish health effects possibly caused by swine ILOs versus other human or agricultural activities. All possible contributing factors should be considered before describing and ascribing a causal relationship associated with swine ILOs. Further research is needed to determine the exact impact of the industry. A preliminary Iowa study described below (Thu et al., 1997), however, found that there are health effects associated with living adjacent to such operations.

A recently completed preliminary health study in Iowa (Thu et al., 1997) suggested that there were physical health effects for neighbors of hog intensive livestock operations. Ammonia, dust, and endotoxin were found in air samples taken downwind of a large-scale swine operation. The health study indicated that symptoms for near-by residents are similar to those found for workers in the confinement houses only less severe and less frequent (Thu et al., 1997). Residents in Iowa who lived within two miles of a 4000 sow production facility were interviewed in their homes. This facility was one of the largest sow operations in Iowa. Neighbors were asked to complete a survey concerning their physical and mental health status. They were also asked open-ended questions about their impressions of the impacts of the hog industry on the community and quality of life. Standard socio-demographic information was collected.

The particular operation was selected for study based on its size and the fact that some neighbors had expressed environmental and health concerns. Responses of residents living near the operation were then compared to a control group. The selection of a controversial operation for study may have biased the results. The study of neighbors of the largest sow operation in the state would give results that may represent the worse case scenario. Results indicate that residents living within two-miles of the operation reported significantly higher rates of four types of respiratory tract problems, which represent toxic or inflammatory effects. In 14 of 18 symptoms the study population reported higher frequencies than the control group. The symptoms more frequently reported are those that are extensively experienced by swine confinement workers. Thu and Donham's 1997 study found increased symptoms in four interconnected symptom clusters. The symptoms correlated well with those reported in the open-ended questions queried earlier in the interviews.

CLUSTER	SYMPTOMS
Cluster One	Sputum, Cough, Breath Shortness, Chest Tightness, Wheezing
Cluster Two	Nausea, Dizziness, Weakness, Fainting
Cluster Three	Headaches and Plugged Ears
Cluster Four	Runny Nose, Scratchy Throat, Burning Eyes

The first cluster shows interrelated symptoms that indicate inflammation of the bronchi and bronchioles, or chronic bronchitis and hyperactive airways. The particular kind of bronchitis experienced is often associated with environmental exposures. Figure 1 below shows that for most symptoms, the neighbors of the sow operation indicated more health problems than the control group. In the first cluster of inter-related symptoms, increased sputum was most pronounced in the study group.

The inter-related symptoms included in the second cluster are those that are commonly found in employees of swine operations. Residents living near the studied operation reported significantly higher rates for nausea, dizziness, weakness, and fainting, than the control group. Further study is needed to determine the effect of long-term exposure to lower than toxic levels of Endotoxins and hydrogen sulfide. The component gases associated with the air emissions from swine ILOs are individually well below federal standards. However, over 400 compounds have been found in the air, manure, and lagoons on hog farms. The compounds include acids, alcohols, aldehydes, amides, amines, aromatics, esters, ethers, inorganic gases, hydrocarbons, halogenated hydrocarbons, ketones,

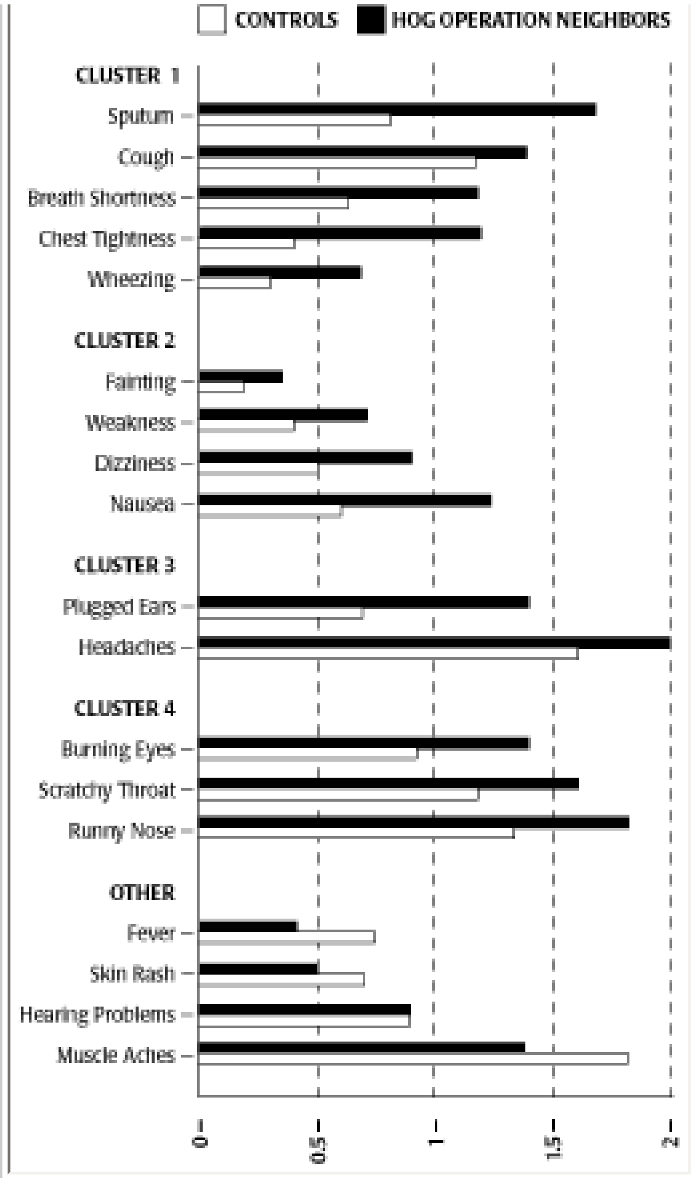

Fig.1. Frequency of physical symptoms experienced by rural residents*(comparison of mean scores, 0=Never, 4=Very Often).*

nitriles, nitrogen heterocycles, phenols, sulfides, mercaptans, and steroids (Schiffman, 1996). The compounds found both in North Carolina and elsewhere tended to be standard volatile organic compounds (VOCs) as associated previously with animal waste. Sixty percent of the compounds found in NC were not found elsewhere. More VOCs were found in NC than reported in other states. This can be explained by: the sensitivity of the gas chromatography testing methods used, temperature conditions in North Carolina, and chemical sprays mixed with the air and lagoon samples were included in the test.

Federal and state standards are only set for one gas at a time and standards have only been determined for a few hundred gases. One hundred and five air toxics are covered by state regulations and 189 by federal regulations, with an overlap between the two of approximately 85 air toxins. Researchers, such as Dr. Lori Todd and Dr. Susan Schiffman, suggest that a synergistic effect of the component parts working together may be of importance and further study is indicated.

The third symptom cluster, which includes headaches and plugged ears, is also often noted by workers in the swine industry. These symptoms are frequently associated with chronic sinusitis, and are found in approximately one-fourth of all active swine producers (Donham, 1993). The final cluster of symptoms noted, which showed the least significance, included symptoms such as: burning eyes, runny nose and scratchy throat. Among swine confinement workers, these symptoms are related to mucous membrane irritation caused by irritation from gases and particulates inside the swine confinement buildings. Nasal irritation has been shown to reduce respiratory volume (Warren, et al., 1994).

The Iowa study found residents to be no more or less depressed or anxious than the control group. These findings may have been influenced by the fact that someone was interviewing the respondents which can bias toward the under reporting of mental health effects.

One of the findings of the Iowa study was, regardless of whether respondents were experiencing any physical health symptoms, that the presence of the swine facility was creating social and political problems and divisions within the community. Respondents saw the facility as a violation of core rural values of what it means to be a "good neighbor". Such values include principles of egalitarian relationships, reciprocal exchanges of neighbors helping each other in times of need, mutual respect, and sharing of information (Thu et al., 1997). Neighbors felt that the facility threatened their sense of control over their land, homes, families, and quality of life. The concerns raised by neighbors encompassed more than physical and mental health issues but were intertwined with personal, environmental, economic, and social health matters. The hog industry is seen to impact both the quality of life and way of life for rural residents living near swine intensive livestock operations. These findings are consistent with citizen testimonials at county meetings in North Carolina. In Duplin County a citizen lamented that marshalls were needed at Board of Health meetings to assure there was no violence among attendees with opposing views.

1.3 Hog ILO Odors

Odors associated with swine ILOs emanate from the confinement houses where the animals are kept, the waste storage areas including the lagoons, and the land application area. The liquid wastewater in the lagoons is periodically sprayed onto fields via spraying systems that eject the wastewater as much as 100 yards. The odors result from a combination of fresh and decomposing feces, urine, and feed. Of these, the more offensive odors emanate from the decomposition of the feces. Emissions from livestock manure include volatile organic acids, alcohols, aldehydes, amines, fixed gases, carbonyls, esters, sulfides, disulfides, mercaptans, and nitrogen heterocycles.

The inhalation of volatile organic compounds (VOCs) causes smell sensations in humans. There are four primary ways in which these odors can affect human health:

- the VOCs can produce toxicological effects;
- the odorant compounds can cause irritations in the eye, nose, and throat;
- the VOCs can stimulate sensory nerves that can cause potentially harmful health effects; and
- the exposure to perceived unpleasant odors can stimulate negative cognitive and emotional responses based on previous experiences with such odors (Schiffman, 1998).

Levels of VOCs in breath have been measured and correlate with the individual's personal air. The body is subjected to some burden as a result of non-occupational exposure to VOCs (Raymer et al., 1991). Low concentrations of multiple VOCs can result in health consequences that a single low-level VOC would not cause (Schiffman, 1998). The volatile organic compounds, which cause odors, can be absorbed directly via gas exchange in the lungs. These VOCs can reach blood and adipose tissue. For hours afterwards, people can still detect the odor as it is expelled from their bodies.

1.3.1 North Carolina Studies of Mental Health Effect

The psychological impact on neighbors of swine intensive livestock operations living in odor concentrated areas was documented by Dr. Susan Schiffman, a medical psychologist with the Duke University Department of Psychiatry (Schiffman et al., 1995). In this preliminary study of North Carolina residents, 44 people living downwind and in the odor affected area of swine operations were compared with a control group of rural people not so affected. The study of mood was considered important not only to better understand the psychological impacts but additionally because negative mood can depress the body's immune response. Unpleasant odors can thus influence physical health. Brain structures broadly involved in smell can affect immune responses. Some studies suggest that sensory stimulation of the limbic forebrain, hypothalamus, and other odor projection brain areas can directly alter immune status (Schiffman et al., 1995).

In Schiffman's study a significant difference was found (at $p < .0001$). The experimental subjects that lived within the hog odor affected area expressed significantly more tension, depression, anger, less vigor, more fatigue, and more confusion.

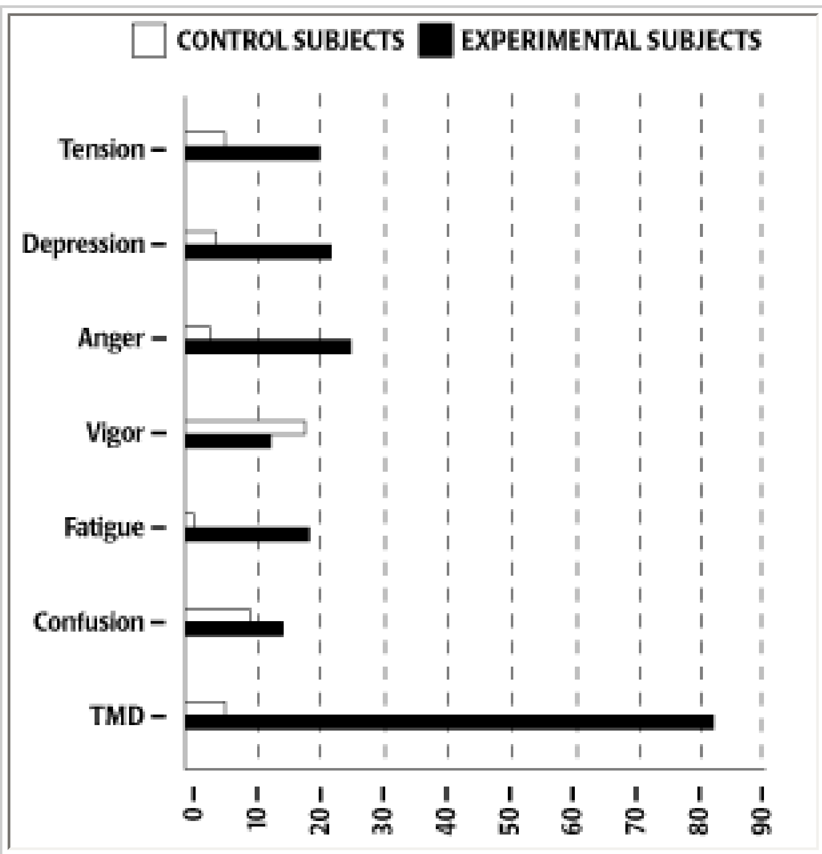

Fig. 2. Mean POMS scores of each factor and the total mood disturbance score (TMD) for experimental and control subjects.

Experimental males had significantly higher scores for anger and confusion than experimental females or control men and women. Scores for experimental females were significantly higher than control males and females.

Odors can have a lingering effect in the body. Volatile organic compounds (VOCs) are absorbed directly by the body into the bloodstream and fatty tissues by way of gas exchange in the lungs. Once absorbed these odorants are slowly released from the bloodstream via air expired from the body. When expired, the olfactory receptors are activated. Some of the compounds found in the waste plume, when absorbed in the body, can be transmitted to the brain through the nasal route (Monath et al., 1983). Some people, who are already experiencing other olfactory problems, may be more sensitive to the smell. Odors affect both the quality of outdoor and indoor air. Clothing, curtains, and building materials absorb the smell. Over time, the odor molecules are slowly released resulting in a prolonged effect from the odor even once the plume has passed over.

The effect of exposure to odors on respiratory responses has not been a subject of research interest. In part, this is due to the fact that animal studies indicate that changes in breathing patterns may require far higher chemical concentrations than are needed for detection. Recent work, however, shows that in human subjects, as opposed to animal studies, that the sensitivity of respiratory measures may not lag far behind that of perceptual measures of irritation (Warren et al., 1994).

People respond differently to the hog waste smell depending on their association with the odor. Some swine operators say the smell does not bother them and that they associate it with providing for their family. Many come from multi-generational hog farming families and see the operation and its smells as a way of life. At public hearings, owners of hog operations often say the odor smells like money to them.

But for the neighbors, often those not directly economically benefiting from the activity, they may associate the smell with unpleasant thoughts and lack of control. Strong livestock odors in one's home are considered inappropriate by most. One community activist tells the story of a birthday party for her child, when one of the children came to her and asked if she could please go home because the stink was so bad.

For others, the smell may result in environmental concerns, fear of loss of use and value of property, or an interference with the use of ones property. Some neighbors in Duplin County report being surrounded by hog confinement buildings that result in the odors from such operations being regularly present. Other neighbors report a frequency of one out of every three days that the odor affects their home with the early morning and evening as the time when the smell is usually strongest and most regular. Others may consider the smell to be a taboo odor and something that they shouldn't have to endure (Schiffman et al., 1995). As the public has learned more about the health consequences of breathing in the malodorous smell of second hand cigarette smoke, heightened consciousness can be applied to concerns about living in areas with regular exposure to the odors and air emissions from the hog operations.

Some people living in proximity to hog ILOs find conditions practicably unlivable. In a lawsuit, Parker v. Barefoot (No. COA97-713) against a Johnston County hog operation holding approximately 2,880 hogs in four hog houses and one open pit lagoon, 27 neighbors reported that fumes from the hog ILO were so noxious that at times it burned their eyes and noses, making it difficult for them to see and breathe. The stench from the lagoon was described as 'unbearable'. Plaintiffs sought injunctive and monetary relief alleging that the swine facility constituted a nuisance. In this case, the NC Court of Appeals on July 7, 1998 overturned the lower court's decision and granted plaintiffs' right to a new trial. In the earlier trial, the plaintiffs had submitted a written request for instructions to the jury that the law did not recognize as a defense to a claim of nuisance that defendants used the best technical knowledge or "state-of-the-art" technology available at the time to avoid or alleviate the nuisance. The trial court denied this request. Judge Howard E. Manning in Johnston County Superior Court entered the judgment in favor of the defendants on August 30, 1997. The appellate decision now focuses juries to the validity of neighbor's complaints of a nuisance when an operation is found to be so offensive as to have an intolerable impact on its neighbors. The offense can be great enough to affect neighbors ability to enjoy their homes. In a July 11, 1998 editorial of the *News & Observer*, the paper calls attention to the need for the state and local governments to set odor standards to protect the health and well being of neighbors of such facilities. In the fall of 1998, the NC Environmental Management Commission began work to regulate odors from hog operations.

In an odor study of NC residents (Schiffman, 1998) who did not live near agricultural operations, 68% of the subjects who were classified as 'More Sensitive' and 62% who were considered 'Less Sensitive' reported that exposure to animal odors would make them ill if exposed for 30 minutes or more.

Multiple factors can play a role in the changed mood of people exposed to odors from nearby swine operations. These factors include: the unpleasantness of the sensory quality of the odor; the intermittent nature of the stimulus; learned aversions to the odor; potential neural stimulation of immune responses via direct neural connections between odor censers in the brain and lymphoid tissue; direct physical effects from molecules in the plume including nasal and respiratory irritation; possible chemosensory disorders; and unpleasant thoughts associated with the odor (Schiffman et al., 1995).

The intermittent character of hog odors affecting neighboring properties is also an unpleasant factor. Although no one would want such strong odors to be constant, the fact that they come and go draws attention to the offense (Aitken et al., 1991). The odorant molecules associated with hog farms can cause nasal and respiratory irritation. The irritation of the nasal area can result in an elevation of adrenaline, which stimulates feelings of anger and tension.

1.3.2 Differences Between Psychological Findings in the North Carolina and Iowa Study

The Schiffman study results in North Carolina of the psychological effect on neighbors of swine ILOs differed from the findings in the Thu/Donham study in Iowa. The Iowa study found little difference in depressive and anxiety symptoms between their respondents and the control group. The authors concluded that the study population was neither suffering from anxiety related nor depressive psychological symptoms. In the Iowa study, researchers interviewed all subjects in person, which may have biased people from admitting to psychological problems. In the North Carolina study, subjects completed a written survey on their own. Most importantly, they were asked to complete the survey during an odor incident. This may have increased their attention to the event and their consequent response.

The Iowa and North Carolina studies took different approaches in selecting their study populations. Dr. Schiffman studied residents that lived downwind of swine intensive livestock operations and in the odor affected area. The Iowa study surveyed people who lived within a two-mile radius of a particular 4000 sow operation and did not limit themselves to subjects living in the odor-affected areas. The Iowa operation selected was one that had a history of community complaints. Schiffman chose people from multiple counties from across North Carolina. People living downwind and in the odor affected area of swine intensive operations experience the impacts of such operations differently from those that might live near-by but not necessarily affected by the odor (Schiffman et al., 1995).

1.4 Odors and the Effect on Asthmatics- A Potential Health Concern that Needs Researching

No research to date has focused specifically on the effect the exposure to air emissions from hog waste has on asthmatics. However, some reported anecdotal stories reveal that there is potentially a relationship and that further study is needed. People report that odor events trigger asthmatic episodes and cause severe reactions. Research does show that many odors, both those generally considered pleasant and offensive, can have an impact on asthmatics. Sir John Floyer first noted the relationship between exposure to certain odors and a response in asthmatics in 1698 in his classic, "A Treatise of the Asthma." Odors, both those generally associated positively, as in perfume, and negatively, as in waste or insecticides, have been found to cause asthmatic responses in some patients (Shim et al., 1986). Of 60 patients studied in Shim and Williams' research, 57 claimed a respiratory reaction to at least one odor. Of the particular odors that most frequently worsened asthma, the most common offender was insecticide (85%), then household cleaning agents (78%), cigarette smoke (75%), fresh paint smell (73%) and perfume and cologne (72%). The asthmatic response to odor is often severe. Of the 60 patients studied, 23 claimed that they had to make an emergency room visit, and 9 required hospitalization. Symptoms include shortness of breath, tightness of chest, wheezing, and cough.

Many clinicians seem to be unaware of the association between exposure to odors and an asthmatic response, however, most patients are aware of such a potential and have found ways to avoid the offending odors in their daily life (Shim et al., 1986). There has been an increase in the prevalence of asthma, especially among children under 18 years of age (Koren, 1995). Asthmatics are more sensitive to the effects from exposure to ozone, sulfur dioxide, particulate matter, and nitrogen dioxide. The increase in asthma rates is in part associated with air pollutants, including volatile organic compounds. One of the compounds found in hog odors is formaldehyde, HCHO, which can cause asthma-like symptoms. Further study needs to be conducted to determine if chronic exposures to both the gases and particulate matter can result in potential toxicity (Schiffman, 1998).

The response of asthmatics to certain odors is most commonly found in sensitive asthmatic patients and in those who are having difficulty controlling their disease. The asthmatic response to particular odors may result from reactions occurring in the bronchial mucosa. This response can be caused either by a direct irritant effect, from an immunologic reaction with secondary chemical mediator release or from a local neural reflex (Shim et al., 1986). Further research is needed to determine if the emissions from hog ILOs are having any effect on the health of nearby asthmatic populations.

Section Two: Groundwater Contamination and Related Health Issues

Hog waste when stored in lagoons and later applied to fields can result in nutrients and pathogens ending up in nearby groundwater. Although nutrients, such as nitrogen and phosphorus, are essential to life, in excess they can send aquatic ecosystems into disorder, as seen in the Neuse River in the New Bern area. Too much nitrogen is also of concern regarding human health. Once ingested through nitrogen-contaminated water, in the human gut nitrate is reduced to nitrite and is absorbed into the blood (Swinker, 1998). Nitrite compromises the oxygen-carrying capacity of the blood. Likewise, pathogens found in the gut of hogs can be of concern if they come into human contact. North Carolina has focused extensive resources on testing for nitrogen in groundwater but has not concurrently investigated for possible coliform contamination.

2.1 Nitrates and Drinking Water - A Concern for Human Health

Nitrates occur naturally in drinking water and in common vegetables, such as beets, celery, and lettuce. However, if the nitrates are present above a certain amount (10 ppm) they can be harmful to people who drink the water. Especially at risk are newborn infants. Nitrates can get into the drinking water from the overuse of chemical fertilizers and improper disposal of human and animal wastes. The nitrogen in the waste is converted to nitrates in the soil. The nitrates are highly soluble and move quickly and easily through soil, depending on soil type, and into groundwater and surface water. Once in the water, the nitrates can accumulate. In 1989 the NC Cooperative Extension Service conducted a one-year sampling program of rural drinking water supplies for nitrate-nitrogen, chloride, electrical conductivity and pH. Some of the samples were tested for pesticides. Of the over 9026 domestic wells tested, 3.2% exceeded the drinking water standard of 10 mg/L for nitrogen. Most of the contaminated wells were found to be poorly constructed and badly sited near areas of nutrient and pesticide application (Jennings et al., 1991).

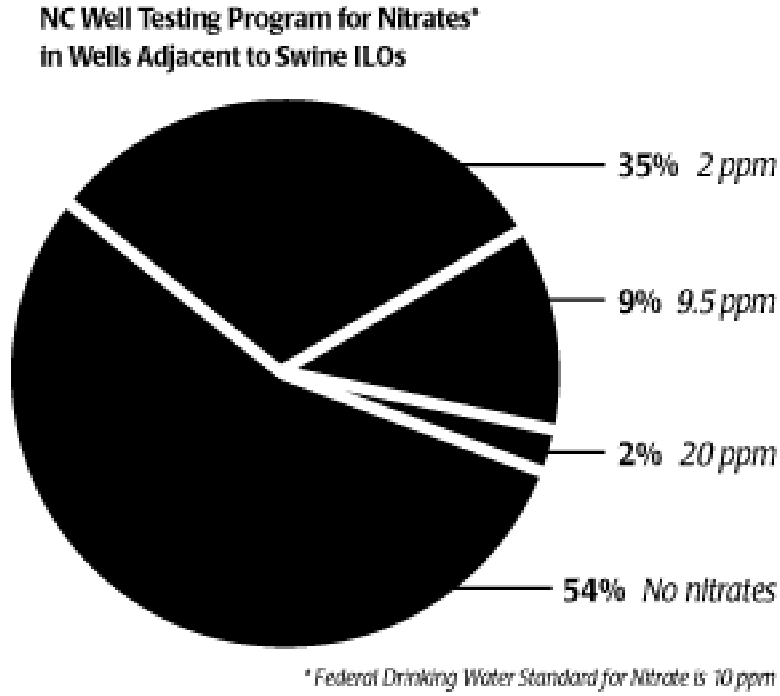
2.2 NC Well Testing Program

In 1996 NC Governor James Hunt called for a free drinking-water well testing program for nitrates in the wells of people living adjacent to hog operations. The testing was begun after several drinking water wells in Robeson County located near swine operations were found to have nitrate levels which greatly exceeded the federal drinking water standard. Dr. Kenneth Rudo, a toxicologist with the Occupational & Environmental Epidemiology Section, headed the program. By December of 1996, Dr. Rudo had tested

948 wells in 50 counties (Rudo, 1996). Approximately 9.4% of the wells tested showed levels of nitrate that were at or exceeded the nitrate drinking water standard of 10 ppm. In a 1998 memo to the new state Health Director, Dr. Dennis McBride, Dr. Rudo stated that continued testing of wells showed that approximately 10% of the wells tested had levels of nitrate that exceeded the federal standard (Rudo, 1998). Three wells in Robeson County had nitrate levels in the 70-100 ppm range. Once tested, if the water was found to exceed the drinking water standard, residents were notified of such. Testing for other possible contaminants, such as viruses, bacteria, or pesticides was not performed, nor were health studies conducted on the families who had been drinking the nitrate contaminated well water.



The following counties in North Carolina showed the highest levels of nitrates in the drinking water wells tested by the state.

Percent of wells with nitrate* levels > 2 ppm and >9.5 ppm respectively

COUNTY	TOTAL NUMBER OF SAMPLES TAKEN
Duplin (24%, 9.9%)	121
Edgecombe (34.7%, 0%)	75
Johnston (57.1%, 4.1%)	49
Robeson (39.5%, 10%)	210
Sampson (48.3%, 22.5%)	209

Potential sources of nitrate include hog waste, human waste, and fertilizers. Further study by the state is continuing to better determine the exact source of nitrate contamination. There is concern that with the explosive growth in swine operations in the last ten years that some of the problems with well-water contamination may still lie ahead, especially in Duplin and Sampson counties where the operations are concentrated. Some Duplin County residents have expressed concern about the amount of hog waste sprayed onto crops in the region's sandy soils. Other issues include that the depth of the lagoons is only slightly higher than the water table in the area, and the status

of abandoned lagoons. These are of particular concern in rural areas where considerable poor people live and often depend on shallow wells for their drinking water.

2.3 Methemoglobin An important health effect resulting from the consumption of high levels of nitrates is methemoglobinemia, more commonly known as Blue Baby Syndrome. The nitrate as it enters the body converts to nitrite which affects the hemoglobin that carries oxygen throughout the body. The hemoglobin converts to methemoglobin that does not transport oxygen as well. This results in less oxygen getting to vital tissues, and of special concern is the brain. Methemoglobinemia can produce cyanosis, dyspnea, lethargy, and coma (Swinker, 1998). If the problem is severe and not corrected, brain damage and even death can result. The syndrome was first identified in the mid-1940s and resulted in the standard for nitrate concentrations in drinking water of 10 mg/L.

Children in the first six months of life are particularly vulnerable to high nitrates because fetal hemoglobin is more reactive than adult hemoglobin. Also the flora found in the stomach of infants facilitates conversion of nitrate to nitrite. Others who are vulnerable include pregnant women, the elderly, and adults with immune deficiencies.

When nitrates are found in groundwater and the source of the contamination is animal waste or effluent from a septic tank, the well water should be additionally tested for other contaminates of concern, such as bacteria, viruses, and protozoa. If the source of nitrates is fertilizer, then the water should be tested for the presence of pesticides. When drinking water is contaminated with nitrates at levels above 10 ppm, other sources of drinking water, such as bottled water, need to be consumed. Sometimes the drilling of a deeper well into a non-contaminated water source may provide the best solution if financing is possible. However, if the nitrate contamination is widespread in a region, a public water system should be explored. Such an option is of course expensive.

2.4 Exposure to High Nitrates and Possible Link to Reproductive Health Difficulties

Research suggests that there may be a link between the consumption of nitrate-contaminated water and human health effects including increased risk of delivery of an infant with a central nervous system (CNS) malformation (Arbuckle et al., 1988) and reproductive problems (MMWR, 1996). Three women in Indiana who lived in close proximity to each other had miscarriages a total of six times within two years. The women were all drinking well water containing high levels of nitrate, which exceeded the federal standard of 10 ppm. The women lived near a hog operation that appeared to be the source of the nitrate contamination. Other women living nearby had given birth without any problems. The women having trouble with the miscarriages all lived the closest to the hog operation. Once the women switched to bottled water they were able to have fullterm healthy pregnancies. Although it was not proven that the source of the nitrates was the hog operation, the point is that the consumption of water contaminated with nitrates appeared to have affected pregnancy outcomes. The CDC recommends that anyone drinking water from a private

well should have the water tested periodically (Meyer, 1996). Additionally, proper well construction with an emphasis on digging the wells deeper than 50 feet can alleviate many problems.

2.5 Waterborne Diseases and Well Water Consumption

Well water consumption is associated with several waterborne diseases. In the U.S. between 1991-92, 76% of the outbreaks of waterborne disease were connected to the drinking of well water (Moore et al., 1993) The total number of outbreaks has remained steady, however, new causative agents are being reported, which includes E coli 0157:H7 and Cryptosporidium (Swinker, 1998). Waterborne Cryptosporidiosis is of greatest concern when it enters municipal water treatment plants causing an outbreak of disease in the population that consumes the water. Such an outbreak occurred in Milwaukee, Wisconsin, when during the spring of 1993, over 403,000 were sickened with prolonged diarrheal illness, of which 4400 required hospitalization (CDC, 1994). Proper management of water supplies and surveillance are vital tools to the prevention of and early detection of such waterborne infectious diseases. Appropriate disposal of animal waste, including hog waste, is important in the control of Cryptosporidiosis and other infectious diseases.

2.5 Cancer and the Need for More Research

Several studies have shown an apparent increase in leukemia and brain tumors in children whose parents work in farming or in occupations where they are exposed to pesticides. A study was conducted of 323,292 children in Norway. The children were followed for a ten-year period. For children aged 0-14, there was a higher incidence of brain tumors associated with hog farming (Kristensen et al., 1996). The study, however, did not include individual exposure data and can be better used for hypothesis-generation than for drawing conclusions about risk of specific childhood cancers (Ross, 1996).

2.6 Community Concerns about Groundwater Contamination from Hog Operations- Difference Between Community Perception and Policies

Rural residents have expressed concern about the impact of hog intensive livestock operations and the impact on drinking water (Holtkamp et al., 1994). In Iowa, the number one hog producing state in the nation, 440 people completed a survey sent to residents of a two-county area in the southern part of the state. Respondents were asked to comment on their level of concern about the potential location of a new 1000 sow confinement near their home and the possible impact on groundwater.

Over 80% said they were 'somewhat' to 'seriously concerned' about the potential for nitrate contaminating their drinking water supplies. They indicated that even at a distance of five miles from a residence that they would be very concerned about the risk of contamination of their drinking water supplies. If such a facility was sited a half-mile from a residence, 77% of the

respondees said they would be 'seriously concerned' about the potential for nitrate contamination. The survey results indicate that responses were sensitive to educational level. The lower the education attainment of the respondee, the lower the concern. Overall, rural residents surveyed did indicate a strong interest in environmental issues and 58% thought it was a 'top' or 'high' national priority. Sixty percent thought it was a 'top' or 'high' priority local political issue.

Section Three: Surface Water Health Issues - Associated Issues to the Hog Industry

Increased attention and concern over the hog industry's environmental and health impacts followed the dramatic rupture of the Onslow County hog waste lagoon during the summer of 1995. This resulted in the spillage of approximately 25 million gallons of hog waste onto neighboring fields, roads, and streams, and eventually into the New River. In addition to such dramatic crisis events, waste from hog ILOs gets into surface water when it is unintentionally or illegally discharged into ditches, wetlands, and directly into streams.

Public awareness of nitrogen enrichment and the resulting eutrophication of the Lower Neuse, Cape Fear, and Tar-Pamlico river basins and the Albemarle and Pamlico sounds has focused attention on the hog industry as a major source of such nutrients (Aneja et al., 1998). The nitrogen either directly enters such surface waters from other water sources, from the runoff from ILOs, and/or through the deposition of airborne nitrogen in the form of ammonia. Ammonia emissions in eastern North Carolina are almost solely associated with intensive livestock operations, especially from hog ILOs. Testing for airborne ammonia starting in 1980 in Sampson County has shown a dramatic increase, almost a four-fold increase since 1990, in the annual mean ammonium ion concentration in rainfall (Aneja et al., 1998). Such an increase correlates with the dramatic increase in the hog population in Sampson County during that same time period.

Other sources of increased nutrients include wastewater treatment plants resulting from population growth in the Piedmont, and the residential and commercial application of fertilizers throughout the river basins. Even elementary, middle, and high schools contribute to the problem. Although the state can clearly show that there is a problem with too much nitrogen, it is less clear as to what the different sources of nitrogen are and how much they contribute. The state has called for a 30 percent reduction (Brown, 1998) in the nitrogen load of 8.7 million pounds of nitrogen that reaches New Bern, NC. The reduction plan calls for the first mandatory comprehensive environmental requirements of agricultural operations. These cumulative water contamination problems resulting in high nutrient waters, although not clearly understood, appear to be associated with the preponderance of the dinoflaggelate, Pfiesteria. The relationship between water contamination, especially nutrients, and the presence of the micro-organism continues to be studied. This micro-organism over the years has been associated with some of the major fish kills, especially in the Neuse.

There is concern about related human illness caused by exposure to Pfiesteria. Some people who

spend considerable time in the water experience skin lesions similar to those found on the fish caught in some fish kill areas. Local physicians in the area of New Bern, North Carolina have expressed concerns about the negative contribution of the hog industry on the health of their patients.

3.1 Physician Petition in Support of Hog Moratorium in Craven County

In February of 1997 seventy-five physicians of the medical staff of Craven Regional Medical Center signed a petitioning letter endorsing a one-year countywide moratorium on new and expanding hog operations for Craven County, located in eastern North Carolina. The petition was submitted at a public hearing of the Craven County Board of Commissioners. The petitioning letter read:

"We, the physicians of Craven, Jones and Pamlico counties, by our signatures on this letter, express our deepest concerns for the environment and citizens of our counties. We understand that the issues of industrial and agricultural waste disposal are complex and highly technical, while at the same time, political and intensely emotional.

Our role as physicians requires that we be vocal advocates for our patients' health and well being. We believe that the issues of agricultural and industrial waste disposal pose a health risk to our patient population. We therefore petition the Board to grant the moratorium, which will allow these areas of concern to be addressed more fully."

At the Craven County public hearing to discuss a county moratorium on new and expanded hog operations, Dr. Chris Delaney spoke in favor of such and presented slides of a man's legs with crusty sores. The sores had allegedly appeared after the man submerged his legs in the nearby Neuse River (Clabby, 1997). An increasing number of people who have had contact with the Neuse are experiencing similar skin lesions. Especially at risk are people whose livelihoods require that they spend considerable time on or in the water, such as professional underwater divers and commercial fishermen.

Dr. Peter Rowlett from Craven County in NC raised an additional issue during the public hearing. He stated that he would like to see North Carolina state health officials be more proactive (Clabby, 1997) in responding to some of the problems physicians are detecting in his area of the state. He stated that doctors routinely treat people with lesions with antibiotics with no effort made to establish the causative agent. He would like the state to establish a system where such lesions were cultured and sent to a state lab. Such a lab could assure identification of the lesion's origin and assist the state in its understanding of the cause and frequency of such.

3.2 Pfiesteria - A Potential Marker of Polluted Waters

Some medical reports indicate that humans who spend a lot of time on or in the water, such as

commercial fishermen and underwater divers, are experiencing similar problems, including but not limited to open sores on their skin. Researchers at North Carolina State University studying the dinoflagellate, Pfiesteria, experienced both short term and long-term memory problems and balance difficulties after a heavy dosage exposure to the associated toxins. Since 1991, this organism has been found in the vicinity of more than 100 fish kills in the Neuse, New and Pamlico rivers (Clabby, 1997). What stimulates the dinoflaggelates' growth and activity is still not understood (Clabby, 1997). For five years, the controversy surrounding research and scientists' and policymakers' understanding of Pfiesteria has raked the state (Barker, 1997).

Dr. JoAnn Burkholder, a North Carolina State University scientist, and a colleague in her lab, experienced neurological disorders resulting from exposure to Pfiesteria. The exposure produced short term and long-term memory problems and disorientation. Duke University researchers found that the dinoflagellate, Pfiesteria, caused serious learning impairment in rats (Levin et al., 1997). The learning deficits seen in this study may provide a partial model for the cognitive problems seen in the NCSU laboratory personnel who were accidentally exposed to Pfiesteria. However, the study does not necessarily translate to an understanding of risks involving human exposure in the field.

In August of 1997, the state of Maryland responded quickly to a major fish kill on the lower Pocomoke River, which left thousands of fish dead or covered with bleeding sores (Environmental News Service, 1997). A special medical team was brought in to respond to the reported health effects. People were reporting burning skin sensations following contact with the water, respiratory irritation, and the onset of concentration difficulties. The Maryland Department of Health and Mental Hygiene announced that a toxin, similar to Pfiesteria, might be the cause of the symptoms. Maryland Governor Parris Glendening felt there was enough information to act and felt the public should be informed of the connection to human health concerns. The response of Maryland officials brought this issue to attention of the nation. As a result, increased federal money for research is now available.

Further work investigating the connection between exposure to Pfiesteria and human health effects was reported by Maryland researchers (Grattan et al., 1998). The first complaints indicating there might be a problem for commercial fishermen began in the spring of 1997 when some reported to the county health department experiencing fatigue, headache, respiratory irritation, diarrhea, weight loss, skin irritation and rashes, and memory difficulties. The Maryland Department of Health and Hygiene called for further assessment of those exposed.

Twenty-four people who had been exposed to the Pfiesteria toxin were followed over a several month period. Exposure history and symptoms were recorded; in addition, a complete medical and laboratory assessment was conducted. A neuropsychological screening battery was performed and test results were compared to the performance of a control group. Results indicated that people with high exposure were significantly more likely to complain of symptoms such as: new or increased forgetfulness, headache and skin lesions or a burning sensation of the skin upon contact with water. Additional tests showed the exposed group was having difficulty with learning and

higher cognitive functions. The higher the exposure the greater the difficulty. Eight- seven percent of the high exposure group experienced learning and memory problems (Roper, 1998). Approximately 3-6 months after the cessation of the exposure, test scores returned to within a normal range. However, those most severely exposed continued to have some deficient performance, although overall improvement was noted. When studied again at 6 months post-exposure, they reported improvement in memory function and had normal performances on all cognitive measures.

Further research conducted by Dr. Kenneth Hudnell, an EPA neurotoxicologist, found that contact with Pfiesteria contaminated waters might adversely affect a person's ability to distinguish visual patterns. In a preliminary study, Dr. Hudnell found that one's ability to detect visual patterns was reduced by about 30 percent (Brown, 1998). Such a deficit in contrast sensitivity may cause people to perform tasks more slowly and may have the effect of increasing the risk of accidents. This was the first study to show that exposure to Pfiesteria contaminated waters may affect vision. Since none of the subjects had been exposed recently, this study is the first suggestion that persistent health effects are possible. In a North Carolina study of people potentially exposed to Pfiesteria water, medical evaluations did not find severe, chronic or widespread effects (Roper, 1998). Further studies are underway to address the limitations of the NC study.

The NC Department of the Environment and Natural Resources has recently responded to the environmental and human health concerns about Pfiesteria by:

- **creating in the Spring of 1998, a Harmful Algal Blooms program to monitor the potential health effects of Pfiesteria;**
- **setting-up a toll-free hotline for citizens to report potential problems and to receive information;**
- **posting warning signs on the Lower Neuse to advise people to avoid dead, dying and sick fish;**
- **setting a 30% nitrogen reduction plan for the Neuse;**
- **creating rapid response teams for the Neuse and Tar-Pamlico rivers to investigate fish kills and gather water quality information;**
- **using $365,000 in federal funds for further monitoring efforts;**
- **seeking $221 million to assist farmers in the control of nutrient run-off; and**
- **working with CDC and researchers from Maryland and Virginia to track 100 individuals exposed to Pfiesteria (Brown, 1998).**

3.3 Vibrio Vulnificus

Another related issue to the hog industry and the increase of nutrients in surface waters is the appearance of the marine vibrios, Vibrio Vulnificus. Researchers are studying the correlation between the deadly organism and high nutrient waters polluted in part by livestock. The CDC considers vibrios an emerging disease and NC health officials plan to track reports of the illness.

Section Four: Infectious Disease

Within the intestinal tract of swine, many bacteria, viruses, and protozoa live, some of which can be pathogenic to humans (Swinker, 1998). Those at most risk from exposure are pork production employees, especially those that have contact with the animals, carcasses, parts or by-products associated with the killing floor of the swine processing/slaughter plants (Fowler, et al., 1998). As the waste from hogs is spread over the soil and infiltrates some water supplies, there is concern about the exposure of humans to possible infectious diseases.

Coliform bacteria, when found in drinking water, indicates microbiologic activity and contamination by fecal material. The presence of E. coli is usually caused by fecal matter from warm-blooded animals. In Indiana, there was an outbreak of sickness due to exposure to E. coli bacteria (Wire Report, 1998). Twenty-one people became ill in a two-day period. E-coli causes diarrhea, nausea, fever, and dehydration. All of the Indiana cases were adults. Added to this concern of exposure to coliform bacteria is the increase in potency of some of the viruses and bacteria found in animals, including hogs. Some of these bacteria are increasingly resistant to common antibiotics.

Enteroviruses are carried by swine and predominantly spread from hogs to humans through direct contact with the animals. Enteroviruses aerosolized by agitation tanks in municipal wastewater treatment plants can pose a health risk to workers at the plants (Swinker, 1998). As North Carolina looks to phase out anerobic lagoons and possibly replace them with aerobic lagoons, exposure to enteroviruses will need to be watched. Aerobic lagoons entail the agitation of the wastewater to introduce oxygen to assist in the breakdown of organic matter. Workers will need protection from possible exposure to aerosolized Enteroviruses resulting from this process.

The intestinal tract of hogs is an important reservoir of salmonella. A study of over 2200 North Carolina swine found that 25% harbored salmonella species in their feces (Davies, et al., 1997). Several of the species found are capable of infecting humans. From 1989 to 1995 the hog population increased in North Carolina from 2.7 to 7 million. During this time, the annual incidence of reported salmonella infections was constant at a mean of 1173 cases annually. The 11 leading hog-producing counties contribute 10-12% of the reported salmonella cases, with the majority of the state's reported cases coming from the urban, more densely populated areas. At

present, modern production methods, although still fairly new in the state, do not seem to increase nor reduce the prevalence of enteric organisms in the hog population (Fowler et al., 1998). The salmonella rate should continue to be studied as the hog waste is continuously applied to soils.

Although the rate of salmonella infections has remained steady, the risk of human infection remains a concern. Future efforts to ensure the safety of pork should include attention to the control of salmonella. Due to the salmonella reservoir of infection present in hogs and the fact that modern intensive livestock production practices result in large pools of contaminated water and soil, this has raised concerns about the safety of the water supplies of nearby neighbors. The soil and water in the drainage areas should be checked for infectious agents around hog intensive livestock operations. Additionally the state should follow closely hog-associated infections. This can be facilitated by adding such infections to the list of reportable conditions (Fowler et al., 1998).

4.1 Worker Exposure to Infectious Agents

Similar to the concerns about air pollutants, workers are more at risk than the general population concerning exposure to infectious agents present in hogs. In addition to the exposure to hazardous dusts and gases, certain infectious agents that affect the respiratory tract can pass from the animals to humans. These include: swine influenza, ornithosis, and Q fever. Workers employed in the hog industry are also exposed to infectious agents through exposure to animals in the slaughterhouse and in particular on the killing floor. In 1961, a unified national program was mounted to eradicate brucellosis from the nation's hog population. Although highly successful, the bacteria is still found in some herds throughout the country. In December of 1993, thirty-four swineherds nationwide were under quarantine for brucellosis in seven states. Packing plants that handle infected swine, however, do not follow special procedures to prevent occupational exposure.

North Carolina workers who were employed in hog slaughterhouses were exposed to brucellosis (Trout et al., 1995). In a study of workers at a particular facility, 19% of the kill floor workers were found to have evidence of recent or persistent brucellosis. Of the 154 study participants, one hundred and five (68%) reported experiencing two or more symptoms consistent with brucellosis during the previous year. The most common symptoms included chills, fever, headache, and myalgia/arthralgia.

Transmission of the bacteria, brucellosis, to humans can occur during the slaughter of infected swine through worker skin lesions, inhalation of aerosols, conjunctival contact and ingestion. Person-to-person transmission is rare. The study results pointed to skin exposure, and possibly conjunctival contact, as the most likely path of exposure. Infectious tissue or body fluids appeared to be the primary exposure route in the plant. Brucellosis is considered an under-diagnosed disease. Periodic and ongoing screening is warranted, in addition to the exclusion of infected herds from entering the slaughterhouses in the first place. Although the disease is treatable with antibiotics, fatigue can persist for months afterwards and can result in disability. Relapse illness

can occur.

4.2 Increased Virulence in Salmonella

Virulent forms of salmonella are on the increase in the United States. In 1996 34% of the salmonella cultures sampled in labs were found to be of the type DT104 (Salmonella enterica serotype typhimurium), which is resistant to most major antibiotics, including ampicillin, streptomycin, and tetracycline (Glynn et al., 1998). In 1979-80 only .6% of the bacteria salmonella that was tested was found to be DT104. The routine prophylactic use of antibiotics in livestock feed has helped fuel the evolution of this drug-resistant bacterial strain. This type of Salmonella is recognized as a major cause of illness in humans and animals in Europe. Glynn et al analyzed data collected by local and state health departments and public health laboratories. They concluded that multi-drug-resistant typhimurium has become a widespread pathogen in the United States and recommended a more prudent use of antimicrobial agents in farm animals and more effective disease prevention on farms. They estimate that in the United States, that each year there are an estimated 800,000 to 4 million salmonella infections, of which 500 are fatal, and approximately 40,000 are confirmed by culture (Glynn et al., 1998).

In addition to the above mentioned Salmonella, E-coli strains that are antibiotic resistant are becoming more common. A new potent version of staph has emerged. Staphylococcus aureus bacteria has recently not responded to the most potent antibiotic, vancomycin, and appears to have taken the life of a patient in New York (Dobnik, 1998). Doctors have been warning of the emergence of several drug-resistant bacteria, which can be attributed to the misuse and overuse of antibiotics both by humans and in animal production operations.

Some of these antibiotic resistant organisms arise from animal farming practices, including swine production, which involves the prophylactic use of antibiotics in the feed. With time, bacteria develop resistance to antibiotics by various means including by creating chemicals that weaken a drug's potency. Resistance can develop quickly. Vulnerable populations, such as the elderly, infants, and people with suppressed immune systems, are at a greater risk to drug-resistant species, as are farm workers themselves (Galvin, 1998). Human exposure to antibiotic-resistant bacteria from animals is most likely caused by improper food processing, storing, or cooking.

Of great concern is the increase in infections with antibiotic-resistant staphylococci and enterococci that cannot be treated (Witte, 1998). Such infections have a prime opportunity to develop and transfer in the hospital environment given the concentrated combination of bacteria adapted to this environment, patients prone to infections, and antibiotic use. Each year it is estimated that as many as two million Americans acquire a nosocomial infection, meaning one that they did not have when they were admitted to the hospital. As estimated by Dr. Stuart B. Levy, with the Tufts University School of Medicine, over 20,000 people die from these hospital-borne infections each year (President and Fellows of Harvard College, 1997).

4.3 The Prophylactic Use of Antibiotics

The nation's hogs, poultry, and cattle are fed 19 million pounds of antibiotics a year to enhance growth and protect against disease (Mansur, 1998). In a recently released study by the National Research Council, it was acknowledged for the first time that this practice presents a threat to public health. The study noted that this practice has in some instances led to the passage of resistant bacteria from animals to humans. The prophylactic use of antibiotics at subtherapeutic amounts allows more animals to be raised at lower costs (Galvin, 1998). There are two to three times more livestock than people in the U.S. and therefore many consider the use of antibiotics in animals to be a more important contributor to the environmental pool of resistant strains than that from humans (Harvard College President and Fellows, 1997).

The dependence on the use of antibiotics is caused by the emergence of intensive livestock operations, where by definition large numbers of animals are produced in close proximity. Hogs grown in ILOs are often in constant contact with other hogs, which results in a need for antibiotics to fight against the transmission of infections. Because these animals are regularly exposed to small amounts of antibiotics, any microbes they are carrying are more likely with time to develop a resistance. Antibiotics are also used in animal husbandry for prophylaxis, chemotherapy, and growth promotion. Antibiotic resistance affects such zoonotic pathogens as Salmonella serovars and Campylobacter spp., both of which are associated with diarrheal diseases, and Escherichia coli and Enterococci. The microbial ecosystems in humans and animals are intertwined and microbial antibiotic resistance readily crosses boundaries (Witte, 1998). Since meat products are traded worldwide and bacterial populations do not limit themselves to geographic boundaries, the problems caused by the inappropriate use of antibiotics are global in nature.

An examination of current animal-management practices, and improvement of such, could result in a reduction in the need for antibiotics. In addition, the development of effective vaccines will help reduce the demand for antibiotics (Galvin, 1998).

Drug resistant bacteria can pass from animals to humans by multiple means. They include: direct contact with the animals or their waste; exposure to food contaminated by the bacteria; or by person-to-person contact (Mansur, 1998). Commenting on the National Research Council study, Jean Halloran, the director of the Consumer Policy Institute for the Consumer's Union of United States Inc., who served on the study committee stated: There's been some debate, especially in agribusiness, that says the use of antibiotics in animals is a separate pool (from the human pool) and the animal usage can't affect the resistance problem that people have....The committee concluded this was not a debate. It said, "This is not true. The pools overlap."

The Center for Science in the Public Interest has advocated for a policy response to this issue. They have asked for a government ban on the routine use of antibiotics in food animals. The findings of the National Research Council committee called for better oversight of the issue through the creation of a national database on the use of antibiotics and resistance trends; the

establishment of a national oversight panel; and more research money for the development of new antibiotics (Mansur, 1998). Vigilance is needed to prevent the spread of bacteria that are resistant to present drugs.

Of further concern is the tainting of the nation's meat supply and its impact on human health. Some polls show that consumers are more worried about bad meat than violent crime. Figures estimate that there are as many as 81 million cases of food-borne illnesses a year, which result in approximately 9,100 deaths. It is believed that the cost of foodborne disease is as high as 5 billion dollars (Altekruse et al., 1997). The exact numbers of illnesses are being challenged by the CDC, which expects to release their own numbers. The Clinton administration, however, is trying to toughen national food laws in response to these concerns regardless of the exact numbers determined (*LA Times,* 1998).

4.4 Other Swine Intestinal Tract Pathogens

The intestinal tract of swine can carry numerous bacteria, viruses, and protozoa, which can be pathogenic to humans in addition to E-coli, Salmonella and Brucellosis. They include: Trichinosis, Toxoplasmosis, Leptospirosis, Erysipelothrix, Cryptosporidium, Streptococcus suis, and Yersinia enterocolitica (Fowler, 1998; Swinker, 1998). Although these pathogens may be fairly uncommon, there may be incidents that go undetected and unreported given lack of physician training in infectious diseases and insufficient resources to properly diagnose such.

Dr. Hervey Kornegay, a Duplin County physician, has taken a leadership role in working for improved safeguards to protect public health concerning the impact of hog ILOs in his county. Dr. Kornegay's interest in the health impacts of the industry are based on his professional background as a practicing physician in the community, his community service work as Chair of the Duplin County Board of Health, and as a father. During the summer of 1996, Dr. Kornegay's son attended a camp in Johnston County. The camp's lake was situated downhill from two ILOs, including a swine ILO. While at camp, his son contracted leptospirosis, a rare and unusual disease. Dr. Kornegay's son was hospitalized for five days with high fever. Dr. Kornegay recommends that physicians in eastern North Carolina consider this pathogen as a potential causal agent when children and adults report unusual febrile illnesses. The origin of the infection was never determined, however, one possible source was from the large adjacent hog operation. Even with assistance from the Centers for Disease Control a final determination was not made.

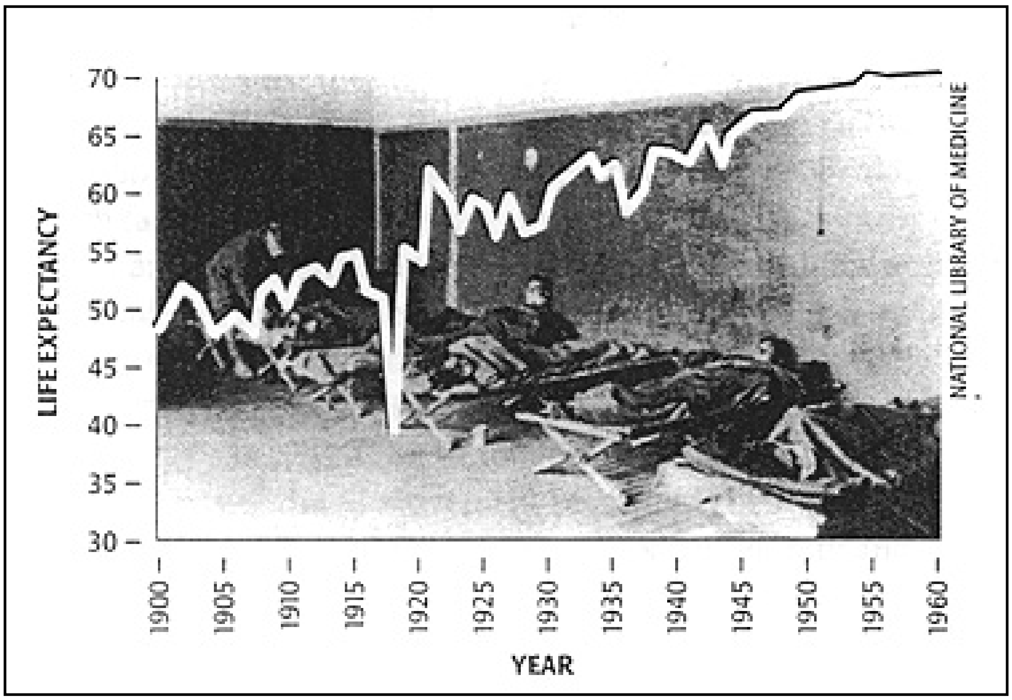
4.5 Swine or Spanish Flu of 1918

Here in North Carolina, close attention is paid to the possible transmission of disease from humans to swine. When people enter a hog house, they must wear special gear to protect the animals from exposure to viruses or bacteria carried by humans. Two family members can not seek employment in differing hog ILOs given concern over cross contamination between the herds. Equal protection and attention does not appear to be given concerning human exposure

from viruses and bacteria that are found in hogs. This omission could have catastrophic repercussions.

In 1918, the flu pandemic, which was also known as the Swine flu, Pig flu, and Spanish flu, swept the world and in little over one year's time between 20-40 million people died. In the United States alone, approximately 675,000 people died. It is estimated that 28% of the U.S. population was infected with the virus. (Taubenberger et al., 1997)

Ten times more people died from the swine flu than during World War I and almost twice as many as have died from the AIDS epidemic. Additionally, most of the deaths from the Swine Flu took place within a one-year period, whereas the AIDS' deaths have been spread over a fifteen-year period. The Swine Flu of 1918 was particularly virulent with mortality rates among the infected of over 2.5%, while other flus have less than a 0.1% death rate. The death rate was so high that it depressed the life expectancy in the U.S. by more than 10 years.



The Swine Flu of 1918 was different from any other flu before or since. Usually the youngest and oldest sectors of the population or those with a repressed immune system are most vulnerable. However, in 1918 young adult males, seemingly exceptionally healthy ones, were most likely to be struck by the disease. Once afflicted, most died within 24-48 hours. Young males were at the time of the flu outbreak mobilizing for World War I and were concentrated in military camps and on boats. This facilitated the spread of the flu among the troops and enabled the virus to move quickly through populations worldwide.

Researchers today are examining the virulent form of the Swine Flu virus. Knowledge of what this virus looks like could help health officials to identify dangerous flu strains as they emerge. Nancy Cox, a virologist with the Centers for Disease Control and Prevention (CDC), stated that study of this particular strain of the virus is needed to, "help us prepare for what we need to be prepared for." (Pennisi, 1997) The flu virus of 1918 infected the respiratory system, replicated, and then dispersed into the air via the lungs. Often all traces of the virus had disappeared by the time an autopsy was performed. Given the number of deaths from the Swine Flu, coupled with the war deaths, just disposing of the bodies became a problem, let alone having the resources to perform autopsies.

4.6 Hog as 'Mixing Vessel' for Avian and Human Viruses

Influenza A virus can escape the human immune response through antigenic drift (mutation), antigenic shift, or by the introduction of an avian virus into pigs. When introduced into the pig, the virus adapts to the new host, and is then passes on to humans (Scholtissek, 1994). Rarely does an avian influenza virus pass directly to humans. More commonly, the virus first passes through the pig. Data suggest that at the time of the Swine/Spanish Flu that a human influenza A (H1N1) virus entered the pig population and clustered with an "avian like" virus.

Pandemic strains are most likely formed when there is a reassortment of the genes. To assure the earliest possible identification of a pandemic strain, worldwide collaborating laboratories and surveillance system are required (Scholtissek, 1994). Close, continuous, and intensive monitoring of the world's swine population for the earliest possible detection of avian-like influenza viruses needs to be a basic part of global health planning.

Recent successful attempts to study the flu virus by means of polymerase chain reaction methods have allowed researchers to amplify small amounts of DNA and RNA in adequate amounts for sequence analysis. As a result, researchers now believe that the flu-virus genes closely resemble viruses isolated from pigs and that this virus had been in the pig population for a long period. The virologist, Dr. Robert Webster of St. Jude Children's Research Hospital said, "What this says is we had better watch what's happening in the pig populations of the world." (Pennisi, 1997) The pig trachea provides cell surface receptors for both human and avian influenza viruses (Ito et al., 1998). The pig trachea is conducive to viral replication and genetic reassortment. As the viruses replicate, the avian-like swine viruses develop the ability to recognize human virus receptors, and increase the possibility of their direct transmission to human populations (Ito et al., 1998). This allows the pig to act as an intermediate host for the generation of pandemic influenza viruses as seen in 1918, 1957, 1968, and 1977. Apparently, the pig acts as a 'mixing vessel' for such viruses.

Like the AIDS virus, the flu virus is ever changing. The CDC and the World Health Organization primarily spend their flu-surveillance efforts in examining flu strains in human populations, and not in the potential source itself, the hog. There is an obvious risk of studying such a virulent virus, which can be justified by the need to understand its structure and mechanism. Dr. Webster, when commenting on the 1918 Swine Flu, stated, "We want to know what killed these people. The potential is there for this kind of virus to return." (Pennisi, 1997).

Section Five: Wholistic View of Health Impacts

Our understanding of health and the determinants of health are limited and socially grounded. The language we use to describe the impacts of the intensive livestock operations and NC's newly structured vertically integrated agribusiness rarely includes the issues raised by community

members (Wing, 1998). For instance, the vocabulary used to describe the industry is determined by the industry itself, such as, the use of the word 'lagoon' vs. 'cesspool'; 'hog waste' vs. 'hog feces and urine'; 'hog farm' vs. 'hog operation'; 'growing house' vs. 'confinement facility'; 'harvest' vs. 'slaughter'; 'family farm' vs. 'factory farm'; 'agriculture' vs. 'agribusiness' and 'hog farmer' vs. 'hog operator/producer'. The top, powerful, rich controllers of the industry are called 'integrators'. The industry preferred vocabulary frames the way in which the industry is conceptualized in a more friendly, positive manner. One would not mind living near a 'lagoon' but would object to residing next to a 'feces and urine cesspool'. Don Webb, a NC community activist and founder and leader of the Alliance for a Responsible Swine Industry (ARSI), has worked arduously to recapture the vocabulary used to describe the industry, its activities and impacts.

Other issues surrounding the hog industry which are rarely raised include race and class, and the potential disproportionate effect of the industry on poor people of color. Such factors are raised by the environmental justice movement and their consideration of such are included in the Principles of Environmental Justice (EJ). In part fueled by the impacts of NC's hog industry, the state's first ever Summit for Environmental Justice was convened in Edgecombe County, in eastern NC, in October of 1998. National and state leaders of the EJ movement presented their ideas, in addition, to representatives of grassroots community and environmental organizations, state environmental organizations, state environmental agencies, and federal agencies, including EPA and NIEHS. Additional issues not often discussed are the agricultural determinants of nutrition, the loss of natural resources, and the emergence of conditions conducive to new diseases (Wing, 1998).

Policy development looks to risk factor epidemiology for guidance, which uses the paradigm of dividing the population into exposed and unexposed individuals. Such research does not ask the broader questions like:

- **where do the exposures come from;**
- **why are some groups exposed and others not;**
- **who benefits from producing the exposures;**
- **are the full range of exposures openly identified and studied;**
- **are the exposed populations fully informed;**
- **do they have access to medical care to remedy their exposure; and**
- **are the exposed populations fully compensated and made whole for their exposure (Wing, 1998)?**

These are some of the broader questions the environmental justice movement is trying to raise.

Professionals and community activists who challenge the dominant scientific account of health and disease argue that current epidemiological approaches are more likely attuned to protect the economic health of industry versus the health of the population or the environment. Such issues were discussed at the EJ Summit meeting.

By dividing scientific studies of the impact of hog intensive livestock operations into small units where specific diseases and exposures are examined one at a time, the overall effects of the industrial operations are never fully seen nor understood. This is also true of how we study the environment and set standards for emissions and is of importance when considering the effect of the hog industry. Air emissions from hog intensive operations consist of hundreds of constituent gases, none of which routinely exceed federal standards. However, the synergistic effect of all these gases has not been examined. A similar effect is seen when people take multiple medicines, where each one is taken at the prescribed amount, and yet together they can have serious effects when they interact with each other.

Victims of environmental exposures are too often blamed, questioned, isolated, and harassed (Wing, 1998; Tesh, 1988; Reich, 1991). The needs of subpopulations that are particularly vulnerable, such as pregnant women, asthmatic children, or adults with chronic respiratory disease, are rarely considered in policy deliberations. Other groups often overlooked are poor people of color.

Section Six: Recommendations

To assure the health and safety of North Carolina citizens who live near hog intensive livestock operations, further study needs to be made of the health impacts. It is particularly appropriate that such studies take place here since NC is the birthplace of this new concentrated livestock configuration. Additionally, the state's hog ILOs are more concentrated in one particular area of the state with sandy soils and a high water table. The impacts may prove to be greater here, especially due to the concentration of operations in two counties, than anywhere else in the nation. Based on the review of the research literature of hogs and human health, the following recommendations are made:

- **conduct a health study of the families who were found to be consuming nitrate contaminated well water (state and university researchers)**
- **test well water for coliform, in addition to nitrates (county staff);**
- **study the mental and physical health effects on residents of Duplin and Sampson counties, especially those living in odor affected areas (state and university researchers):**
- **conduct a clinical study of the impact of exposure to hog waste odors on asthmatics (state**

and university researchers);

- **establish a state standard for odor (NC Environmental Management Commission);**
- **check North Carolina's hog herd periodically for such infectious agents as Salmonella DT 104, and any avian viruses (NC Department of Agriculture);**
- **establish a protocol for communication and collaboration (NC Dept. of Ag., NC Occupational Safety and Health, county health department, and the State Health Director's Office) to assure a comprehensive response to the detection of swine diseases that could transfer to humans. This should include a protocol for handling potential emergencies and informing of the public; and**
- **develop a central database of demographic, psychological, and medical variables for persons exposed to hog odors and contaminated water and soil. Such a data base should include such markers as immunologic, neurologic, endocrinologic, psychologic and social factors (NC State Health Director's Office).**

Conclusions

There is a well-established literature describing the health effects of workers employed in both the confinement houses and the slaughter facilities of the hog industry. Two preliminary studies of the impact of the hog industry on neighbors were recently conducted. They concluded that in the physical health area, adjacent neighbors experience similar symptoms to employees only less severe and less frequent. In the mental health area, residents living in the odor-affected area were found to have increased incidents of mental health problems. These preliminary studies need to be redone in a more comprehensive and rigorous manner to ascertain the validity of their findings. The current status of the understanding of the potential threat to human health from hog operations is better described as what appears to be a problem or a potential problem, versus what is clearly understood. More research is needed to better understand the impacts of air and water emissions from hog intensive livestock operations and possible exposure to hog infectious agents. This is especially important given the potential for pandemic disease as the hog acts as a 'mixing vessel' between human and avian influenza viruses. Of additional concern is the increased presence of antibiotic resistant strains of bacteria, such as Salmonella (DT104), of which the pig is one of several potential sources. Increased funding for research efforts is needed to address such issues.

Groundwater Contamination of Private Drinking Well Water by Nitrates Adjacent to Intensive Livestock Operations (ILOs)

- Nitrate standard - 10 ppm in drinking water.

- Nitrate-contaminated drinking water can cause blue baby syndrome in infants six months of age and younger resulting in serious illness and at high levels may be fatal. Nitrates may also be toxic to older children and adults.

- First private drinking water wells to be contaminated by a hog farm operation in North Carolina - October 1995, Robeson County.

- In response, Governor Hunt ordered free well water testing for all North Carolina citizens living adjacent to ILOs to protect their health.

- Well water testing program consists of testing at property owner's request and responding to request with lab analysis and health risk evaluation of testing results in each instance.

- As of August 7, 1998, 1595 wells in 57 counties have been tested for nitrates adjacent to ILOs.

- 34.2% of the wells (546 out of 1595) have exhibited nitrate contamination above 2 ppm.

- 10.2% of the wells (163 out of 1595) have exhibited nitrate contamination at or above the drinking water standard and may pose an increased health risk upon consumption.

- The percentage of contaminated wells adjacent to ILOs is approximately three times the statewide average for nitrate contamination of well water based on historical extension surveys.

- Five eastern North Carolina counties have potentially serious groundwater problems associated with ILOs - Duplin, Edgecombe, Johnston, Robeson, and Sampson Counties (see attached table).

- The majority of contaminated wells are still being investigated in regards to determining the responsible party.

- Hog farms in Robeson, Duplin, Johnston, and Lenoir Counties have been identified as responsible parties in the contamination of some offsite private wells.

- Leaking hog lagoons and hog wastewater spray fields have been responsible for well contamination in these instances.

- The poor condition of private wells, especially in eastern North Carolina counties contributes to the availability of nitrates in wells. Poorly constructed, shallow bored or drilled wells have exacerbated the nitrate contamination of many of the wells in this program.

Recommendations

- A well monitoring requirement be included in any future ILO regulations, which would be a prudent preventive public health measure that identifies groundwater contamination before it impacts private drinking water wells.

- Due to the elevated percentage of nitrate contaminated wells adjacent to ILOs, a more aggressive well sampling program will identify North Carolina citizens (especially infants under six months of age) who may be at risk from nitrate toxicity from contaminated well water.

- A well protection program that upgrades the quality of private wells, especially in eastern North Carolina, where these programs are for the most part, non-existent.

- A phasing out of the hog farm lagoon and spray field system which will provide a greater degree of proactive public health protection by eliminating the possibility of groundwater/well water nitrate contamination by hog farm operations.

- An extension of the moratorium until these public health protective measures are implemented.

Governor's Well Water Testing Project near ILOs Private Well Test Results for Nitrates

Environmental Injustice in North Carolina's Hog Industry

Steve Wing,[1] Dana Cole,[1] and Gary Grant[2]

[1]Department of Epidemiology, School of Public Health, University of North Carolina, Chapel Hill, North Carolina, USA; [2]Concerned Citizens of Tillery, Tillery, North Carolina, USA

Rapid growth and the concentration of hog production in North Carolina have raised concerns of a disproportionate impact of pollution and offensive odors on poor and nonwhite communities. We analyzed the location and characteristics of 2,514 intensive hog operations in relation to racial, economic, and water source characteristics of census block groups, neighborhoods with an average of approximately 500 households each. We used Poisson regression to evaluate the extent to which relationships between environmental justice variables and the number of hog operations persisted after consideration of population density. There are 18.9 times as many hog operations in the highest quintile of poverty as compared to the lowest; however, adjustment for population density reduces the excess to 7.2. Hog operations are approximately 5 times as common in the highest three quintiles of the percentage nonwhite population as compared to the lowest, adjusted for population density. The excess of hog operations is greatest in areas with both high poverty and high percentage nonwhites. Operations run by corporate integrators are more concentrated in poor and nonwhite areas than are operations run by independent growers. Most hog operations, which use waste pits that can contaminate groundwater, are located in areas with high dependence on well water for drinking. Disproportionate impacts of intensive hog production on people of color and on the poor may impede improvements in economic and environmental conditions that are needed to address public health in areas which have high disease rates and low access to medical care as compared to other areas of the state. *Key words*: African Americans, environmental health, environmental justice, epidemiology, geographic information systems, rural health. *Environ Health Perspect* 108:225–231 (2000). [Online 8 February 2000]
http://ehpnet1.niehs.nih.gov/docs/2000/108p225-231wing/abstract.html

Environmental injustice refers to the disproportionate burden of pollution on people of color and the poor (*1–3*). In contrast to rural America's traditional image of unspoiled territory free of industrial pollution, poor rural communities have been targeted in recent years for urban, industrial, and military wastes that are unwanted by communities with larger populations and more political power (*4–6*). Other threats of environmental injustice in rural areas have come about because of the industrialization of agricultural activities (*7,8*). In this work we consider the environmental justice implications of the transformation of hog production in North Carolina from a system dominated by small independent farmers to large vertically integrated agribusiness production.

Between 1985 and 1998 North Carolina moved from fifteenth to second in hog production among U.S. states, with approximately 10 million head outnumbering the state's human population of approximately 7.5 million (*7,9*). The expansion of production has been accompanied by a declining number of operations and an increasing average size of operations (*10*). In 1998, market prices for hogs dropped to their lowest levels since the 1920s, which accelerated the demise of smaller independent producers. Most hogs are now produced by operators who work under contract to corporate integrators, which provide the management plan and own the animals, feed, and transportation; the operators own the land, buildings, and waste (*11*). In the past, hog production was dispersed throughout the state, but it has become consolidated in the coastal plain region, which concentrates waste and the potential for environmental damage in a region that is sensitive because of low-lying flood plains and high water tables (*10*).

Intensive swine production may pose environmental health dangers because of the high volume of waste, the chemical and microbial content of the waste, and the practice of using liquid waste management systems that are not isolated from the environment (*12*). In intensive hog production facilities, referred to as confined animal feeding operations (CAFOs), thousands of hogs are housed in large buildings. Waste is collected in cesspools for anaerobic decomposition and is subsequently sprayed on fields. Airborne emissions from confinement houses, cesspools, and spray fields contain ammonia, hydrogen sulfide, hundreds of volatile organic compounds, dusts, and endotoxins. These mixtures, which cause respiratory dysfunction in hog confinement-house workers (*13–28*) and possibly lower level symptoms in nearby residents (*29,30*), are highly obnoxious odorants that affect quality of life (*29–31*) and may be associated with mood disorders and lowered immune function (*32,33*).

Leaking cesspools and waste sprayed on fields can contaminate groundwater with nitrates and pathogens. The North Carolina State Health Department's (Raleigh, NC) well-testing program for the neighbors of intensive hog operations has documented elevated nitrates from hog operations (*34*). Groundwater contamination is a particular problem in eastern North Carolina because the water tables are high and many wells are shallow and unlined. No active population-based surveillance data are available to document pathogen contamination or the incidence of infections. Hog operations also contaminate surface waters, which may lead to high pathogen loads, eutrophication, and the promotion of algae and dinoflagellate growth (*35–39*).

The coastal plain region of North Carolina is also part of the southern Black Belt, a region where the agricultural economy was first built on the basis of slave labor and where a majority of rural African Americans in the United States still reside. The concentration of hog production in this poor region of the state has therefore raised the issue of environmental injustice (*40*). As in the case of other environmental justice problems, the presence of this polluting industry is a threat to public health because it may lower land values and quality of life and impede healthier economic developments that are needed in communities which suffer from low wages, lack of access to medical care, and poor nutritional options. Environmental injustice in the North Carolina hog industry has previously been investigated for counties (*7,9*) and U.S. Census Bureau (Suitland, MD) block groups (*41*). Using data for census block groups (areas of approximately 500 households), we

Received 14 July 1999; accepted 29 September 1999.

examined the extent to which hog CAFOs are located disproportionately in communities with high levels of poverty, high proportions of nonwhite persons, and high percentages of households dependent on well water. In addition, because agricultural activities are located in rural areas where land is inexpensive, and because many rural areas are poor and nonwhite, we also considered whether relationships between the locations of hog CAFOs and poverty, race, and well use can be explained by the rural nature of these areas.

Materials and Methods

We obtained a list of all animal operations registered with the North Carolina Division of Water Quality (DWQ; Raleigh, NC) as of February 1998. Animal operators report information on the number of head, species and type of animals, aspects of the liquid waste management system, the latitude and longitude coordinates of the facility, and the name of the corporate integrator, if any, with whom the operator has a contract. Swine operations are required to register with the DWQ if they have > 250 head and if they use a liquid waste management system. The steady state live weight (SSLW) of the herd was calculated by the DWQ as a function of the number of head of each type (breeding sows, farrow to wean pigs, wean to feeder pigs, feeder to finish hogs, boars, and gilts) and the average weight for each type hog. Finished hogs, ready for market, weigh approximately 240 lb.

Of the 3,039 animal operations in the database, 2,585 were swine operations (Figure 1). Facilities with missing data or head counts < 250 were excluded. We located the facilities within the state using latitude and longitude data. For 257 facilities, geographic coordinates placed the facility outside of the county of operation, outside the state, or the coordinates were missing. Missing and incorrect geocoordinates were corrected using local maps, geographic information systems software, and the driving instructions provided to state inspectors. The DWQ was contacted to provide information for operations that were missing road instructions or had incomplete instructions, and on those that were out of business. Operations with coordinates inside the correct county were not examined further. Three university-owned operations, which are not subject to the same commercial location considerations as other facilities, were excluded from the analysis. The remaining 2,514 swine CAFOs were included in the analysis (Figure 1).

We used geographic coordinates for the swine operations to locate the facilities within the boundaries of block groups. The number of facilities in each block group was the dependent variable in analyses quantifying the association between number of hog CAFOs and the characteristics of block groups. Because airborne emissions from hog CAFOs may affect the environment well beyond their boundaries, we also conducted analyses considering buffer zones of 1 and 2 miles, in which the count of operations for a block group consisted of the number of hog CAFOs that were within 1 or 2 miles of the block group's boundaries.

Information on race, poverty, and water source was obtained for 1990 census block groups, the smallest geographical unit for which economic and demographic data can be obtained and the unit most closely approximating neighborhoods or communities. The 1990 census provided the most recent block group level geographic information available, and corresponded to the time during which hog production in North Carolina began to accelerate rapidly. Three environmental justice variables of interest were defined as the percentage nonwhite population, the percent of persons in poverty, and the percent of households that used well water. We also obtained the total number of persons, land area in square miles, and population density for each block group.

Some areas of the state, including metropolitan areas, have no presence of the commercial swine production industry. These areas, including mostly white Appalachia and some largely African American areas in central cities of the Piedmont, could have skewed the evaluation of the relationship between hog operations and the environmental justice variables. Therefore, we excluded from the analysis 14 of the state's 100 counties that did not border a county with a hog CAFO and the state's five cities with 1990 populations > 100,000. The remainder of the state considered in the analysis included 4,177 block groups with a population of approximately 4.9 million persons.

Relationships between the environmental justice variables (poverty, race, and water source) and the presence of hog CAFOs were first evaluated by summing the total number of hog CAFOs in quintiles of the distribution of each environmental justice variable. Because quintiles have the same number of block groups by definition, the ratio of the number of hog CAFOs in each higher quintile as compared to the lowest quintile of the variable is equal to the prevalence ratio of the number of operations per block group at higher levels as compared to the lowest level. This unadjusted measure is referred to as a crude ratio.

We prepared maps to show the spatial distribution of the major study variables. Chloropleth maps of poverty, race, and population density are keyed to bar graphs indicating the numbers of block groups in each category. Because block groups vary greatly in land area and because the visual impact of the chloropleth map is influenced by land area, categories based on quintiles of block groups are not sensitive to the spatial distribution of the variables. Therefore, we chose category boundaries for maps to reflect the distribution of each variable.

Agricultural operations of all types are located in rural areas, where population density is low and land is inexpensive. Rural areas have higher poverty rates, much of the southern Black Belt is rural, and rural areas are often not served by municipal water systems.

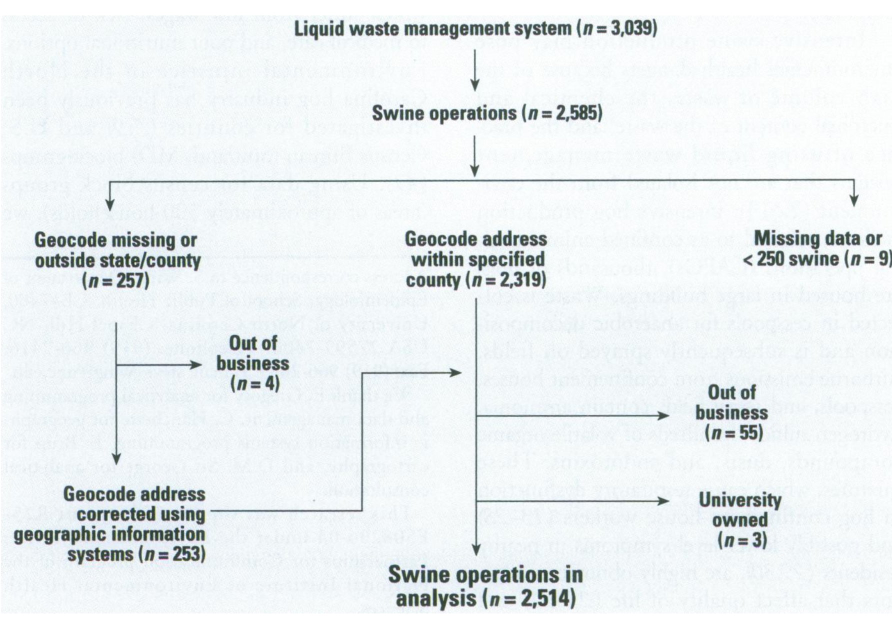

Figure 1. The identification of swine CAFOs from the DWQ data, February 1998.

It was therefore of interest to determine the extent to which excess numbers of hog operations in poor, nonwhite, and well-water-dependent communities could be considered a function of their low population density. We used Poisson regression to model the relationship between the natural log of population density and the number of hog operations per block group. We used linear, quadratic, and cubic terms for the log of population density to obtain an adequate fit of the model to the data. Higher order terms did little to improve the fit of the model.

Because Poisson models were overdispersed (model deviance/degrees of freedom > 1), we set the scale parameters for the models equal to the overdispersion values, which ranged from 1.6 to 1.8. We included indicator variables to represent each of the higher quintiles and we calculated the ratios of the number of hog CAFOs in block groups in each higher quintile of the environmental justice variables as compared to the lowest. We adjusted these ratios for population density using the cubic polynomial regression. Models were fit separately for operations under contract to corporate integrators and for those that were independent.

Results

Figure 2 shows the locations of hog CAFOs in North Carolina and the areas of the state excluded from the analysis. Each red dot represents one hog operation. The dense area of operations in the southeastern part of the state is centered on Duplin and Sampson Counties, the two largest hog-producing counties in the United States.

The size distribution of the 2,514 North Carolina hog CAFOs is shown in Table 1. The smallest 277 operations had an SSLW of < 100,000 lb each, which accounted for 11.0% of the operations and 1.4% of the state's SSLW. The SSLW of the largest 369 operations was ≥ 1 million pounds, which accounted for 14.7% of the operations and 44.4% of the SSLW in the state.

The geographic distribution of poverty is shown in Figure 3. Figure 3B shows the number of block groups in each category of poverty. For example, the categories with 0–5 and 5–10% persons in poverty each include approximately 1,000 block groups. Low-poverty areas predominate in the central Piedmont region of the state, whereas the higher poverty areas are located in the eastern coastal plain and in the northwest region (the edge of Appalachia).

Figure 4 shows the percentage nonwhite population. Most of the approximately 1,800 block groups with < 10% nonwhite population are located in the western part of the study area. These include 454 block groups that are 100% white. Areas with larger proportions of nonwhite population (mostly African Americans) are primarily in the eastern part of the state. An exception to the primarily African American makeup of the state's nonwhite population is Robeson County, located just southeast of the angle formed by the two straight lines along the central southern boundary of state. Robeson County is home to the Lumbee Indians and its population is approximately one-third Native American.

Table 2 presents the characteristics of block groups in relation to the environmental justice variables. Larger numbers of persons in the lowest categories of poverty live in a smaller land area, which results in higher population densities in areas with less poverty. Block groups in the lowest quintile of poverty contained only 43 hog CAFOs with 17.5 million lb of hogs, an average of 406.8 thousand lb/operation. In comparison, there are 225 hog operations in the second quintile

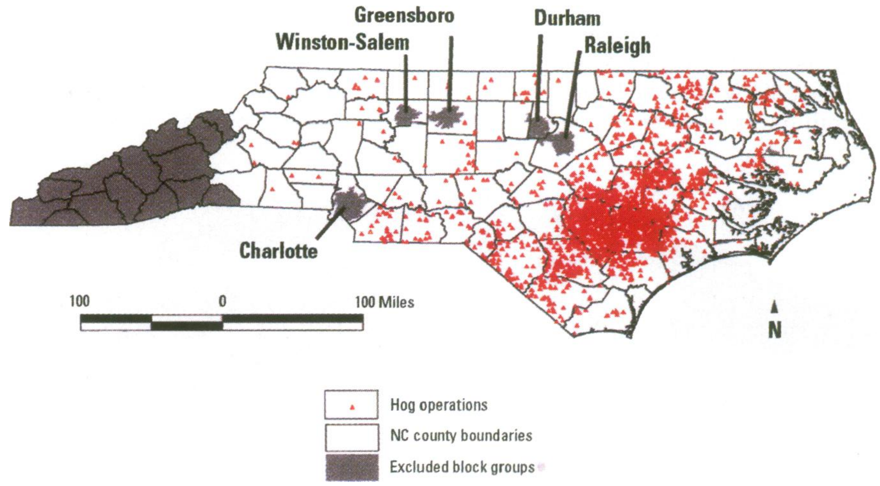

Figure 2. North Carolina study areas and locations of intensive hog operations, 1998.

Table 1. SSLW of North Carolina hog CAFOs, 1998.

SSLW (millions of pounds)	Operations (*n*)	Operations (%)	Cumulative SSLW (millions of pounds)	SSLW (%)
0.02 to < 0.10	277	11.0	20.8	1.4
0.10 to < 0.25	583	23.2	97.6	6.8
0.25 to < 0.50	708	28.2	268.2	18.6
0.50 to < 1.0	577	23.0	414.5	28.8
1.0 to < 10.1	369	14.7	639.7	44.4
Total	2,514	100	1,440.8	100

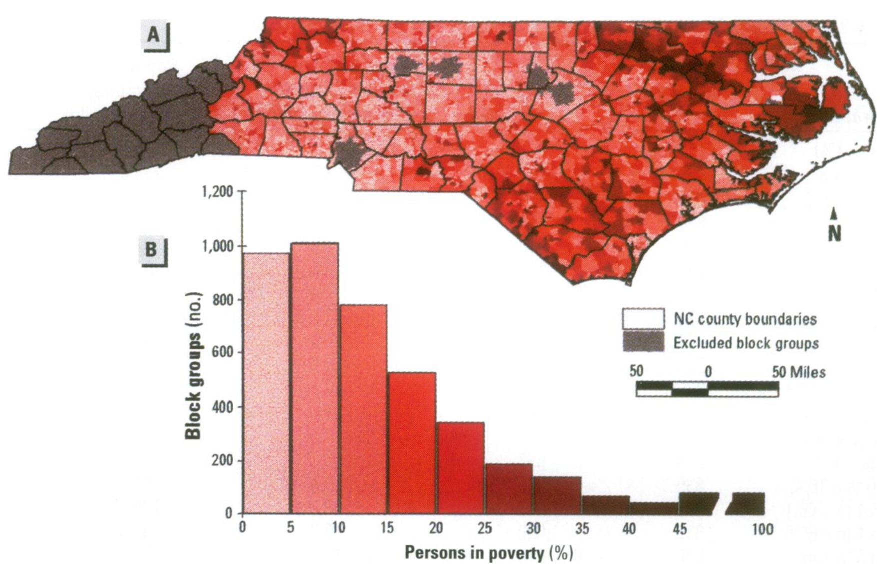

Figure 3. (*A*) The percent of persons in poverty in North Carolina, 1990. (*B*) The number of block groups in each category of poverty.

of poverty, 585 in the third, and > 800 in the fourth and fifth quintiles. Increases in total SSLW in areas with higher poverty levels are due to both larger numbers of operations and higher SSLW per operation.

Table 2 also shows the distribution of persons, land area, and hog operations for categories of the percentage nonwhite population. Population densities are lowest in the fourth and fifth quintiles of the percentage nonwhite variable. The 123 hog CAFOs in the lowest quintile have an SSLW of 48 million lb. The number of hog CAFOs in higher quintiles of the percentage nonwhite population increases to a maximum of 820 in the fourth quintile. The largest SSLW is in the highest quintile, 513 million lb, and the average size of operations increases with increases in the percentage nonwhite population.

Table 2 also presents information for block groups in quintiles of percentage of households using well water. This variable is most clearly related to population density, which declines from 1,315.4 persons/square mile in areas where < 1% of households have well water to 53.9/square mile in areas where > 85% of households have well water. Only five hog CAFOs, with a total SSLW of 1.2 million lb, are found in the lowest quintile of well-water use. Almost half of all hog CAFOs are located in block groups where > 85% of households have well water.

Although Table 2 shows clearly that there are more hog CAFOs in areas with higher percentages of persons in poverty, nonwhite persons, and households that use wells, it also shows that areas with the highest levels of these characteristics have lower population density, indicating that they are more rural areas. Population density is generally low throughout the eastern part of the state as compared to much of the Piedmont (Figure 5). Figure 6 shows that the number of hog operations per block group is strongly related to population density and that the observed number of operations per block group is predicted well by a cubic polynomial on a log–log scale. The number of operations per block group is lowest at the highest density, reaches a peak at approximately 20 persons/square mile, and declines somewhat at the lowest levels of density. The total number of operations in each category, shown in Figure 6 beside the observed values for the number of operations per block group, shows that the vast majority of operations are in block groups with fewer than 100 persons/square mile.

Table 3 summarizes the relationship between environmental justice variables and the presence of hog CAFOs in terms of the ratio of the number of operations per block group among block groups in the higher quintiles as compared to the lowest quintiles. The crude ratio of the number of operations per block group can be calculated from the data in Table 2. The ratio, adjusted for population density, is shown in the second column under each variable in Table 3. The large ratios for the higher levels of poverty, which vary from 5 to 20, are substantially reduced with adjustment for the rural nature of those areas. Adjusted ratios increase in a stepwise fashion with higher levels of poverty, from 3.0 in the second quintile to 7.2 in the highest.

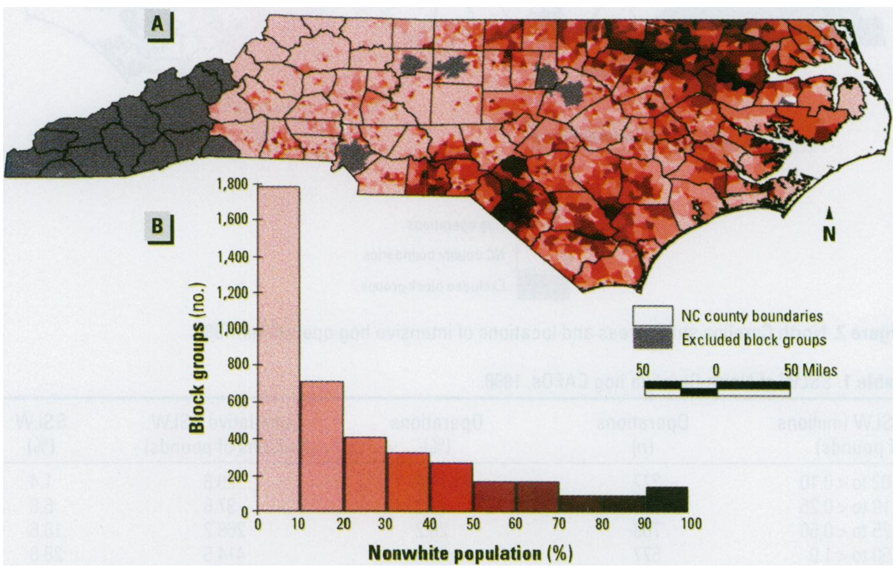

Figure 4. (*A*) The percentage nonwhite population in North Carolina, 1990. (*B*) The number of block groups in each category of the percentage nonwhite population.

Table 2. Characteristics of block groups in relation to poverty, race, and water source.

Characteristic	Block groups (*n*)	No. persons (thousands)	Land area (thousands of square miles)	Population density (people per square mile)	Total operations	Pounds of hogs (millions)	SSLW per operation (thousands)
Poverty (%)

Total[a]	4,177	4,937	42.1	117.4	2,514	1,440.8	573.1

[a]Sum for each variable.

Crude ratios for the percentage nonwhite population are smaller than the crude ratios for the percent of persons in poverty, ranging from 1.3 in the second quintile to 6.7 in the fourth quintile. Furthermore, the ratios are less affected by adjustment for population density. The ratio for the second quintile increases to 1.9, whereas ratios in the fourth and fifth quintiles are somewhat decreased. Adjusting for population density, the third, fourth, and fifth quintiles of the percentage nonwhite population have approximately 5 times as many hog CAFOs as those in the lowest quintile.

Hog CAFOs show a strong and monotonically increasing relationship to the percent of households using well water, with prevalence ratios ranging from 37.0 in the second to 240.8 in the fifth quintile. Most of this strong relationship, however, can be explained by the lower population density of areas with a high dependence on wells. Adjusted ratios in higher quintiles as compared to the lowest range between 4 and 5.

Table 4 shows the prevalence ratios for hog CAFOs in block groups cross-classified by poverty and the percentage nonwhite population, adjusted for population density. Block groups in the 0–5% poverty and 0–2% nonwhite population category are considered the referent group. Table 4 shows that increases in the percentage nonwhite population have little effect on number of hog operations among block groups in the lowest poverty group. Similarly, only modest increases in the numbers of operations are seen with increasing poverty levels among block groups in the lowest percent nonwhite category. However, prevalence ratios increase dramatically in areas with higher proportions of poor and nonwhite persons, reaching a ratio of 9 times as many operations in block groups with ≥ 12% poverty and ≥ 10% nonwhite population, adjusted for population density.

Most of the growth in NC pork production during the 1990s has been in large operations managed for corporate integrators rather than in independent operations. Therefore, we repeated the analyses for poverty and race separately for operations that listed corporate integrators on their permit applications (n = 1,603) and those that did not (n = 911). Prevalence ratios for integrator and independent CAFOs, adjusted for population density, are shown in Table 5. Although there is an excess of both types of operations in areas with greater percentages of poor and nonwhite populations, the excess is substantially larger for integrator operations at every level of poverty and race. Among the areas in the poorest quintile of block groups there are 20 times more integrator CAFOs than in the least-poor quintile, adjusted for differences in population density, whereas the excess of independent CAFOs in those areas is only 3.5 times. Similarly, block groups in the highest three quintiles of the percentage nonwhite population show an excess of integrator operations of 7 to 8 times, whereas the excess of independent operations is approximately 3 times.

Our analyses reported above consider only populations within the block groups containing hog CAFOs as potentially affected. However, airborne emissions and water pollution from CAFOs may travel some distance. Therefore, we reclassified the number of hog CAFOs in each block group considering 1- and 2-mile buffers around each operation. In these analyses, the number of hog operations in a block group is considered the number within the block group's boundaries plus the number within 1 or 2 miles of the block group, under the assumption that CAFOs located within 1 or 2 miles may impact the populations of neighboring block groups. We conducted analyses for the percent of persons in poverty and the percentage nonwhite population using the cubic polynomial model to adjust for population density. The ratios for the percent of persons in poverty were somewhat reduced, ranging between 2.2 and 5.9 under 1 and 2-mile buffers, as compared to a range of 3.0–7.2 with no buffer (Table 3). The ratios for the percentage nonwhite population were similar to ratios using a zero buffer, ranging from 1.9 to 5.3.

Discussion

We examined the locations of North Carolina's approximately 2,500 intensive hog confinement facilities in relation to poverty levels, race, and household water source of neighboring populations. These facilities are located disproportionately in communities with higher levels of poverty, higher proportions of nonwhite persons, and higher dependence on wells for household water supply. The disproportionate location of hog CAFOs in these areas raises numerous public health and social justice issues (*7,9,42,43*). Intensive swine production and its attendant pollution are concentrated in areas of North Carolina that have the highest disease rates (*44,45*), the least access to medical care, and the greatest need for positive economic development and better educational systems (*46*). The adverse effects of hog CAFOs on the quality of life and on community aesthetics (*29–31*) threaten the community economic and social developments that are fundamental to improved public health (*47*).

This study did not address siting decisions for particular hog operations. The reasons why a facility is located in a specific place are, in some ways, particular to the historical situation, business climate, local culture, and personal or family decision making. However, the pattern of location of industries reflects institutional factors and the political and economic power of local populations.

These institutional inequalities are critically important issues to consider in addressing the public health problem of the disproportionate burden of polluting industries among poor and nonwhite populations (*1,2,5,40,48*).

Both poverty and race are strongly related to the location of hog operations, as shown in Tables 2 and 3. However, the combination of the two characteristics is of particular interest (Table 4). Increasing levels of poverty have only a modest effect in block groups with < 2% nonwhite populations. Similarly, increasing levels of nonwhite populations have little effect on the prevalence of hog operations among the block groups with < 5% poverty. It is the combination of a high percentage nonwhite populations and high poverty levels that is associated with the greatest excess of hog CAFOs, reaching a prevalence ratio of almost 10 for block groups with ≥ 12% poverty and ≥ 10% nonwhite population as compared to block groups with < 5% poverty and < 2% nonwhite population.

The industrialization of agriculture has brought about not only changes in size, but also in ownership. All of the hog operations considered in this research are large and fall under state regulations for intensive livestock operations. However, among these large operations, some are owned and operated by independent farmers who make their own management decisions. Other operations are owned by or are operated under contract with large agribusiness integrators that own and control the animals, feed, veterinary supplies, transportation, financing, and marketing of the product. Although both types of operations are large and industrialized, integrator operations have been responsible for most of the recent expansion of the industry (*7*). Because of their corporate structures, they may be in the best position to locate facilities based on economic considerations such as proximity to other operations, transportation routes, and slaughterhouses, as well as low land prices and the low local political power of host communities. Furthermore, there is a net decrease in jobs in regions where hog production has been industrialized because of the displacement of the independent producers who purchased locally (*49*). The concentration of hog CAFOs in poor and nonwhite areas is much greater for integrator than for independent operations (Table 5). Because the industry is moving rapidly toward greater economic concentration while family-owned businesses are in decline (*9,10,50*), the evidence of greater environmental injustice for integrator operations suggests that this problem may increase in the future.

This study was conducted using census block groups as the units of analysis. These areas, averaging approximately 500 households, are the smallest unit for which population data are available from the U.S. census and should provide better sensitivity and specificity to the characteristics of populations in greatest proximity to hog operations than would larger geographic units. The most recent block group data available are from 1990; more recent economic data from other sources are not available with this level of geographic detail. In any case, 1990 is an appropriate year for which to measure socioeconomic characteristics in our study of the location of hog operations because the period of rapid growth in the industry began in the late 1980s.

We depended on data from the DWQ for information on the locations and characteristics of intensive livestock operations in February 1998. Because a moratorium on the construction of new industrial operations was imposed by the North Carolina General Assembly in March 1997 (*7*) and has not yet been lifted (as of 1999), information from 1998 remains relevant. However, the validity of analyses reported here depend on the quality of information recorded by the state. We detected and corrected hundreds of errors in latitude/longitude coordinates for North Carolina hog CAFOs that were not located in the correct county according to the database (Figure 1). The extent of within-county errors in the data is unknown. Information on the size of the operation depends on the quality of data provided by the operator. The database contains information on a number of other characteristics of interest, such as the start date of the operation, the size and number of cesspools, and the acreage of spray fields. Unfortunately, these data were too incomplete to use in our analyses. Future studies of environmental justice and public health impacts of this industry would benefit from more complete and accurate data.

The public health implications of environmental injustice in the North Carolina hog industry are of special concern. Exposures in the environment of confinement houses are clearly related to impaired respiratory function, occupational asthma, and organic dust syndrome (*51*). This is an occupational health concern in areas with a large industry presence. In addition, environmental exposures to airborne emissions from hog CAFOs may be associated with respiratory effects (*29,30*) and impaired mood (*32,33*) in neighboring populations. Groundwater from hog CAFOs has been contaminated by nitrates in North Carolina (*34*). This is a special concern considering the findings presented here, which show that approximately half of the hog CAFOs are located in block groups of the state where > 85% of households depend on well water for drinking (Table 2). The eastern coastal plain of the state where most operations are located (Figure 1) has sandy soils and high water tables that facilitate the movement of water pollution from cesspools and

spray fields into groundwater, and older rural homes occupied by the poor and people of color often have shallow wells with less protection from contamination. Surface water pollution is a concern because of the spread of microbial contamination and the nutrient loading of rivers and estuaries.

Community concerns about environmental injustice in the distribution of hog operations in North Carolina are real. Predominantly poor and nonwhite communities that host a disproportionate number of hog CAFOs have a great need for positive economic development, environmentally sound industry, and better schools and medical care. Such community resources are important to public health (*47*). However, future prospects for these communities are threatened by an industry that produces highly obnoxious odors and reduces the quality of life for neighbors (*29–31*), which can hamper the growth of cleaner industries, reduce land values, and contribute to loss of locally owned land (*9,40*). Our findings should be taken into consideration as growth, technological change, and environmental remediation in the industry are considered.

Edited by Paul Behrens, Leiden University, Leiden, The Netherlands, and accepted by Editorial Board Member B. L. Turner March 18, 2021 (received for review June 30, 2020)

Agriculture is a major contributor to air pollution, the largest environmental risk factor for mortality in the United States and worldwide. It is largely unknown, however, how individual foods or entire diets affect human health via poor air quality. We show how food production negatively impacts human health by increasing atmospheric fine particulate matter ($PM_{2.5}$), and we identify ways to reduce these negative impacts of agriculture. We quantify the air quality–related health damages attributable to 95 agricultural commodities and 67 final food products, which encompass >99% of agricultural production in the United States. Agricultural production in the United States results in 17,900 annual air quality–related deaths, 15,900 of which are from food production. Of those, 80% are attributable to animal-based foods, both directly from animal production and indirectly from growing animal feed. On-farm interventions can reduce $PM_{2.5}$-related mortality by 50%, including improved livestock waste management and fertilizer application practices that reduce emissions of ammonia, a secondary $PM_{2.5}$ precursor, and improved crop and animal production practices that reduce primary $PM_{2.5}$ emissions from tillage, field burning, livestock dust, and machinery. Dietary shifts toward more plant-based foods that maintain protein intake and other nutritional needs could reduce agricultural air quality–related mortality by 68 to 83%. In sum, improved livestock and fertilization practices, and dietary shifts could greatly decrease the health impacts of agriculture caused by its contribution to reduced air quality.

air quality | agriculture | fine particulate matter | food | pollution

The health and environmental consequences of feeding the increasingly large and affluent global population are becoming increasingly apparent. These consequences have spurred interest in identifying food production practices and diets that improve human health and reduce environmental harm. Recent work has demonstrated that many of the opportunities for food producers and consumers to improve nutritional outcomes also have environmental benefits, such as reducing greenhouse gas emissions, land and water use, and eutrophication (1–6). It is largely unknown, however, how individual foods and diets affect air quality, even though air pollution is the largest environmental mortality risk factor in the United States and globally (7, 8), and agriculture is itself known to be a major contributor to reduced air quality (8, 9). In the United States alone, atmospheric fine particulate matter ($PM_{2.5}$) from anthropogenic sources is responsible for about 100,000 premature deaths each year, one-fifth of which are linked to agriculture (10, 11).

Here, we show how different foods affect human health by reducing air quality. We consider the emission of pollutants that contribute to atmospheric $PM_{2.5}$, the chronic exposure to which increases the incidence of premature mortality from cardiovascular disease, cancer, and stroke (12, 13). These pollutants include directly emitted $PM_{2.5}$ (primary $PM_{2.5}$) and $PM_{2.5}$ formed in the atmosphere (secondary $PM_{2.5}$) from the precursors ammonia (NH_3), nitrogen oxides (NO_x), sulfur dioxide (SO_2), and nonmethane volatile organic compounds (NMVOCs). From a spatially explicit inventory of emissions of primary $PM_{2.5}$ and secondary $PM_{2.5}$ precursors from agricultural supply chain activities for commodities in the contiguous United States (*SI Appendix*, Figs. S1 and S2) (14, 15) (*Materials and Methods*), we estimate increases in atmospheric concentrations of total (primary + secondary) $PM_{2.5}$ attributable to agricultural emissions; total $PM_{2.5}$ transport, chemistry, and removal; and exposure of populations to total $PM_{2.5}$ using an ensemble of three independent air quality models (16–19). We describe damages attributable to 95 agricultural commodities and 67 final food products (full list in *SI Appendix*, Table S1), which cover >99% of US agricultural production (20).

SUSTAINABILITY SCIENCE

Results

We find that US agriculture results in 17,900 deaths (range across models: 15,600 to 20,300) per year via reduced air quality (Fig. 1 and *SI Appendix*, Figs. S3–S7). Damages are driven by NH_3 emissions (Fig. 1; "Pollutant"; 12,400 deaths; 69% of total) mainly from livestock waste and fertilizer application (Fig. 1; "Process").

Significance

Poor air quality is the largest environmental health risk in the United States and worldwide, and agriculture is a major source of air pollution. Nevertheless, air quality has been largely absent from discussions about the health and environmental impacts of food. We estimate the air quality–related health impacts of agriculture in the United States, finding that 80% of the 15,900 annual deaths that result from food-related fine particulate matter ($PM_{2.5}$) pollution are attributable to animal-based foods. By estimating these impacts and exploring how to reduce them, this work fills a critical knowledge gap. Our results are relevant to food producers, processors, and distributors, and to policymakers and members of the public interested in minimizing the negative consequences of food.

Published May 10, 2021.

Primary $PM_{2.5}$ is also a major contributor (4,800 deaths, 27% of total), largely from dust from tillage, livestock dust, field burning, and fuel combustion in agricultural equipment use. NO_x, SO_2, and NMVOCs are minor contributors (collective total: 700 deaths; 4% of total). Areas causing the greatest damages are spatially concentrated, with the top 10% of the most damaging counties (308 counties) together responsible for 8,400 deaths per year (47% of total deaths). These counties are mainly located in California, Pennsylvania, North Carolina, and along the Upper Midwest Corn Belt (Fig. 2 and *SI Appendix*, Fig. S4 and Table S2).

We also attribute total deaths from agricultural supply chain emissions to the production of specific commodities, which we combine into 16 groups (Fig. 1; "Commodity"). This analysis shows that 57% of deaths are from crops and 43% from livestock. However, a substantial portion of crops is used as animal feed and nonfood products (Fig. 1; "Product"). In attributing direct damages to final products, we find that 89% (15,900 deaths) of the total deaths caused by agriculture are linked to food production, with the remaining 11% (2,000 deaths) linked to biofuels and other nonfood products (e.g., plant and animal fibers) (Fig. 1; "Source"). Of food-related damages, 80% (12,700 deaths) are attributable to animal-based foods (when impacts of animal feed production are included) and 20% (3,200) to plant-based foods.

Next, we consider the per-unit damages of 11 food groups (Fig. 3 and *SI Appendix*, Table S1), taken as the production-weighted average of the foods in each group, and using four metrics suited to meet different nutritional needs (per 10^9 kg, 10^9 serving, 10^9 g protein, and 10^9 kcal, each measured as raw edible portion). We find that red meat dominates in air quality–related health damages, whether normalized by total mass, serving, protein mass, or caloric value. Per serving, production-weighted averages of red meat are 2× greater than those of eggs, 3× greater than those of dairy products, 7× greater than those of poultry, 10× greater than those of nuts and seeds, and at least 15× greater than the production-weighted average of any other plant-based food. Similar trends hold when these food groups are compared using the other three metrics. The lowest-impact production of red meat has a greater impact than the highest-impact production of any other food, absent the dietarily insignificant comparison of red meat to fruit as measured on a per-protein content basis. We observe a wide range of spatial variation in per-unit damages of major crops and livestock commodities (*SI Appendix*, Fig. S8). Damages vary spatially because of site-specific production practices, atmospheric chemistry and transport, and population density (Fig. 2 and *SI Appendix*, Fig. S4), consistent with prior studies focused on maize (21) and switchgrass (22). Limitations of supply chain information (e.g., where the crops that are fed to animals in a given location are grown) restrict our understanding of the spatial variation in per-unit damages for animal-based foods as final products.

We also estimate the air quality–related health benefits that can be achieved through the actions of food producers and consumers. We identify interventions that reduce $PM_{2.5}$-related emissions, focusing on interventions that target the most harmful agricultural processes, promote dietary shifts, reduce food loss and waste, and encourage healthy per capita consumption levels (*Materials and Methods*). We generate spatially explicit inventories for each intervention scenario and compare them to a baseline scenario for current production practices and diets (*SI Appendix*, Fig. S9 and Table S3), modeling the resulting changes in $PM_{2.5}$ concentrations and annual deaths.

We find that improvements in agricultural production, such as changing livestock feed practices to reduce the amount of excess protein ingested and therefore excreted as nitrogen, or using fertilizer amendments and inhibitors, can greatly reduce air quality–related health damages (Fig. 4). Implementing measures to reduce agricultural emissions across all producers could prevent 7,900 deaths per year (50% of total deaths from food production). The greatest benefits are from changes in livestock waste management and fertilizer application practices. Producer-side interventions in the 10% of counties with the highest mitigation potential alone could prevent 3,600 deaths per year (22% of total deaths from food production). Expanding such interventions to the top 50% of counties would prevent 41% of total $PM_{2.5}$-related deaths linked to food production.

Our findings suggest that the monetized $PM_{2.5}$-related health benefits of such interventions could greatly exceed implementation costs. For example, using a Value of Statistical Life of $10 million (23, 24), we find that the annual monetized damage cost of

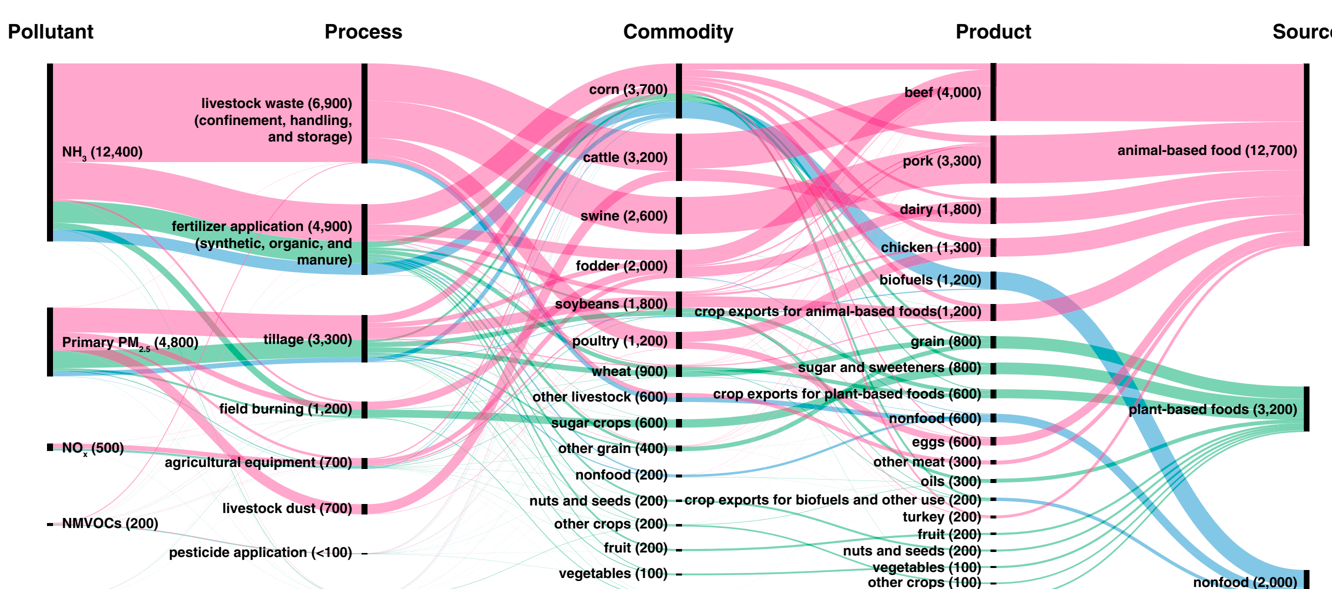

Fig. 1. Annual premature deaths attributed to increased atmospheric $PM_{2.5}$ from agriculture. Five alternate categorizations (columns) are shown: pollutant, process, commodity, product, and source. Pollutants include primary $PM_{2.5}$ and secondary $PM_{2.5}$ formed from precursor gases (NH_3, NO_x, NMVOCs, and SO_2). The height of each black bar within each column corresponds to the number of attributed deaths; deaths within each column sum to 17,900.

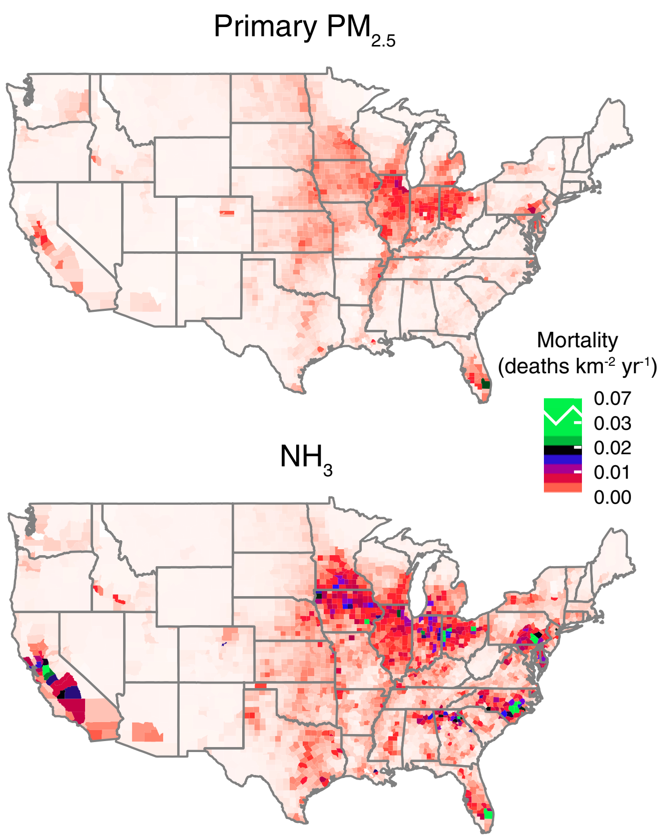

Fig. 2. Spatial distribution of $PM_{2.5}$-related mortality attributed to US agricultural production. Shown are annual premature deaths per square kilometer attributed to primary $PM_{2.5}$ (*Top*) and secondary $PM_{2.5}$ from NH_3 (*Bottom*), which together comprise 97% of agricultural $PM_{2.5}$-related deaths. Maps for the other 3% of deaths (i.e., from NO_x, NMVOCs, and SO_2) are shown in *SI Appendix*, Fig. S4. For each county, the mortality shown is that which occurs somewhere in the United States as a result of emissions from that county; that is, these maps show where the impact originates, not necessarily where it is experienced.

$PM_{2.5}$-related deaths from US food production are \$159 billion. The benefits of many of the explored interventions are 1.3 to 14.7× greater than the highest estimated implementation costs, consistent with the results of coarser resolution global analyses (25). For instance, the $PM_{2.5}$-related health benefits (range: 33.4 to 42.4 $\$ \cdot kg^{-1}$ of NH_3) of interventions for nonorganic fertilizer application, such as improvements in timing, method of application, use of amendments and inhibitors, and a shift to less emissive fertilizer types, greatly exceed the implementation costs (range: –0.8 to 3.2 $\$ \cdot kg^{-1}$ of NH_3).

We also find that nationwide dietary shifts that decrease consumption of animal-based foods can lead to large decreases in agricultural $PM_{2.5}$-related death rates, simultaneously reducing direct damages from livestock waste management and indirect damages from feed production (Fig. 4). Substituting poultry for red meat could prevent 6,300 annual deaths (40% of total deaths from food production). Even greater benefits of 10,700 to 13,100 deaths prevented per year (68 to 83%) could be achieved from more ambitious shifts to vegetarian, vegan, or flexitarian diets such as the planetary health diet of the EAT-Lancet Commission (2). Other demand-side mitigation strategies, such as decreasing caloric intake proportionally across all food groups to be in line with metabolic requirements and decreasing household food loss and waste levels, could lead to more modest reductions in agricultural $PM_{2.5}$-related death rates (range: 700 to 1,200 avoided deaths per year).

Many of the food production solutions that could reduce air quality–related health damages, such as improving nitrogen use efficiency in crop and livestock production, or decreasing food

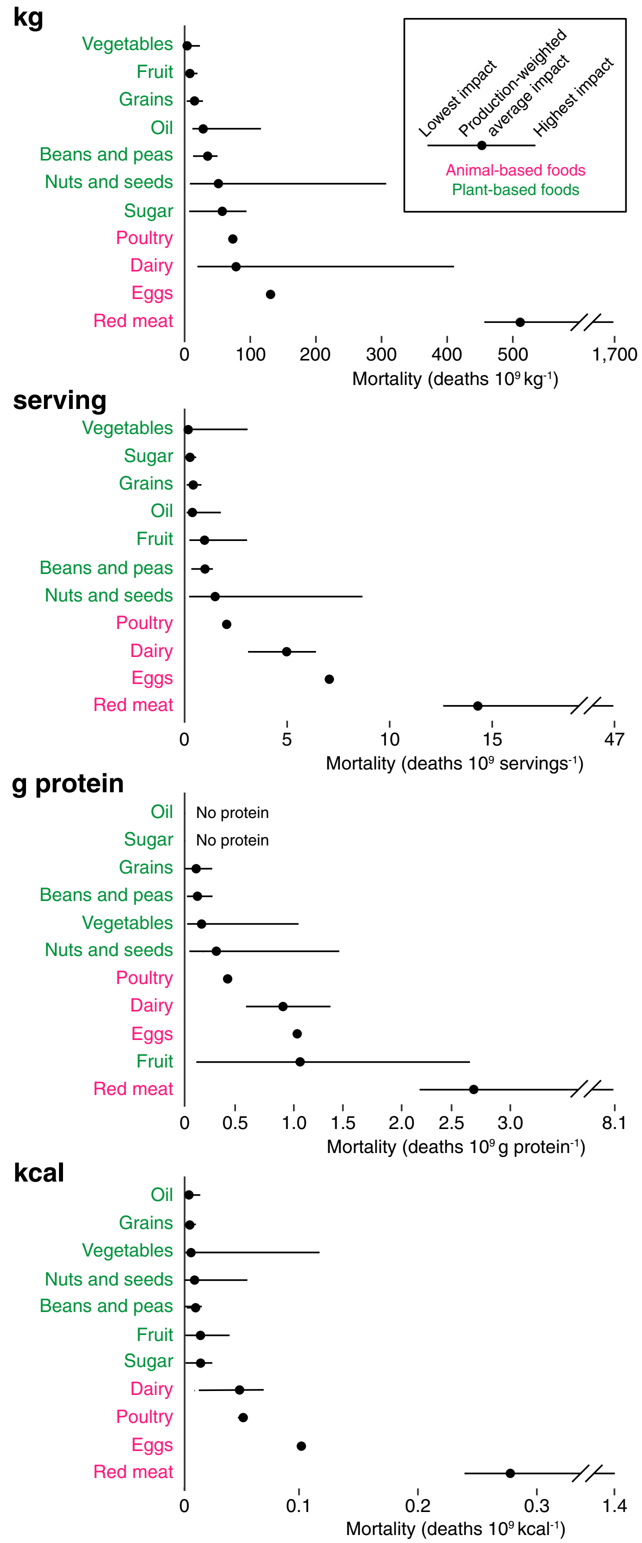

Fig. 3. Annual premature deaths attributed to total $PM_{2.5}$ per unit of food production. Annual premature mortality attributed to total $PM_{2.5}$ per 10^9 kg, 10^9 serving, 10^9 g protein, and 10^9 kcal, each measured as raw edible portion. Horizontal lines indicate the range of per-unit damages within the food group. Food groups are ordered lowest to highest within each panel.

https://doi.org/10.1073/pnas.2013637118

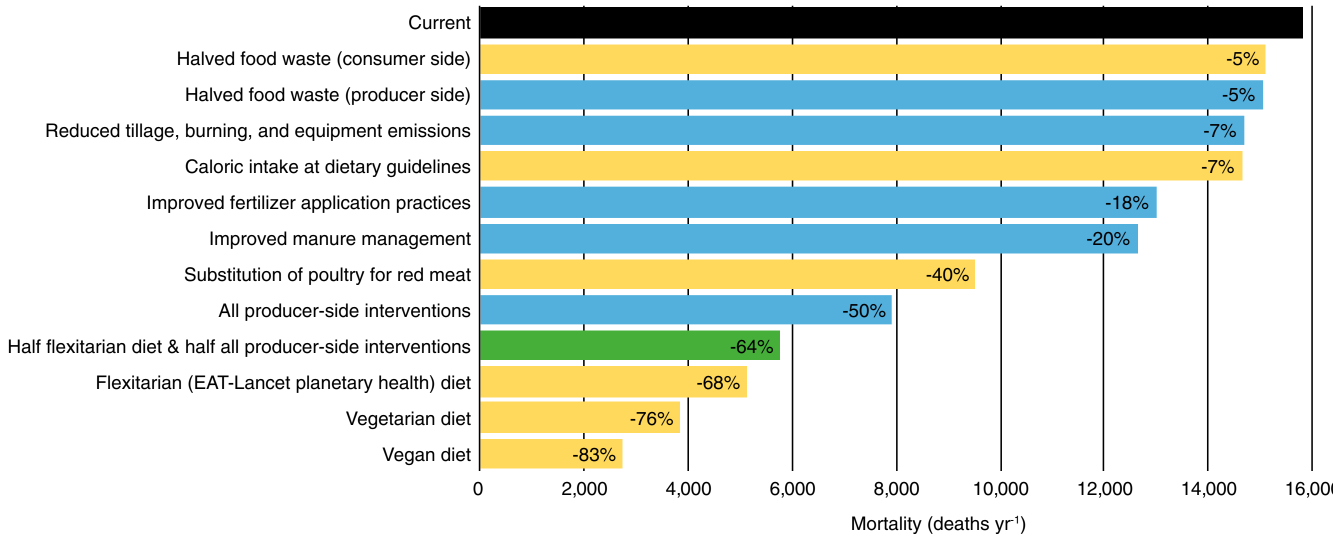

Fig. 4. Annual premature deaths attributed to total $PM_{2.5}$ from food production that could be mitigated by a given intervention or suite of interventions. Yellow bars correspond to consumer-side interventions, blue bars to producer-side interventions, and green to a combination of the two. Values for percent decrease in mortality from current mortality are shown.

loss and waste, are likely accompanied by other environmental benefits, such as decreasing greenhouse gas emissions, nutrient pollution, and undesirable land-use change (26–28). Further, dietary shifts that increase the fraction of kilocalories from plant-based foods can improve diet-related health outcomes by reducing the incidence of chronic noncommunicable diseases, such as type 2 diabetes, coronary heart disease, and cancer (29, 30).

This work contributes to a more comprehensive understanding of the air quality–related health damages of food and identifies solutions for reducing the negative impacts of food across a diverse range of diets, production practices, and other site-specific factors. Current diets and food production practices cause substantial damages to human health via reduced air quality; however, their corresponding emissions sources, particularly ammonia, are lightly regulated compared to other sources of air pollution, such as motor vehicles and electricity production. This is true despite agriculture having comparable health damages to these other sources of pollution (10, 31). Meaningful reductions in air quality–related health damages will likely require simultaneous interventions, such as dietary shifts and changes in how we manage livestock waste and apply fertilizer. Although our results are for the United States, our approach can be applied globally, with mitigation efforts anticipated to reduce premature deaths substantially. Reductions should be especially large in regions where $PM_{2.5}$ concentrations are sensitive to ammonia emissions, where agricultural burning is commonly practiced, and in densely populated regions with high $PM_{2.5}$ exposure levels (25).

Materials and Methods

We estimated the air quality–related annual deaths attributable to the US agricultural sector, which includes annual deaths attributable to 95 agricultural commodities that span the entirety of animal production, and cropland and grassland pastures captured in the 2014 US Department of Agriculture (USDA) Cropland Data Layer (CDL) (32). We then computed the per-unit annual impacts of 67 final products from 11 food groups. Finally, we estimated the air quality–related health benefits that could be achieved through producer- and consumer-side interventions.

Extraction of Agricultural Emissions. County-level air pollution impacts from the agricultural sector were estimated by identifying and extracting emissions data linked to crop and livestock production from the US Environmental Protection Agency (EPA)'s 2014 National Emissions Inventory v2 (NEI2014) (14). Emissions from the contiguous 48 states were included, covering >99% of US agricultural production. We identified agricultural processes from source classification codes (SCCs), with the seven agricultural processes listed as follows: 1) livestock waste (confinement, handling, and storage), 2) tillage, 3) fertilizer application (synthetic, organic, and manure), 4) field burning, 5) agricultural equipment fuel combustion, 6) livestock dust, and 7) pesticide application (15). As 88% of all ammonia, ammonium nitrate, urea, and other nitrogen compounds produced in the United States are used as fertilizer, the same fraction was used to allocate emissions from the production of these chemicals to a "fertilizer production" category (33). All emissions were used as published by the NEI2014, with two exceptions. First, NEI2014 estimates of primary $PM_{2.5}$ from tillage and livestock dust do not account for differences in fugitive dust emissions by land cover, as they depend on dry deposition rates and wind speeds (15). As a result, county-level transport fractions were applied to account for local effects (34). Second, we adjusted the estimates of tillage emissions in NEI2014 using data collected by the USDA in the Agricultural Resource Management Survey to better reflect the current number of tillage passes associated with individual crops (35).

Allocation of Emissions. We categorized emissions by pollutant type (i.e., primary $PM_{2.5}$, NH_3, NO_x, SO_2, and NMVOCs), agricultural process (e.g., livestock waste and fertilizer application), commodity that is the onsite emissions source (e.g., livestock types such as beef cattle, and crop types such as corn), and final product (e.g., beef).

Livestock production. Emissions from livestock production come from either livestock waste management or ancillary livestock dust. These emissions were attributed to specific animal types using SCCs within the NEI2014 (15). Livestock waste emissions of 10 major livestock types (beef cattle, dairy cattle, broilers, layers, swine, turkeys, goats, lambs, horses, and other livestock) were estimated separately by different management stages (confinement, handling and storage, and land application of manure) using the Carnegie Mellon University (CMU) Farm Emissions Model (36) but were aggregated into a livestock-specific emissions category in the NEI2014 (15). To allocate emissions by management stage, we derived the state-level distribution of emissions by management stage by first running the CMU Ammonia Model on which the Farm Emissions Model is based (36). Next, we applied that distribution to emissions published in the NEI2014. All emissions associated with confinement, handling, and storage were attributed to the livestock commodity. Emissions associated with land application of manure were attributed to crop production and further allocated to a specific crop commodity using crop production practices data from the USDA Economic Research Service (ERS) (35).

Crop production. In terms of emissions, crop production processes of interest included fertilizer production, fertilizer application, tillage, agricultural equipment use, field burning, and pesticide application. For fertilizer production and pesticide application, national-level emissions were distributed according to crop fertilizer and pesticide use data published by the USDA ERS (37, 38). For tillage and field burning, SCCs within the NEI2014 were used to allocate emissions to a specific crop type (15). Because the NEI2014 only includes tillage emissions for 21 crops, we introduced tillage emissions from an additional 71 crops available in the 2014 CDL by averaging county-level average emissions factors for annual or perennial crops in the NEI2014; we then applied the appropriate emission factor (annual or perennial) to county-level crop acreage (32).

Emissions from agricultural equipment use and fertilizer application are not preallocated to crops in the NEI2014 and therefore required additional allocation. For agricultural equipment use, we allocated county-level emissions to crop commodities using the county-level crop acreage of 92 crops (including grassland pasture) in the CDL (32). In the case of fertilizer application (for synthetic and organic fertilizers but not manure), we allocated county-level NH_3 emissions to specific crops, in proportion to crop acreages from the CDL (32) paired with crop-specific nitrogen volatilization rates and irrigation rates obtained from the Environmental Policy Integrated Climate (EPIC) model (39). However, the EPIC model only includes crop-specific data for 20 crops, with all other emissions aggregated into an "other_crops" category. As preliminary results suggested that the total emissions of the other_crops category were comparable to those of major crops such as corn and soybean, further resolution in the other_crops category was achieved by allocating emissions in proportion to the county-level distribution of crop acreage from the CDL. Emissions from the roughly 1% of counties listed in the NEI2014 but not included in the EPIC model were conserved and allocated according to the state-level distribution of emissions.

We then allocated emissions from crops to final products (e.g., crop products, animal products, exports, and biofuel) using production data from annual Yearbook Data Tables and the 2015 Agricultural Statistics Report (20, 40). This allowed us to estimate the total annual deaths associated with the production of 95 agricultural commodities as well as the per-unit annual deaths associated with the production of 67 food products (*SI Appendix*, Table S2).

Annual Deaths. We input spatially explicit emissions inventory data into three reduced-complexity chemical transport models (RCMs): Air Pollution Emission Experiments and Policy v3 (16), EASIUR (Estimating Air pollution Social Impact Using Regression) (17), and Intervention Model for Air Pollution (18). All three models include simplified representations of atmospheric chemistry and physics, which reduce computational demands relative to traditional chemical transport models, including linearization that omits meteorological coupling. This enabled us to evaluate a broad range of emissions scenarios. At the same time, each of the models has a different structure and makes different simplifying assumptions, which reduces the likelihood that all three models would make the same type of error. We chose these RCMs as they allow users to distinguish the $PM_{2.5}$-related mortality by emissions source locations and provide higher resolution than other national-scale RCMs, such as the US EPA Response Surface Model (19). The RCMs are described in the *SI Appendix*.

Because the RCMs only cover counties in the contiguous United States, we excluded NEI2014 emissions in noncontiguous states from the analysis. The RCMs are customized to estimate annual deaths according to the American Cancer Society's concentration-response function, which averages a 6% increase in annual deaths per 10 $\mu g \cdot m^{-3}$ in $PM_{2.5}$ concentration. Although NO_x and volatile organic compounds can react to form tropospheric ozone (O_3), which can also result in premature mortality, we excluded O_3 from this analysis because the resulting air quality–related health impacts are overall greatly exceeded by those of $PM_{2.5}$ (8).

Despite key differences between the formulation of the three RCMs, estimated marginal social costs per tonne of primary $PM_{2.5}$, NH_3, NO_x, and SO_2 generally fall within a factor of 2–3 for all US counties (19). The agreement of RCM model predictions is greatest for primary $PM_{2.5}$ (Pearson correlation coefficient = 0.73 to 0.81) for which the atmospheric chemistry that translates pollutant emissions to changes in $PM_{2.5}$ concentrations is relatively straightforward. It is weakest for NO_x and SO_2 (Pearson correlation coefficients of 0.35 to 0.49 and 0.07 to 0.54, respectively) for which the atmospheric chemistry is more complex. Overall, total emission-weighted annual deaths in the United States vary between 12 to 33% for ground-level sources (19).

Sensitivity Analysis. We evaluated the seasonal sensitivity of annual deaths using the seasonal social costs per tonne estimated by the EASIUR model. Specifically, we tested the seasonal sensitivity of NH_3 from livestock waste management and fertilizer application: NH_3 is the primary driver of agricultural emissions, and social costs per tonne of NH_3 are highest (roughly 2.5× greater) when seasonal emissions are relatively low (41). The NEI2014 estimates annual emissions. We obtained monthly NH_3 emissions from livestock waste management and fertilizer application by applying the monthly distribution of emissions from Pinder et al. and Goebes et al., respectively (41, 42). Damages using the seasonal option in EASIUR were comparable to those using the annual average option (*SI Appendix*, Fig. S6).

Mitigation Interventions. We estimated the air quality–related health benefits that can be achieved through interventions by producers and consumers, largely targeting NH_3 as it is a major driver of $PM_{2.5}$-related deaths attributable to food production in the agricultural sector (43). Specifically, we focused on intervention scenarios that could reduce emissions linked to livestock waste management, fertilizer application, tillage, field burning, fuel combustion, dietary shifts, food loss and waste, and per capita consumption levels.

We estimated the air quality–related health benefits of interventions by comparing health outcomes for an intervention scenario with those for a baseline scenario in which food producers and consumers behave according to business as usual. To measure the health outcomes linked to an intervention scenario, we first estimated the emissions reductions that can be achieved from a specific intervention and used that information to create a spatially explicit inventory of reduced emissions. Using the emissions inventory as input for the RCMs, we then modeled the resulting health outcomes.

We estimated emissions reductions of producer-side intervention scenarios by averaging emissions reductions linked to existing interventions as found in a survey of the literature (*SI Appendix*, Table S4). Identified interventions were grouped by agricultural process such as livestock waste management and fertilizer application. When possible, they were further grouped into subcategories such as livestock housing type or fertilizer type. For instance, emissions reductions for interventions targeting dairy cattle at the confinement stage are estimated by averaging emissions reductions for individual interventions, such as installing grooved floor systems with tooth scrapers in the confinement facilities or establishing a tree shelterbelt surrounding confinement facilities.

With regard to consumer-side interventions, we examined two caloric scenarios: 1) caloric intake is at current US levels (average of 2,590 kilocalories per capita per day), and (2) caloric intake is reduced to a level that would maintain a body mass index between 20 and 25 for an average person (average of 2,400 kilocalories per capita per day) (44). In the second scenario, we assumed that caloric intake was reduced proportionally across all food groups to achieve the target caloric level. Six isocaloric dietary scenarios from the EAT-Lancet Commission were considered: 1) business as usual in the United States, 2) the planetary health diet, 3) the planetary health diet with high milk consumption, 4) planetary health diet with high red meat consumption, 5) vegetarian, and 6) vegan (2, 3). In modeling alternative diets, the EAT-Lancet Commission considers national preferences of different food groups. Because foods can be imported or exported, the composition and volume of foods produced in the United States do not exactly match those of foods consumed in the United States, though 87% of food and beverages purchased in the United States are domestically produced (45).

We considered two options for estimating annual deaths linked to diets and food production in the United States for the business-as-usual dietary scenario: 1) we assumed annual deaths in the business-as-usual dietary scenario are equal to annual deaths from the US agricultural sector minus annual deaths from nonfood production, and 2) we assumed that annual deaths in the business-as-usual dietary scenario can be computed by matching the per-kilocalorie annual deaths associated with food groups with the caloric composition of the average United States diet from the EAT-Lancet Commission (2). The EAT-Lancet Commission estimates caloric composition of the baseline US diet using country-specific food availability data and model equations from the International Model for Policy Analysis of Agricultural Commodities and Trade. We found that the estimated annual deaths from both options differed by 8% (option one: 15,900 deaths per year and option two: 17,200 deaths per year). We used the results of the first option to analyze mitigation interventions because that option more closely represents current US food production. We estimated annual deaths linked to alternative scenarios by matching the per-kilocalorie annual deaths associated with food groups with the caloric composition of the diet being examined (assuming all food consumed in the United States is produced domestically). We assumed that the average damage of food groups remained constant with changes in production. More information on the per-kilocalorie annual deaths attributable to food groups and the caloric composition of the diets are in *SI Appendix*, Tables S2 and S3, respectively.

We considered two food loss and waste scenarios: food loss and waste at current US levels (46), and food loss and waste reduced by 50%. We distinguish food loss and waste by food type and by food supply chain stage (agricultural production, postharvest handling and storage, processing and packaging, distribution, and consumption) using estimates for the North America and Oceana region (46). We also assumed that reductions occur proportionally across both food loss and waste.

SUSTAINABILITY SCIENCE

Finally, we explored the cost effectiveness of selected NH_3 mitigation interventions, including changes in practices related to livestock feed, animal housing, manure storage, manure application, and synthetic fertilizer application.

IOWA CONCENTRATED ANIMAL FEEDING OPERATIONS AIR QUALITY STUDY

Final Report

Iowa State University and The University of Iowa Study Group

February 2002

Table of Contents

Acknowledgements

The University of Iowa-Iowa State University CAFO study group thanks Governor Tom Vilsack and Director Jeffrey Vonk for giving us the opportunity to bring scientific discourse to this issue of such great importance to Iowans. The Chairs would like to acknowledge the tremendous effort of the study group in completing this task. Co-chairs Gerald Miller, Gary Osweiler and Peter Thorne are specifically commended for their hard work and diligence. A huge debt of gratitude is owed to Dr. Carol Hodne who served as both a co-author and as the coordinator for the study group. Technical, design and editorial assistance was provided by Leslie Loveless, Kathryn Andrews, Patti O'Neill, Angela Rieck-Hinz, Kathey Testin, Susan Thompson, and Julia Venzke. We also wish to thank Bryan Bunton of the Department of Natural Resources for providing data on odor complaints in Iowa. Lastly, we thank our external peer review group for providing insightful comments in a very short time frame. Participants from the University of Iowa acknowledge the support of the Environmental Health Sciences Research Center which is funded by the National Institute of Environmental Health Sciences (NIH Grant P30 ES05605).

Foreword

In June, 2001, Governor Tom Vilsack asked the Presidents of Iowa State University and of The University of Iowa to assist the Iowa Department of Natural Resources and the Environmental Protection Commission with addressing public health and environmental concerns arising from air emissions from concentrated animal feeding operations (CAFOs). With the concurrence of both presidents, Iowa Department of Natural Resources Director Jeffrey Vonk charged the College of Public Health at the University of Iowa and the College of Agriculture at Iowa State University to recommend standards for air quality and address other issues regarding CAFOs.

The Colleges of Agriculture and Public Health assembled teams of faculty with appropriate expertise to complete a comprehensive review of available scientific information to address five questions asked by Director Vonk. At ISU, faculty from the College of Veterinary Medicine also made important contributions to this effort. The ISU team was led by administrators from both of these colleges. At The University of Iowa, the Environmental Health Sciences Research Center, sponsored by the National Institute for Environmental Health Sciences, assembled a team composed of faculty from the Colleges of Public Health, Engineering and Medicine. Together, these faculty delved into existing research literature, developed a ten-chapter report on the various aspects of these issues and, through a series of meetings, developed responses to Director Vonk's five questions in the form of an Executive Summary. This Executive Summary describes the consensus reached by the study group. Individual chapters are the products and views of the chapter authors. Independent national and international scientists, with appropriate expertise, reviewed and commented on both the Executive Summary and the full report.

The report is based upon the best science available to ensure that rural ambient air is as free of risk as possible in order to protect health and the quality of life at the highest possible level. These science-based recommendations were generated with the goal of providing helpful guidance to the Iowa Department of Natural Resources and the Environmental Protection Commission. It is hoped that the report will provide a sound basis for the development of appropriate administrative rules that will promote confidence in agricultural production and the quality of life in rural Iowa.

CHAPTER 1 Executive Summary

Introduction

In mid-June of 2001, Governor Tom Vilsack requested that the faculty of the two universities address the public health and environmental impacts of concentrated animal feeding operations (CAFOs, also referred to as Concentrated Feeding Operations or CFOs). In response to this request, Richard Ross, PhD, DVM, Dean of the College of Agriculture at Iowa State University and James Merchant, MD, DrPH, Dean of the College of Public Health at The University of Iowa, were asked by the Department of Natural Resources Director Jeffrey Vonk to provide guidance **"regarding the impacts of air quality surrounding CFOs on Iowans and recommended methods for reducing and/or minimizing emissions. Specifically, I am asking your advice and recommendations on how the Department of Natural Resources should address this critically important public policy issue."**

Director Vonk asked five questions. Through a series of discussions and meetings, a combined study group of faculty and consultants (See Attachment 1) was identified, conflict of interest and confidentiality statements were signed by all faculty and consultants, definitions were discussed and agreed upon, a comprehensive report outline was developed and agreed upon and individual teams of faculty agreed to write each of the 10 chapters that constitute the full report. A technical and policy workshop was held in Des Moines on December 18 and 19, 2001, at which time chapter presentations were made and discussions were held regarding the series of five questions asked by Director Vonk. Groups were assigned to summarize the responses to these five questions in this Executive Summary. Peer review of this Executive Summary and the full report was considered to be vital to the validity and integrity of the report. This peer review, completed by national and international scientists who are experts in the areas addressed by the report (See Attachment 2), was completed in January, 2002. Their review comments, as well as comments from members of the combined study group, were discussed at meetings on January 8, 24 and 29 and were useful in completing the final report for submission to the Iowa Department of Natural Resources (IDNR). An agreed-upon glossary, which defines the many technical terms used in this report, is found in Attachment 3.

Response to Question 1

There are two questions contained in Question 1. The first is:

Based on analysis of peer-reviewed, duplicated, legitimate, published scientific research, is there direct evidence of harm to humans by emissions, byproducts, toxic waste, or infectious agents produced by CFOs?

There is now an extensive literature documenting acute and chronic respiratory diseases and dysfunction among workers, especially swine and poultry workers, from exposures to complex mixtures of particulates, gases and vapors within CAFO units. Common complaints among workers include sinusitis, chronic bronchitis, inflamed mucous membranes of the nose, irritation of the nose and throat, headaches, muscle aches and pains. Asthma and acute (cross-shift) declines in lung function are documented among CAFO workers, even though workers with pre-existing asthma usually select themselves out of such employment because of increased asthma severity. Progressive declines in lung function over years are documented among CAFO workers. Those workers with increased acute declines in lung function, which are often accompanied by chest tightness and wheezing (asthma-like syndrome), have been found to have more rapid declines in lung function over time. Very high exposures to hydrogen sulfide, which occurs during pit agitation, may result in death from asphyxia and respiratory arrest; those who survive such high dose exposures often develop reactive airways distress syndrome (RADS), bronchiolitis obliterans and severe respiratory impairment. It is therefore concluded that there is direct evidence of harm to humans from occupational exposures within CAFOs (See Chapter 6.3.2).

However, one cannot directly extrapolate occupational health risks observed among workers inside CAFOs to community health risks that may arise from CAFO emissions. While the discharge of airborne particulates and gases/vapors from CAFOs and manure handling clearly occur, the aerosols at the point source differ from ambient exposures as they move downwind, both in composition and in concentration. The populations at risk (workers) within CAFO units and within the community (community residents) also differ significantly. CAFO workers are generally a healthy population (those fit enough to work), while community residents include children, the elderly, and those with preexisting impairments. Regulatory agencies recognize the need for lower exposure limits to compensate for increased susceptibility among community residents, to allow for uncertainty factors from epidemiological study findings (and for species to species differences when animal data is used) to establish community ambient exposure limits.

The second part of the first question is:

What human research is there to confirm the existence of disease and exactly what are the specific chemical, bacterial, or aromatic causes of such diseases?

Published, controlled studies of odor experienced by community residents living in proximity to CAFOs are limited to two studies in North Carolina and one in Iowa. The first North Carolina study reported more negative mood states (tension, depression, anger, reduced vigor, fatigue and confusion) among those exposed to CAFO odor compared with control subjects. The second North Carolina study reported increased symptoms of headache, runny nose, sore throat, excessive coughing, diarrhea, burning eyes and reduced quality of life measures among community residents living in proximity to a swine CAFO compared with rural residents not living in proximity to livestock operations. The Iowa study found increases in several symptom clusters, mainly eye and upper respiratory symptoms, among those living within two miles of a swine CAFO compared with rural residents living near minimal livestock production. These studies are limited in size and scope, did not make specific environmental exposure or odor measurements, and are subject to recall bias. They are notable in that they are controlled studies that report eye and respiratory symptoms associated with concentrated livestock exposures that are similar to more prevalent and severe symptoms experienced by CAFO workers who are exposed at much higher concentrations of mixed emissions (See Chapter 6.3.3).

Also relevant in responding to this question are many experimental and epidemiological studies of non-CAFO populations exposed to low concentrations of individual chemical components of CAFO emissions, particularly hydrogen sulfide, ammonia and endotoxin. These studies document respiratory symptoms associated with low levels of these individual exposures. Because at least two of these chemicals (hydrogen sulfide and ammonia) are found in CAFO emissions that contribute to ambient community exposures, these experimental and community exposure studies are relevant to this question (See Chapter 6.3.1). Both the Environmental Protection Agency (EPA) and the Agency for Toxic Substance and Disease Registry (ATSDR)[1] have recommended ambient exposure limits for ammonia and hydrogen sulfide based on these studies.

It is concluded that no specific disease(s) *per se* among community residents can be confirmed to arise from a specific chemical, bacteria or aromatic cause. However, the findings of the limited community studies of concentrated livestock exposures are consistent with adverse health effects observed in other experimental and epidemiological studies of some specific chemicals (ammonia and hydrogen sulfide) known to be components of CAFO air emissions. It is, therefore, also concluded that CAFO air emissions may constitute a public health hazard[2] and that precautions should be taken to minimize both specific chemical exposures (hydrogen sulfide and ammonia) and mixed exposures (including odor) arising from CAFOs.

Response to Question 2

Question 2: Based on an analysis of peer-reviewed, duplicated, legitimate, and published scientific research, what specific substances, including aromatic compounds, do you believe require regulatory action to protect the public?

By consensus of the entire study group, the following substances should be considered for regulatory action: (1) hydrogen sulfide; (2) ammonia; and (3) odors. The justification for regulatory action of these substances is based on our assessment of the scientific literature, (See Chapters 2.0-8.0), recommendations by pertinent federal agencies, and review of regulations established in other states (See Chapter 9.0).

Hydrogen sulfide and ammonia are recognized degradation products of animal manure and urine (See Chapter 3.4 in the full report). Both of these gases have been measured in the general vicinity of livestock operations at concentrations of potential health concern for rural residents, under prolonged exposure (See Chapter 8.0).

The World Health Organization lists hydrogen sulfide as a toxic hazard in many environments, and recommends specific exposure limits. The ATSDR lists hydrogen sulfide and ammonia on its registry of toxic substances[1] under its federal mandate to protect the public health according to the Comprehensive Environmental Response, Compensation, and Liability Act, [42 U.S.C. 9604 et seq] as amended by the Superfund Amendments and Reauthorization Act [pub. 99-499]. Furthermore, the ATSDR has published Minimum Risk Levels (MRL's) for these substances to protect the public's health.[1] The EPA historically evaluates scientific information regarding environmental contaminants and the potential threats for human health hazards. Based on a standardized risk assessment process, the EPA identifies hydrogen sulfide and ammonia as potentially hazardous substances.[3] A detailed description of the process and justification used by the EPA and ATSDR to include ammonia and hydrogen sulfide as hazardous substances is provided in detail in Chapter 8.7.

[2] hazard: the potential for radiation, a chemical or other pollutant to cause human illness or injury

[3] Environmental Protection Agency, Integrated Risk Information System, www.epa.gov/iris/subst.html

Minnesota and Nebraska have established air quality standards for hydrogen sulfide based on public health concerns. California and Minnesota regulate ambient concentrations of hydrogen sulfide based upon nuisance and human health effects. Minnesota is in the process of setting standards for ammonia ambient exposures. Monitoring of ammonia ambient exposures is taking place in Missouri. The regulatory actions taken by other states in setting standards are described in Chapter 9.0.

Odors have been a major concern of residents in the vicinity of CAFOs (see Chapter 3.4, 4.0, 6.8 and 8.0). Colorado, Missouri, and North Carolina have recognized the need to promulgate odor regulations. Details of the processes of odor regulations for these states are presented in Chapter 9.0.

Response to Question 3

Question 3: Based on an analysis of peer-reviewed, duplicated, legitimate, and published scientific research, what would you recommend as Iowa or National consensus standards for any proposed substances to be regulated as emissions from CFOs?

The study group recommends that ambient air quality standards be developed to regulate the concentration of hydrogen sulfide, ammonia and odor. There has been considerable discussion on what standard levels should be established for each pollutant as well as where the measurement should take place. Some states measure concentration at the property line of the source while others measure at the residence or public use area. The U.S. EPA has determined that simultaneous exposure of two substances such as hydrogen sulfide and ammonia (both pulmonary irritants) results in an additive effect. Thus, in order to protect against the adverse effects of such binary mixtures the exposure limit for each should be reduced accordingly. While emissions from CAFOs fluctuate over time, they produce chronic rather than acute exposures. Rather than representing single doses, these exposures are recurring and may persist for days with each episode.

The study group reached consensus that measurements for hydrogen sulfide and ammonia should be taken at the CAFO property line and residence or public use area. Measurements for odor should be taken at a residence or public use area and one proposal includes measurements at the CAFO property line. The study group recommends that measurements for hydrogen sulfide and ammonia should be time weighted rather that instantaneous to allow for atmospheric variability.

With current animal production practices, stored manure must be removed and land-applied. During these times hydrogen sulfide, ammonia and odor levels at or near production facilities may be significantly higher than during normal conditions. Therefore, it is also recommended that provisions be made for allowable times to exceed the established standards to allow for proper manure application to land. Notification must be given to the Iowa DNR and nearby residents, at least 48 hours in advance when the operation expects to exceed the standards

The study group provides the following recommendations on the regulation of hydrogen sulfide, ammonia, and odor from CAFOs:

<u>Hydrogen Sulfide</u>
It is recommended that hydrogen sulfide, measured at the CAFO property line, not exceed 70 parts per billion (ppb) for a 1-hour time-weighted average (TWA) period. In addition, the concentration at a residence or public use area shall not exceed 15 ppb, measured in the same manner as the property line

measurement. It is recommended that each CAFO have up to seven days (with 48 hour notice) each calendar year when they are allowed to exceed the concentration for hydrogen sulfide.

Ammonia

It is recommended that ammonia, measured at the CAFO property line, not exceed 500 ppb for a 1-hour TWA period. In addition, the concentration at a residence or public use area shall not exceed 150 ppb, measured in the same manner as the property line measurement. It is recommended that each CAFO have up to seven days (with 48 hour notice) each calendar year when they are allowed to exceed the concentration for ammonia.

Odor

The study group was unable to reach consensus on the regulation of odors. Thus, the following two opinions for odor are presented:

Opinion 1:

It is recommended that odor, measured at the residence or public use area, shall not exceed 7:1 dilutions with an exceedence defined as two excessive measurements separated by 4 hours, in any day. It is recommended that each CAFO have up to seven days (with 48 hour notice) each calendar year when they are allowed to exceed the concentration for odor. At the CAFO property line, odor shall not exceed a 15:1 dilution, with an exceedence defined as one excessive two-hour time averaged sample, in any day. It is recommended that each CAFO have up to 14 days (with 48 hour notice) each calendar year when they are allowed to exceed the property line concentration for odor. Exceedence of a CAFO ambient air quality standard should result in regulatory action similar to that which would be required in regulatory action exceedence of a National Ambient Air Quality Standard. The IDNR should be granted the power to develop an implementation plan to reduce the emissions that led to the violation.

Opinion 2:

Odor recommendations are more difficult to establish because studies relating health impacts to odor exposure have not measured odor concentrations. However, odor concentrations related to annoyance impacts have been established. Measurements for odor should be taken at a residence or public use area. Using sampling events at the source, the frequency, duration, and concentration of exposure to odor at the residence can be modeled using tools currently available, thereby avoiding extensive monitoring.

Polls indicate that residents are willing to tolerate nuisance odors for only up to a reasonable amount of time (see Iowa Rural Life Poll, Chapter 7 in the full report). Thus, the reported odor concentration represents tolerable continuous exposure, above which, concentrations are tolerated only in relation to their frequency and duration. An odor concentration of 7:1 dilutions at a residence is a tolerable odor providing it is not exceeded for periods that extend beyond that considered reasonable.

Response to Question 4

Question 4: What do you think should be done to address any other emerging issues with respect to industrial CFOs in Iowa?

There are other important emerging issues surrounding the intensification of livestock production that extend beyond concerns over air emissions. These include concerns about water quality, the health of CAFO workers, socioeconomic impacts in rural communities, and the emergence of microorganisms resistant to antibiotics used in human and veterinary medicine. There are also concerns about the emission of greenhouse gases from CAFO sites. The effects of siting large CAFOs in or near communities should be recognized and used in making informed decisions on permitting facilities. There is a need to evaluate plans for controlling livestock epidemics and for proper disposal of carcasses in the event of an outbreak. Recent events in Europe associated with foot and mouth disease, plus renewed concerns over agricultural bioterrorism highlight this need. Lastly, the study group makes recommendations regarding the formation of a science advisory panel to advise the IDNR on agricultural and environmental health issues. Each of these issues is further described below.

Some issues discussed in this section may be outside the purview of the IDNR, but all are congruent with science-based conclusions in the body of the report. Some are appropriately addressed by other state or federal agencies, and some can only be addressed through a combination of related public policies.

Water Quality

Water quality is a major issue concerning CAFOs. Concerns include: 1) leakage or rupture of lagoons (both lined and unlined); and 2) runoff from agricultural fields where animal waste has been improperly applied. Nonpoint discharges may result in surface runoff with high concentrations of ammonia, biochemical oxygen demand (BOD), total and fecal coliform bacteria, total suspended solids, and phosphorus which can cause low dissolved oxygen in streams. Ecosystem impacts may include fish kills, changes in the natural food webs, algae growth, and losses of biological diversity in stream habitat. Both the structure and function of aquatic ecosystems can be impaired. Impacts may include increased cost for drinking water treatment of surface water supplies, reduced harvest of fish and shellfish, closed bathing beaches due to fecal coliforms, and loss of aesthetic beauty of Iowa's waterways.

Recently, Iowa has experienced an increase in the number of CAFOs as well as a greater density of animals per operation. Many larger operations are not self-sufficient in grain production and purchase feed from other sources. Therefore, applicators must follow additional application guidelines established by legislation and rules. While some study group members believe manure should never be applied to frozen ground or steep slopes, others recommend that manure application on steep slopes and frozen ground follow guidelines established by USDA Natural Resources Conservation Service "Iowa Nutrient Management Standard 590". In addition, large producers are required to file manure management plans with the IDNR.

Study group members reached consensus that as operations become more numerous and concentrated on limited land bases, there is an increased risk for deterioration of water quality. All members believe that if producers do not follow their manure management plans, the chance for runoff of nutrients and bacteria is increased. In addition, some members felt more strongly on this issue, stating that it is not possible to apply manure at high areal loading rates without runoff of nutrients and bacteria because one cannot foresee intense rainfall events. One cannot assume that manure can always be safely applied to land without a potential for runoff. These members feel the present system of CAFO production disposes of too much manure in too small an area exposed to uncontrolled meteorological conditions to realistically expect acceptable water quality.

Wastes that are stored in lagoons or earthen waste storage structures have a potential for spills and/or groundwater contamination if existing standards are not met. National Pollutant Discharge Elimination System (NPDES) permits are required for large (>1000 animal units) open feedlots which allow discharge only in the event of a 25-year, 24-hour storm. Totally roofed CAFOs are not allowed to discharge into surface waters, and therefore do not require NPDES permits. This is in contrast to small Iowa towns, all of which are required to have NPDES permits and meet effluent discharge requirements.

Occupational Health

The occupational health problems for those who work inside CAFOs have been well recognized since 1977. At least 25 percent of workers in swine CAFOs have been reported to have current respiratory health problems. Recommended maximum exposure levels designed to protect worker health have been defined (See Chapter 6.3). It is apparent that current Occupational Safety and Health Administration (OSHA) limits are not protective of CAFO worker health because a number of hazardous contaminants are not regulated. Importantly, OSHA has not promulgated any Permissible Exposure Limits specifically to protect the health of livestock production workers.

There are several important regulatory problems that have interfered with the protection of workers in CAFOs. Most of the large livestock and poultry producers have not been regulated by OSHA, even though they may have more than 10 employees and are subject to OSHA regulations. The specialization of livestock production has led to increased cumulative exposure, as workers may spend as much as 70 hours per week in these buildings. There is a need to establish exposure standards that protect workers for these extended work schedules. There is enough information to protect workers' health if recognized workplace management procedures are adopted. It is recommended that the livestock-producing industries institute comprehensive worker health protection programs.

Antibiotic Resistance

Antibiotic resistance is a health threat of great concern. Recent documents from the World Health Organization (2000), the Centers for Disease Control, and other health agencies have placed a high priority on the understanding and control of antibiotic resistance (Interagency Task Force On Antimicrobial Resistance, 2000; Tenover and Hughes, 1995). It is clear that certain antibiotic use practices in human medicine have contributed to resistance. Agricultural antibiotic use practices have also been targeted as contributing to this serious problem (Witte, 1998). In particular, the subtherapeutic use of antibiotics in food producing animals has been identified by public health officials as the key factor in the development of resistance among foodborne pathogens (Gorbach, 2001).

Antibiotic resistant organisms or the resistance genes responsible can be spread from agricultural settings into human populations through a variety of mechanisms. Ingestion of contaminated food products, especially animal-derived foods including meat and dairy products, has been linked to spread of antibiotic resistant organisms (Mead et al., 1999). Direct contact between colonized or infected animals and farm workers has also been associated with the acquisition of resistant organisms in humans (Levy et al, 1976).

Various studies have demonstrated that continued use of antibiotics in feedstuffs provides conditions favorable to the selection of resistant strains of bacteria in food animals and their environment (Chee-Sanford et al., 2001; Zahn, Anhalt, & Boyd, 2001). Yet the threats for emergence of resistant strains of bacteria through subtherapeutic use of antibiotics in livestock applies wherever these practices occur; the threat is not restricted to CAFOs. Selection pressure may be enhanced by: (1) the long-term use of antibiotics in animals having endemic subclinical infections; (2) poor environmental hygiene; and (3) management practices that allow for the introduction of naïve, susceptible animals or the movement of carrier animals into a naïve herd. This latter practice allows for the continuous passage of resistant bacteria among susceptible animals. Over the past decade, increasing numbers of organisms isolated from food animals or meat products demonstrate resistance to antibiotics including penicillins, tetracycline, sulfamethoxazole, streptomycin and other compounds (Aarestrup et al, 1998; Centers for Disease Control and Prevention, 1999; Molbak et al, 1999; Smith et al., 1999; Threlfall et al., 1996; White et al., 2001).

Antibiotics are critically important in human and veterinary medicine, and in the current context, food animal production. Organisms resistant to all classes of available antimicrobial agents have been identified in human medicine and the incidence of community acquired highly drug resistant organisms is increasing (Neu, 1992). No new classes of antimicrobial agents will be available in the foreseeable future. It is critical that the appropriate state and federal agencies and the research community in the United States take a leading role in defining the risks associated with different antibiotic use practices and develop strategies to improve our antibiotic stewardship both in human and agricultural settings (American Medical Association, 2001).

Greenhouse Gas Emissions

Regarding air pollution, air permits are not required for emissions from CAFOs, so there is not a good method to quantify their inputs. However, emissions of particulate matter, sulfur compounds, and nitrogen oxides are believed to be a very minor portion of Iowa's total emissions. CAFO emissions of these pollutants are small compared to emissions from stationary sources (power plants and industry) and mobile sources (automobiles and truck diesel). Greenhouse gas emissions from CAFOs are significant for methane. On a radiative basis (greenhouse gas impacts), methane is about 10-15% of the total greenhouse gas produced in Iowa, and methane from manure management is about 25% of the total (approximately 3% of total greenhouse gas estimated in Ney et al., 1996). The Iowa Greenhouse Gas Action Plan calls for capture of methane at large feed lots (Ney et al., 1996). Nitrous oxide emissions from manure management at CAFOs is a small contribution, and the emissions of carbon dioxide from CAFOs are a negligible portion of the state's CO_2 emissions.

Community and Socioeconomic Impacts

A number of important community and socioeconomic issues have developed with the emergence of CAFOs, as described in Chapter 7. Research has explored some of these issues, and posed and evaluated alternatives, including some alternatives for livestock production. To a significant extent, these issues are tied to overall changes in agriculture and rural life in America. Importantly, these issues are complex and generally outside the purview of the IDNR.

These issues include the concern about increased concentration of control of livestock supply chains, lack of public price discovery, and loss of family farmers' control of production. Another concern is decline in local economic activity and increases in purchases of some animal production inputs from outside the local area, as CAFOs increase in size and number. This is a complex issue since we must estimate what purchases would have been made had the structure remained the same. Of equal importance is the fact that decision-making on questions that matter at the local level are increasingly more centralized with the growth of corporate CAFOs.

Devaluation of property near hog CAFOs and related legal challenges are documented. Studies in Michigan, North Carolina, and Missouri found that the value of real estate close to CAFOs tended to fall. These and other data show that CAFOs are defined by present and potential neighbors as at least a nuisance.

Studies showing a decline in neighborliness, or community social capital, have been conducted in Iowa, North Carolina, Minnesota, and Missouri. This decline was measured by diminished opportunities to socialize, lack of trust, increased community conflict, and related variables in communities where CAFOs are concentrated.

A more diverse livestock sector that was able to remain competitive and responded to increasingly differentiated consumer preferences would likely result in greater environmental (Donham, 2000), social (Wright, et al., 2001), and economic sustainability of rural areas than one dominated by large-scale CAFOs. Policies that encourage more diverse livestock/crop farms, particularly those using sustainable production systems, could also reduce the regulatory burden of the IDNR and other agencies.

The most clearly recognizable socioeconomic issue for CAFOs that impinges on the IDNR's responsibilities is what CAFOs may do to aquatic, wildlife, and aesthetic qualities of living in Iowa, as well as tourism in Iowa. If air and water quality is compromised, the interest of persons and businesses considering relocation to Iowa will be lessened. A compromised environment could have an economic impact on tourism by keeping Iowa a low priority destination for visitors as well as driving fishing and hunting activity away from Iowa and toward less challenged environments.

Livestock Epidemic and Disposal Issues

The current state plan for Foot and Mouth Disease (FMD) in Iowa is multi-agency and is called the Foot and Mouth Disease Response and Recovery Plan. As part of its responsibilities in the state plan, the IDNR has developed the FMD Carcass Disposal Plan. Burial and composting are given high priority compared to burning, in order to reduce air pollution consequences. However, the potential impacts of a FMD epidemic like that of last year in the United Kingdom and Europe should be evaluated to assess if the current plans are sufficient for isolation of pathogens and destruction of carcasses. In addition, these plans should be evaluated for other pathogens, including bioterrorist introduction of anthrax and other potential agents of agricultural bioterrorism.

Formation of a Science Advisory Panel

To enhance the effectiveness of responses to emerging issues, the study group recommends formation of a science advisory panel to contract with the IDNR on agricultural and environmental issues. The University of Iowa and Iowa State University participants have found the current review of scientific literature on CAFOs and the ensuing discussions to be very useful. University faculty could continue in a more general role as a scientific advisory panel. This would provide the opportunity to develop closer collaboration and planning in a prospective manner. The partnership of the IDNR and other appropriate state agencies with a continuing advisory group of specialists in the sciences germane to agricultural, environmental, and public health issues would strengthen Iowa's ability to plan for prevention or remediation of emerging problems in a thoughtful and positive manner with sufficient lead-time to engage the needed resources and evaluation. A science advisory panel could suggest areas for needed research to better resolve or control the factors related to emerging issues. The panel could recommend consultants, establish standard operating procedures for resolving questions, and be prepared with the necessary background, literature resources and ongoing discussion to support science-based advice as needed by the IDNR or other agencies in Iowa.

Response to Question 5

Question 5: Finally, I am seeking your recommendations regarding available methods of reducing or minimizing the emissions from CFOs and the impact of those emissions on the ambient air surrounding sites.

Emissions from CAFOs originate from three primary sources: (1) air emissions from housing units; (2) air emissions from manure storage facilities, and (3) air emissions during and following land application events. Documented emission reduction strategies exist for all three of these sources. Some of the documented strategies are more effective than others and some are more economical than others, however, economical strategies exist for dealing with emissions from all three sources.

<u>Housing Unit Air Emissions</u>

Housing unit air emissions ultimately are carried out with the ventilation air exhausted from buildings. Emissions originate from the feeding floor itself, where deposited manure and urine decompose anaerobically resulting in airborne gases and particulates from dried fecal material. In addition, emissions originate from under-floor manure storage in slatted systems and from bedding pack in deep-bedded systems. Studies have shown that, in slatted-floor housing systems, the emission contribution from the feeding floor itself can exceed 60 percent of the total with the remaining contribution from the under-floor storage compartment. Use of smooth cleanable surfaces along with frequent and complete scraping, and/or frequent flushing of the feeding floor with minimal air exchange between the housing air and the under-floor slurry, is a good strategy for reducing housing unit emissions.

If housing unit emissions are post-processed, (i.e., exhaust ventilation air is treated), additional strategies exist. Scrubbing the ventilation air with biofilters, where the exhausted air is passed through a bed of gas-scrubbing microorganisms, has been shown to reduce ammonia and odor emissions by more than 90 percent. However, effective use of biofilter technology requires simultaneous use of power ventilation. Biofilters are difficult to implement under high ventilation rate situations typical of Iowa summers and, of course, are not useful in naturally ventilated housing systems.

Gases and odors adhere to dust particles. Natural biomass filters such as corn stalks and chopped-straw have been used to capture a portion of the larger dust particles emitted with ventilation air. The evidence on this strategy is still being documented but research to date indicates that about 60 percent of the odor can be reduced using this technique.

Tree barriers are being evaluated for effectiveness in reducing odor and particulates and enhancing mixing and dilution. However, the impact on a large scale relative to livestock or poultry production sites is unknown. Tree barriers surrounding production sites have high aesthetic value.

Storage Unit Air Emissions

Outside manure storage systems can be a source of additional gas emissions. Regardless of whether the storage system is formed concrete, steel-lined, or earthen basin, these open exposures to the atmosphere can result in high emission rates. Emission rates are highly influenced by weather conditions. The most effective and economically feasible strategy for reducing emissions from outside storage units (not including anaerobic lagoons) is accomplished by covering the entire surface area of the storage unit. Research has been conducted on many covering materials, ranging from expensive impermeable covers, to relatively inexpensive chopped-straw covers with a maintained minimum depth of coverage. Inexpensive, chopped-straw cover, with a maintained minimum depth is as effective in reducing emissions as the more expensive covers. However, the key to success with this strategy is maintenance of a minimum depth of straw.

The best method for minimizing odors from anaerobic lagoons is to simply practice good management. It is most important to use adequate dilution water and load at or below design capacity. There has been much discussion recently about the use of anaerobic digesters which can significantly reduce storage odors and generate energy in the form of methane gas.

Air Emissions from Land Applied Manure

Emissions during land application of livestock and poultry manure can be intense if the manure is surface-applied. The majority of total emissions, roughly 80 percent, occur during the first six hours after land application. To significantly reduce emissions of gases and odors during land application, injection or immediate coverage (within 1 hour) is required. Odor reduction is, in turn, dependent upon the degree of soil coverage. Poorly injected manure slurry with little soil coverage is only marginal in effectiveness in reducing gas and odor emissions. To take full benefit of the natural odor absorption capacity of soils, the slurry must be completely covered. The evidence is clear that 85-90 percent emission reduction is possible with complete soil coverage compared to surface application when coverage is delayed for more than 3-6 hours.

Policy Strategies for Long-Term Viability of the Livestock Industry in Iowa

Emission of gases and particulates from livestock and poultry systems is an inevitable outcome requiring special attention. Strategies for emission reduction for all stages of production have been outlined, with most being economically feasible. The strategies outlined previously are documented techniques that have gained fairly widespread acceptance with scientists and engineers working in this area.

A few strategies have been discussed for years. They lack the scientific evidence to document their specific benefits, but nevertheless deserve discussion. The study group is unanimous in the belief that a long-term strategy of better facility siting, setbacks, and landscape considerations, in addition to the implementation of available odor and gas reducing technologies, will benefit both the producer and residents in the community. The study group strongly urges that the following topics receive careful consideration.

Statewide Spatial Planning

Facilities built today, under current siting and setback practices, have a lifetime of roughly 15 years. In the long-term, guidelines should be established based on siting and spatial planning considerations that require siting of new and replaced facilities in accordance with a statewide spatial plan. Some areas of the state are currently over-populated with facilities. A statewide spatial plan, based for example on animal units per acre, would help guide and distribute animals in a manner that takes full advantage of Iowa's soil/nutrient capabilities and minimizes the impacts of air emissions on the community.

Local Siting Guidelines

The study group feels strongly that current siting guidelines are outdated and not reflective of the changing demographics in rural Iowa. Current siting guidelines use a simple distance and size regulation for new facilities. The study group feels that this method of siting is not conducive to the long-term viability of the livestock and poultry industries in Iowa. A strategy that takes into account proposed facility size and type, distance and orientation to surrounding neighbors, local weather patterns, odor control measures, existing recreational and public-use facilities, and other existing production facilities in a community would provide better placement guidance of facilities and contribute positively to spatial planning considerations. Siting models that utilize the above mentioned inputs have been developed, are currently being calibrated, and should be used in community-wide applications.

Aesthetic Considerations for Livestock and Poultry Production Sites

Evidence exists in the literature that foliage (primarily trees) will enhance mixing and capture some of the odor-producing gases and particulates emitted from livestock and poultry production facilities. Currently, research projects are being planned, and some have already been conducted, to test the use of strategically placed tree barriers around production sites. Although evidence documenting odor, gas, and particulate-capture-percentages on a production-size scale is limited, the study group feels strongly that landscape changes such as strategically placed tree lines will positively impact producer/community relationships. This is a researchable area and one that holds promise as a natural, aesthetically pleasing strategy for producers to implement.

Conclusion to Executive Summary

The consensus responses summarized in this Executive Summary provide a science-based summary of this inquiry from the Iowa Department of Natural Resources. The study group recognizes the importance of livestock production and the vital role it plays in the livelihoods of Iowa producers and suppliers and the state's economy. It is, therefore, critically important that science-based policies be developed to sustain livestock production. It is equally vital that such policies protect the public's health, sustain and enhance the communities in which livestock production takes place, and protect and enhance the environment and Iowa's natural resources through sound production practices, environmental controls and the development of a long-range, sustainable, community health and environmentally conscious spatial plan for CAFOS.

Abstract

Animal production trends in the United States and Iowa are reviewed to illustrate the changes in the animal industry over the past 50 years. Total production from the major industries are presented along with the changes in numbers of producers and average size of production units. Rapid consolidation of the industry is evident in both poultry and swine production systems in Iowa. Cattle numbers continue to decrease in the state.

2.0 Introduction

The structural changes of the animal industry in Iowa and the related concentration trends are very similar to those seen in most industries in the United States. Overall consumption of animal products has either increased or remained stable over the past 20 years while the number of farms producing these products has greatly diminished. These trends are very similar to those seen in other industries such as construction, food processing, banking, general manufacturing, real estate, services and pharmacy. This results in a large increase in the average size of the active farms in Iowa. The number of active farms in Iowa has been reduced from over 200,000 in 1950 to fewer than 100,000 in the late 1990s as seen in Figure 1(6).

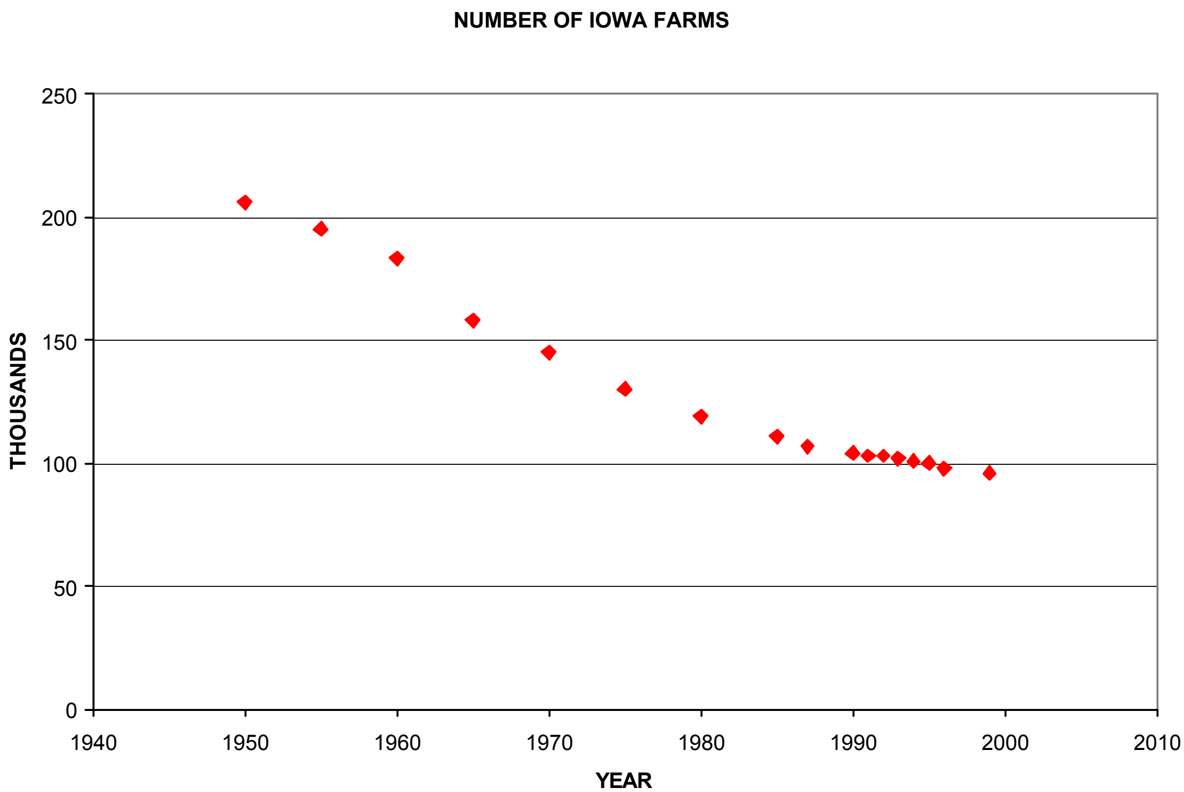

Figure 1. Number of Iowa farms.

A farm in Figure 1 is defined as any operation that sold more than $1,000 in agricultural products. The number of farms owning and operating confined animal feeding operations (CAFOs) will be much less than the above table. However, the trend in declining numbers of farms is obvious. The trend toward fewer farms in Iowa is accompanied by a reduction in the percentage of Iowa farms that have hogs or cattle as a component of their agricultural business. Figure 2 shows that in the early 1960s over 80% of Iowa farms had cattle as part of their operation and 70% had hogs as part of their farming operation. The percent of Iowa farms that included cattle in their farming operation has declined to less than 40% as of 2000, while the percent of Iowa farms that included hogs in their farming operation has declined to approximately 12%.

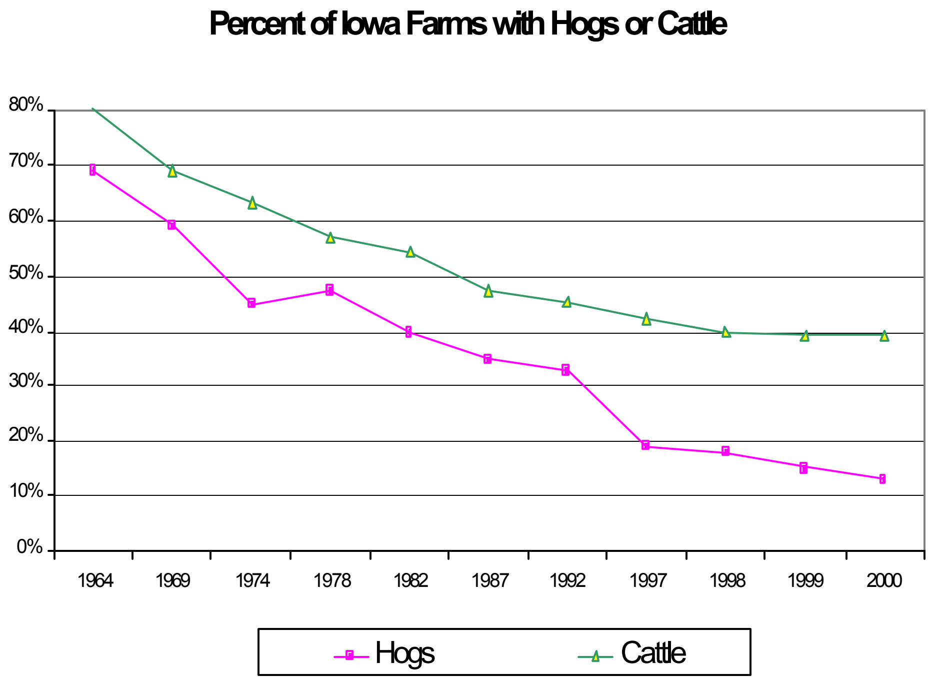

Figure 2. Percent of Iowa farms with hogs or cattle.

2.1 Swine Industry Changes

There are several very distinct trends that can be seen in the U.S. pork industry in the areas of production, processing, environment, vertical integration/coordination and the adoption of technology. The trends being seen in production of pork are shown in the following Table 1. (Lawrence and Grimes, 2001).

Table 1. Changes in USA Pork Production in Number of Farms and Percentage of U.S. Marketings

	Number of Farms			% Marketings	
Herd Size	1997	2000	% Change	1997	2000
1-50	69,460	54,513	-27%	3%	2%
50-250	20,142	17,464	-15%	28%	17%
250-500	1,978	2,627	+33%	10%	10%
500-2500	1,318	2,501	+90%	16%	19%
2500-25,000	127	136	+7%	16%	17%
25,000+	18	20	+11%	27%	35%

The production structure of the U.S. swine industry has changed dramatically in terms of size and location over the past few years. The above table shows the change in numbers of pig-producing farms and marketing percentages over just the past three years. We have recently seen a great reduction in the number of small hog farms (<250 sows) as producers have either gone out of pork production or have increased their herd size to function under the new terms of commodity pork production. The percentage of pigs marketed by this small producer type has decreased from 31% of all pigs marketed in 1997 to only 19% of pigs marketed in 2000. This dropout from production of the smaller farms has been largely picked up by expansion within the corporate pig production segment (greater than 25,000 sows) as the percent of marketing accounted for by this segment has grown by 8%. The mid-level swine production segment has picked up the rest of the fallout from the small producer. Interestingly, the increase in farm numbers (at 250+ sows) coincides with the minimum farm size to implement a weekly farrowing schedule, one of the most basic management technologies. And the herd size that has seen the greatest increase in size (500+ sows) coincides with the minimum herd size needed to market pigs in lot sizes that fit semi-trailer delivery, the most preferred method of delivery by packers (7).

One reason for the increased herd sizes is the greater potential for profit. The following table shows the profitability by herd size recently reported in the United States by Lawrence and Grimes (2001).

Table 2. Profitability by herd size (number of sows) in the U.S. (2000).

Herd Size	Net Profit	Breakeven	Net Loss
1-50	50%	30%	20%
50-250	70%	20%	10%
250-500	78%	13%	9%
500-2500	77%	12%	11%
2500-25,000	90%	5%	5%
25,000+	95%	5%	0%

This table shows the percentage of farms that reported a profit for the year 2000. It is clear that a higher percentage of smaller farms were in the breakeven or net loss return categories when compared to larger farms. The reasons for this are many, but do include those mentioned earlier. Very simply, larger farms are more consistently making a profit when compared to smaller farms.

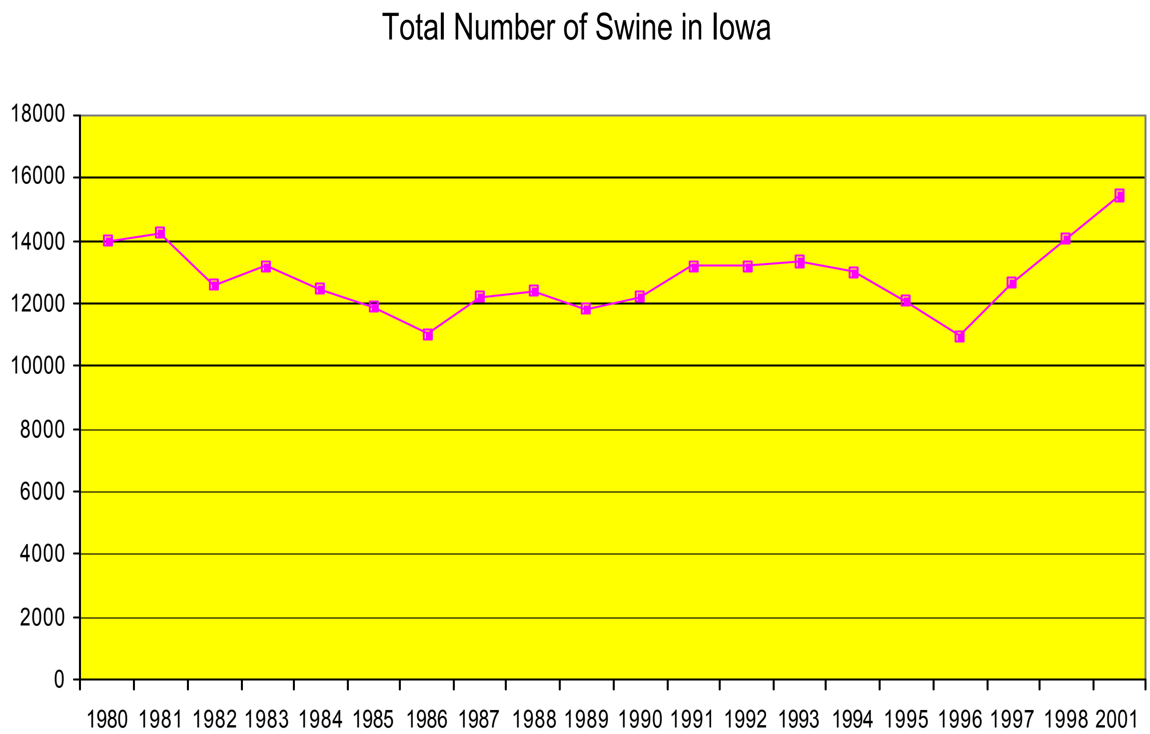

Figure 3 shows the number of swine in Iowa has stayed fairly constant in the past 20 years. However, while the numbers of pigs in Iowa have been somewhat stable, the proportion of hogs that are breeding sows versus market swine has changed markedly, as shown in Figures 4 and 5.

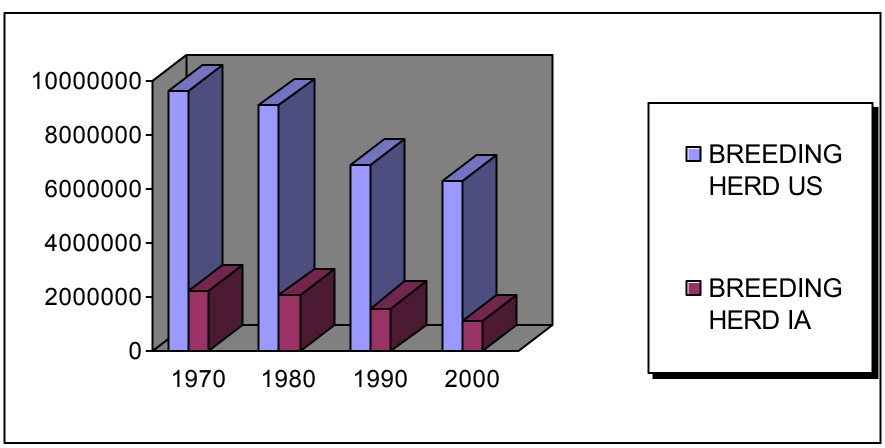

Figure 4. Swine breeding herd in USA and Iowa.

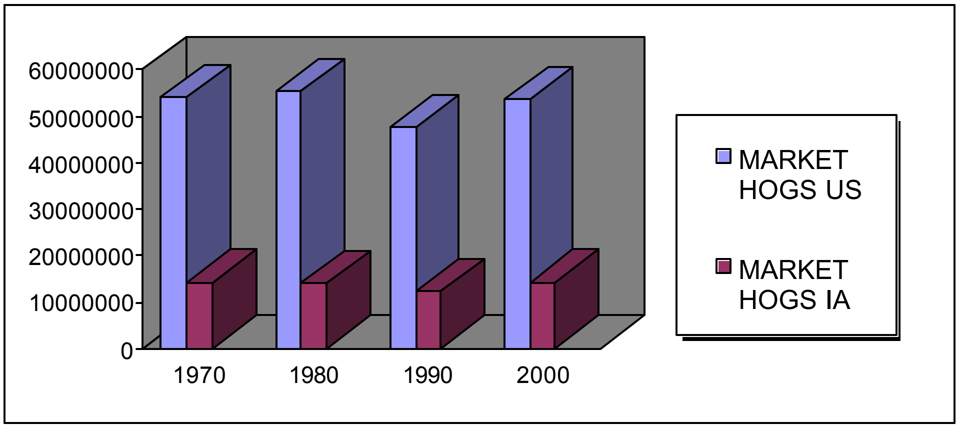

Figure 5. Market hog inventory for USA and Iowa.

Over the past 30 years the breeding herd size in the United States has decreased from just under 10 million sows to just over 6 million sows (Figure 4). However, increases in productivity have allowed total swine production to remain fairly steady. The size of the breeding herd in Iowa has declined from over 2 million sows in 1970 to 1.1 million in 2000. However, the number of market hogs in Iowa has not seen the same decline (Figure 5). One of the primary trends that has potential environmental implications is the trend towards farms having more concentration of hogs. As the number of farms with hogs has declined and the number of total hogs has been more stable, the inevitable result is that the average number of hogs per farm has increased, as shown in Figure 6. As production units increase, there is the associated concentration of waste produced in fewer, larger units. More workers are concentrated to work in the facilities, as well as larger volumes of feed and manure transport. In addition to the increased potential for emissions from these operations compared to smaller units, there is increased traffic volume servicing the unit. Increased traffic volume has the unintended affect of more dust and noise in and around the production unit.

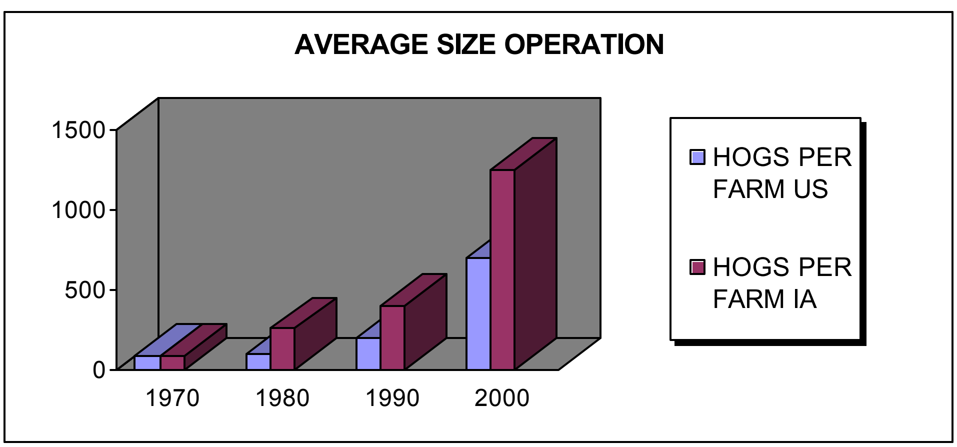

Figure 6. Average swine farm size in USA and Iowa.

The trend in unit size in Iowa mirrors that of the rest of the United States in that the number of hogs per farm has increased greatly over the past 30 years.

2.2 Beef and Dairy Cattle Industry Changes

The total number of cattle on farms in the United States has been somewhat stable over the past 20 years, but has declined over the past 40 years, as shown in Figure 7. However, Iowa has seen a steady decrease in the number of cattle on farms since a peak in the late 1970s to early 1980s. These cattle numbers can be broken down into three primary groups: dairy cattle, beef cows and cattle on feed. The number of dairy cows compared to beef cows on Iowa farms is shown in Figure 8.

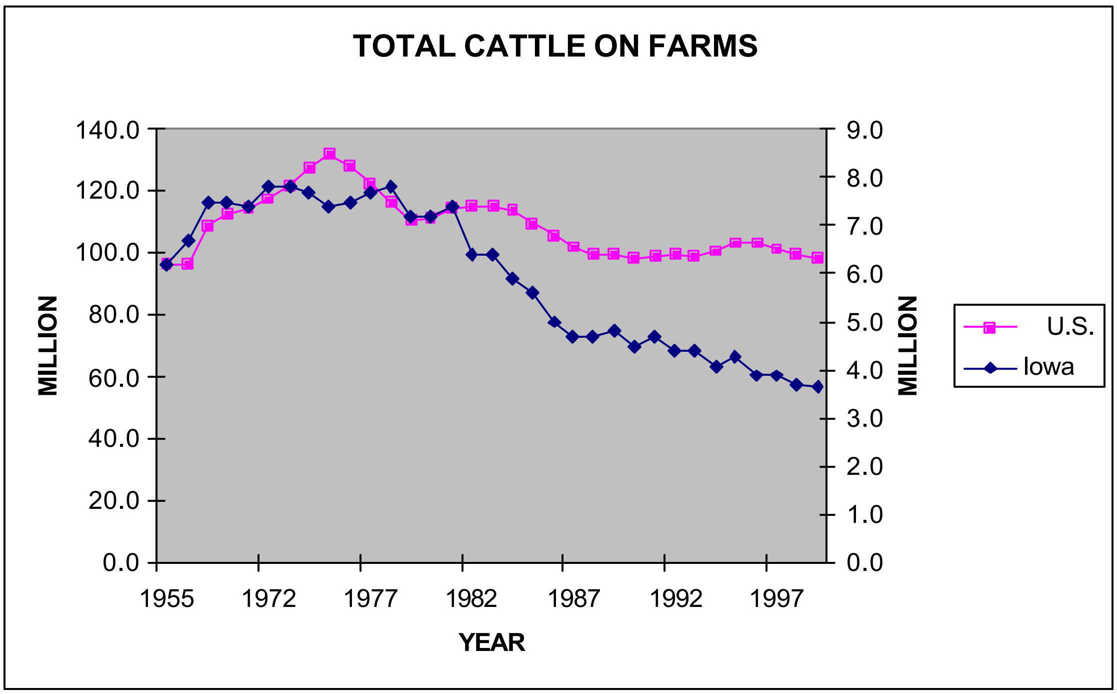

Figure 7. Total cattle on farms in USA and Iowa.

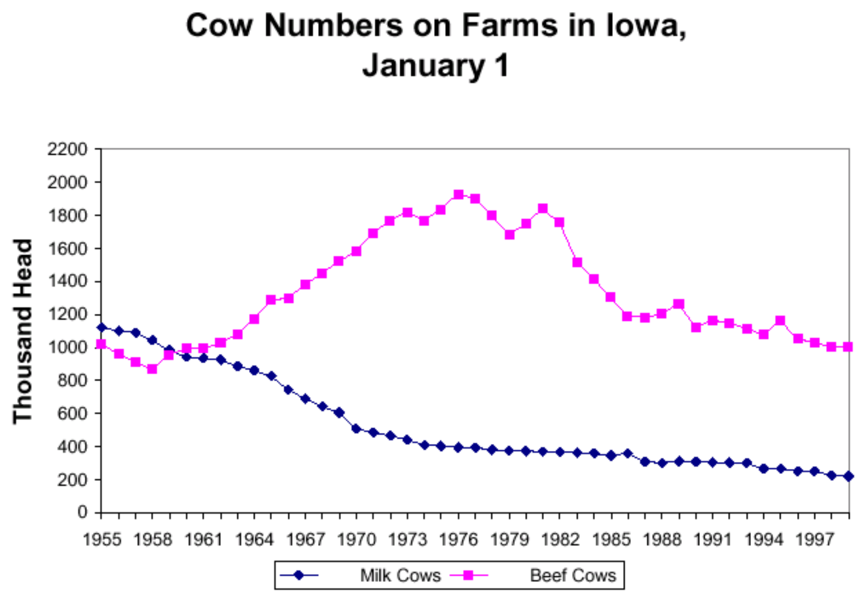

Figure 8. Beef and dairy cow numbers in Iowa.

A slow and steady decline in the number of dairy cows in Iowa has occurred over the past 40 years. Beef cow numbers increased from 1955 until the late 1970s and then began to decline in numbers.

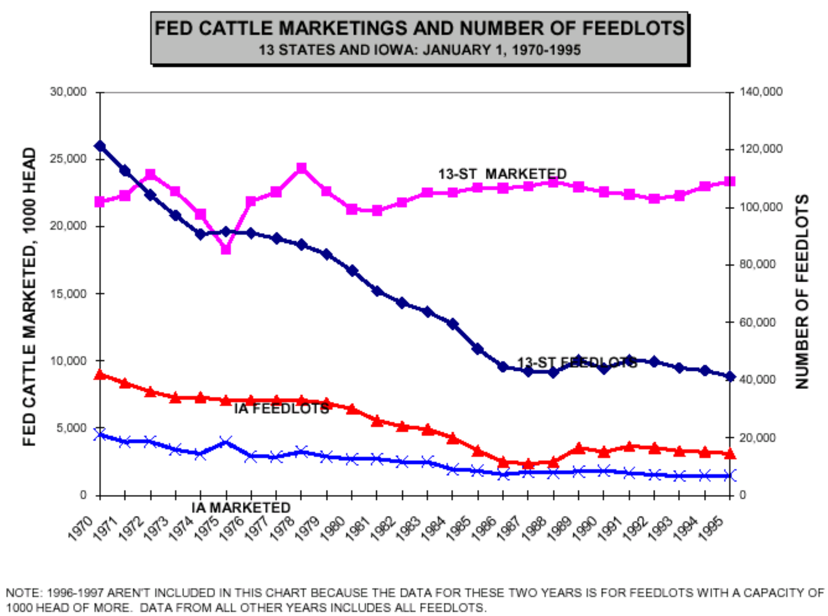

Figure 9. Fed Cattle marketed and number of feedlots for 13 states and Iowa.

The numbers of feedlots and fed cattle in Iowa and 13 states are shown in Figure 9. Iowa has dropped from the number one state in fed cattle production in 1970 to number six in fed cattle marketings. Fed cattle marketings have decreased from 4.7 million annually in 1968 to 1.7 million in 1999. This loss was experienced as fed cattle marketings increased in the Southwest. The number of Iowa feedlots has declined by almost one-half since 1970 while the number of cattle marketed has declined at a somewhat slower rate. This suggests the average size of a beef feedlot in Iowa has increased over the past 30 years.

Poultry Industry Changes

The poultry industry in Iowa consists primarily of egg production and turkey production. The greatest changes in Iowa have been seen in the layer industry as shown in Figure 10. While

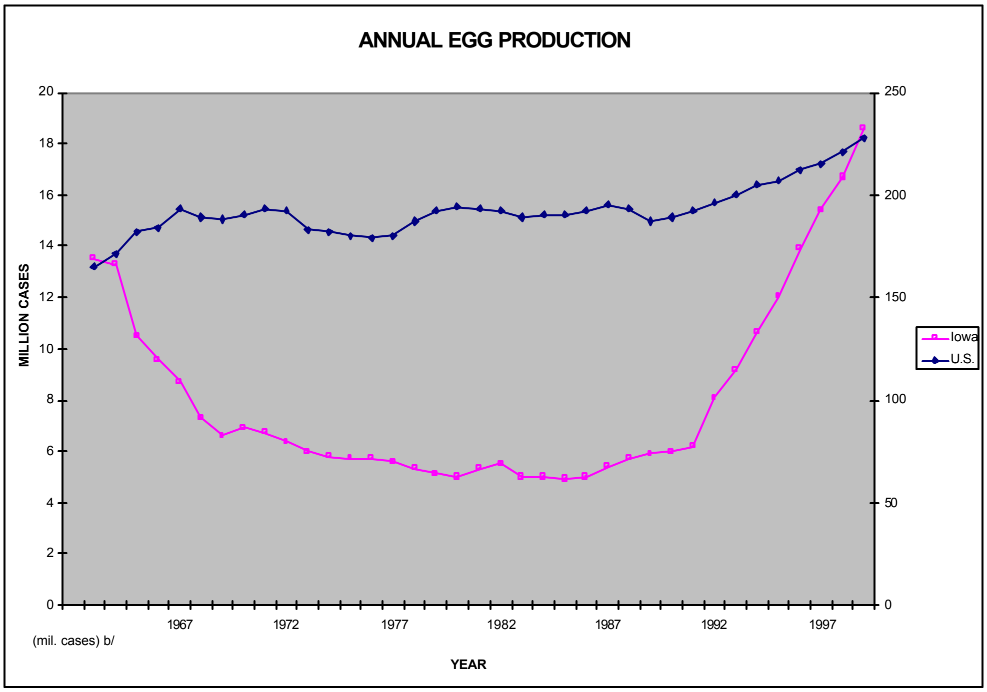

Figure 10. Egg production in USA and Iowa.

Egg production in the US has slowly increased over the past 40 years, the egg production industry in Iowa dropped off dramatically in the 1950s and stayed very small until the 1990s. Since 1990, the egg production industry in Iowa has rapidly grown to the point that Iowa is now number one in the United States in layer numbers.

The trend in turkey production has also been stable, as shown in the Figure 11.

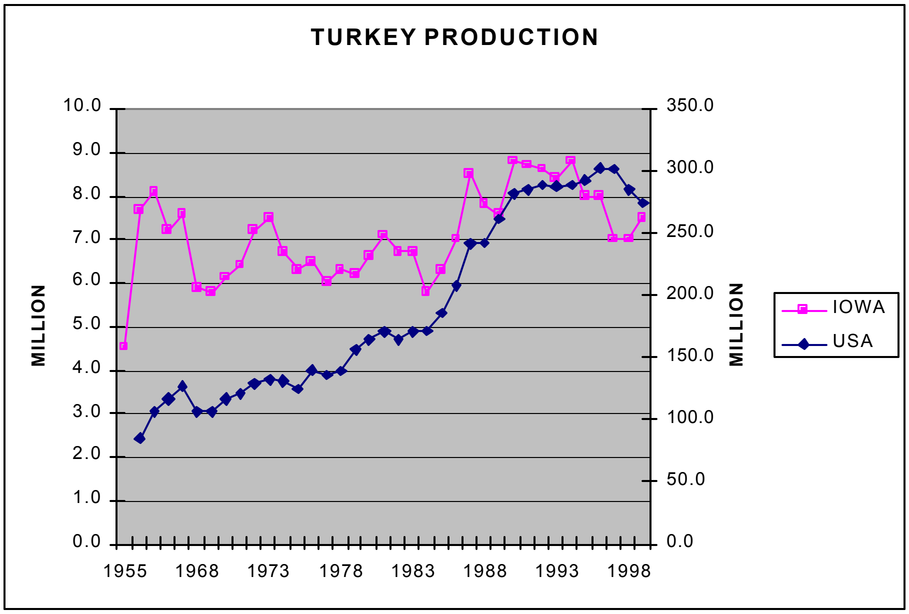

Figure 11. Turkey production in the US and Iowa

2.3 Census of Agriculture Information

Many of the trends shown before in this chapter are documented by Census of Agriculture data comparing changes from 1987 to 1997 presented in tabular form in Table 3. This information is somewhat dated since significant changes have occurred since the last Census of Agriculture in 1997. However, this information shows that major livestock sectors are being restructured in Iowa. As Buttel and Jackson-Smith (1997) point out, this process involves a sharp decline in number of farms, increasing scale, concentration of market power, and increased vertical integration, generally involving greater subordination of the producer to stronger actors in the supply chain. This process can be seen in certain—but not all—livestock sectors in Iowa. During the decade from 1987 to 1997 (date of the most recent U.S. Agricultural Census), hog and poultry production became much more concentrated on fewer farms.

The impact of these changes is greatest in hog production: the number of farms raising hogs halved while the number of hogs and pigs sold per farm more than doubled—and total production grew steadily (by 17% over 10 years). (Recent reports indicate that number of swine farms in Iowa in 2000 is now less than 11,000). The greatest *percentage* shifts occurred in broilers and laying hens. Numbers of layers grew 2.6 times over the period, but the number of layers/farm increased nearly seven-fold. In 1997, Iowa ranked third in the nation in egg production, and has since moved to number one, surpassing Pennsylvania and Ohio. The number of farms engaged in dairying fell by 45 % and the number of dairy cows declined by nearly 25% in the decade, although milk production declined less. The dairies that remain are only modestly larger than before, indicating that the scale revolution in dairying has not greatly affected Iowa, apart from the shift of production to large dairy farms in the West. Stock cattle production declined modestly and beef herd size grew only modestly. The decline in number of farms raising beef cattle (-15%) paralleled the decline in total numbers of farms of all kinds in Iowa (-13.7%). Ruminants are efficient in converting roughage and thus resist complete industrialization. It appears that cattle feedlots did not grow in size, partly because beef CAFOs in Iowa were limited by capital and environmental concerns, while fed cattle production continued the shift to the Great Plains.

Table 3. Changes in Livestock and Poultry Production, Iowa, 1987-1997

Cattle:	**Livestock/farm numbers,1997**	**1987**	**1992**	**1997**
				% Chg 87-97
Farms with cattle/calf sales	38,548			*- 23.7%*
Cattle & calf numbers sold	2,881,122			*- 18.6%*
Cattle and calves sold per farm		**70.0**	**73.6**	**74.7**
Farms with beef cows	27,452			*- 15.0%*
Beef cow numbers (inventory)	1,029,172			*- 8.4%*
Beef cows per farm		**34.8**	**35.5**	**37.5**
Farms with dairy cows	4,208			*- 45.7%*
Dairy cow numbers (inventory)	222,142			*- 24.7%*
Dairy cows per farm		**38.1**	**44.1**	**52.8**
Hogs:				
Farms with hog/pig sales	18,370			*- 52.5%*
Number of hogs/pigs sold	27,495,818			*+ 17.1%*
Hogs and pigs sold per farm		**608**	**787**	**1497**

2.4 Iowa DNR Permitted CAFOs

The Iowa Department of Natural Resources has recently estimated current livestock numbers in the state and the numbers of operations large enough to have manure management plans or operation permits. These values are given in table 4.

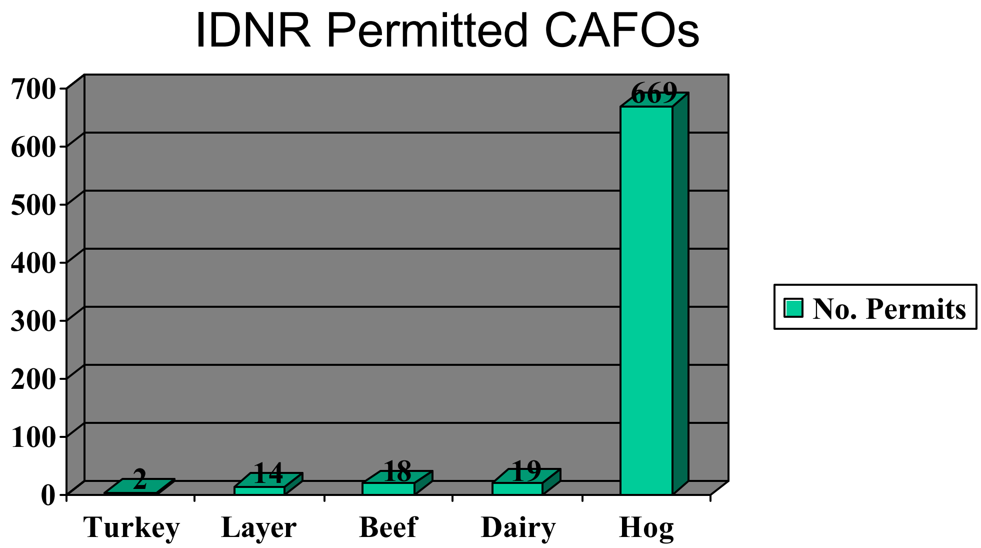

Figure 12. IDNR permitted CAFOs.

The Iowa Department of Natural Resources issues construction permits to confined animal feeding operations that are above a certain threshold of capacity based on live animal weight. The distribution of these permitted CAFOs as of 2001 is shown in Figure 12.

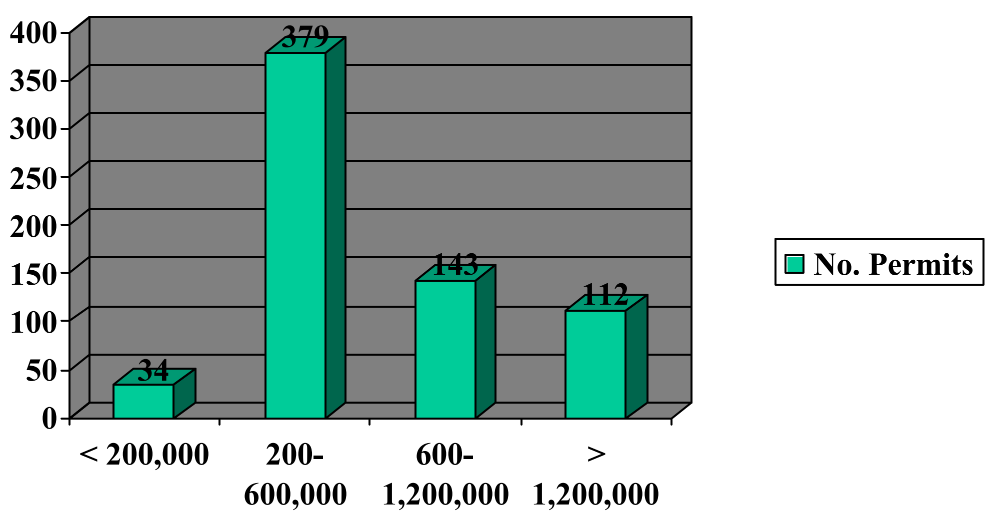

Figure 13. IDNR permitted swine operations by size (weight).

The most prevalent permitted CAFOs in Iowa at the present time are those occupied by hogs. These permitted hog CAFOs are somewhat variable in their size, as shown Figure 13.

Table 4. IDNR animal number estimates.

Livestock Production Numbers

PORK		Animal Unit conversion	
12,900,000 head	Pork produced in facilities large enough to require manure management plans (including permitted operations) = 3,500 operations (85% of IA hogs raised)	5,160,000 au	
2,277,000 head	Pork produced in facilities not required to submit manure management plans, nor required to be permitted.	910,000 au	
15,177,000 head	Total Production		

BEEF		Animal Unit conversion	
365,000 head	Beef produced in facilities containing over 1,000 head	365,000 au	
635,000 head	Beef produced in facilities containing less than 1,000 head	635,000 au	
1,000,000 head	Total Production		
COW/CALF		Animal Unit conversion	
1,200,000 head	Iowa Cattlemen's Association estimation	1,200,000	

DAIRY		Animal Unit conversion	
32,400 head	Dairy animals produced in facilities requiring a manure management plan	45,360 au	
183,600 head	Dairy animals produced in facilities that are not required to have a manure management plan	257,040 au	
216,000 head	Total Production		

TURKEY		Animal Unit conversion	
7,5000,000 head	Estimate production from Iowa Turkey Federation	135,000 au	
7,5000,000 head	Total Production		

POULTRY		Animal Unit conversion	
35,000,000 head	Layers – estimated by Iowa Poultry Association	350,000 au	
5,000,000 head	Broilers – estimated by Iowa Poultry Association	50,000 au	
40,000,000 head	Total Production

Locational Trends in Iowa

Figure 14 illustrates the location of CAFOs in Iowa where there are registered open feedlots or manure management plans have been required under current Iowa regulations. There is a definite concentration of these units in north central, west central, and the extreme northwest corner of the state. Manure management plans are required for all operations with animal weight capacity of over 400,000 pounds of cattle or more than 200,000 pounds for all other species and the operation was constructed or expanded after May 31, 1985.

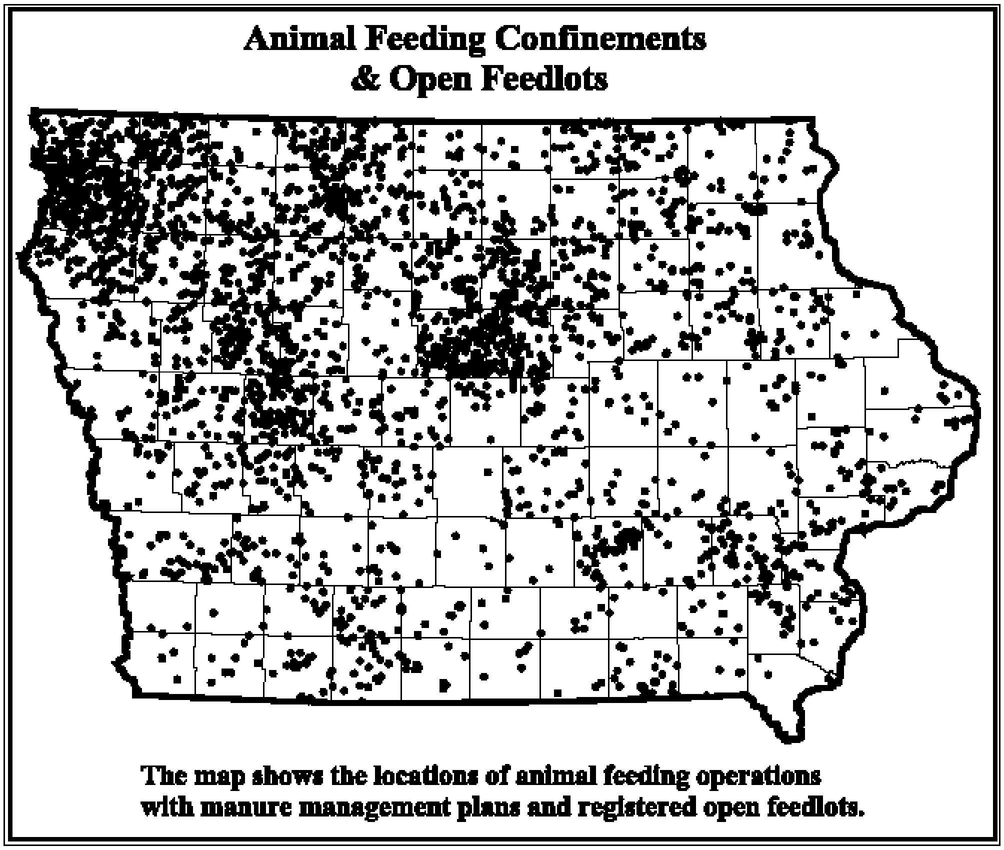

Figure 14. Location of larger animal feeding operations in Iowa(Source IDNR)

Figures 15 and 16 illustrate the changes in concentration of the swine industry in Iowa over the ten-year period from 1987 to 1997. In 1987, there is a relatively uniform distribution of animals across the state whereas in 1997, there are significant concentrations of swine in various parts of the state, especially in northwest and north central Iowa where significant new operations were developed during that time period. The total number of animals has not changed significantly. Therefore some areas have lost swine populations while others have gained significant numbers during the ten-year period. This trend for concentration has continued since 1997.

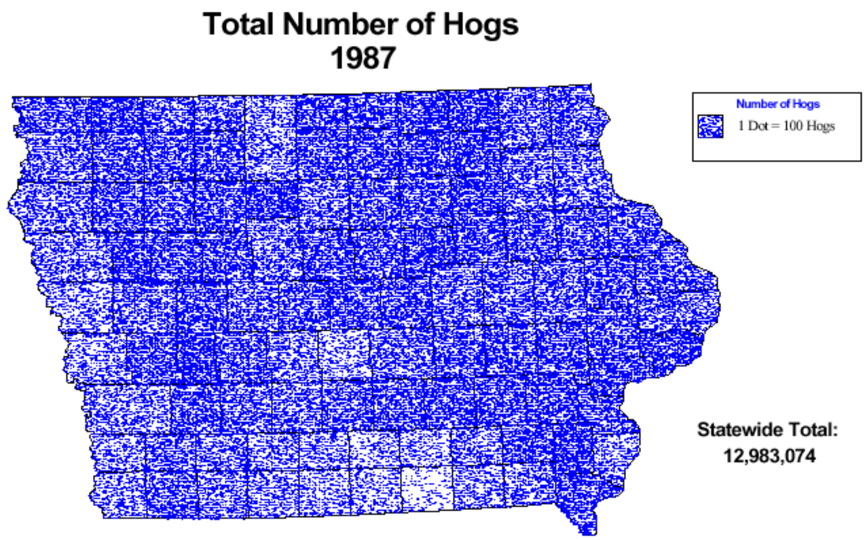

Figure 15. Map of swine numbers in Iowa per county, 1987(Miller, 2002)

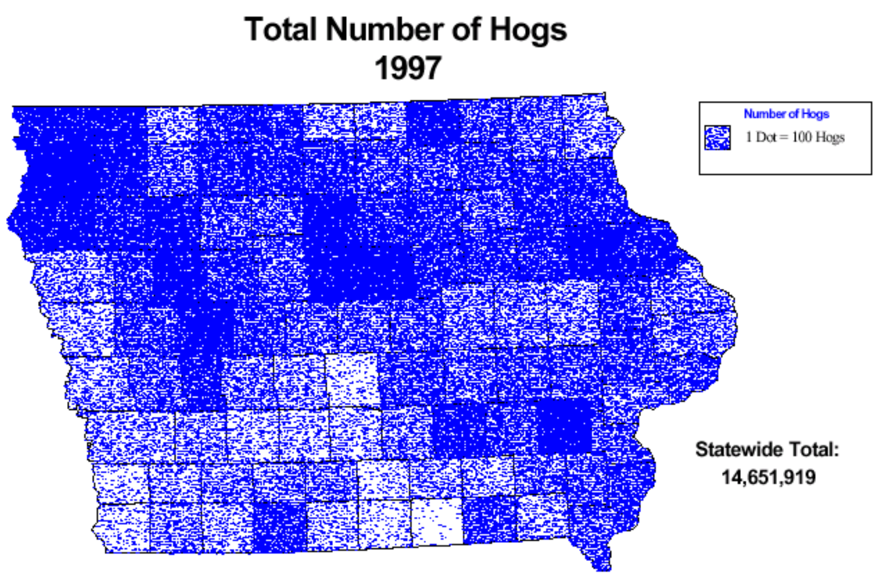

Figure 16. Map of swine numbers in Iowa per county, 1997(Miller, 2002)

Conclusions

It is obvious that animal agriculture in the United States and in Iowa has changed over the past years and will continue to change. There is an increased awareness of environmental and other problems associated with current production systems. This awareness is leading to a rethinking of our current approach to animal production. Changing consumer preferences and lifestyles offer new options and alternatives for animal production. Policies are needed to protect both producer and consumer from being adversely affected.

Many forces impact the livestock industry. The bottom line is that profitability and sustainability are needed. Over time the industry had fewer and larger farms with a higher level of specialization. Access to information is becoming more vital for effective management decisions such as technology adoption. These decisions can be odor management or a host of other production/management issues. Collaborative efforts are increasing. These efforts involve all industry stakeholders, input suppliers, producers, processors, retailers, and policy makers. Information access is increasingly important and cuts across all stakeholders. Among other issues it aids in establishing workable and effective policy decisions.

Animal production is an important part of the Iowa economy but this production needs to be conducted in environmentally sound and sustainable systems to provide the best quality product to consumers while protecting the environment. Iowa can and should remain a leader in production of high quality, environmentally sound animal products.

Odors and emissions from CAFOs have been of concern in Iowa for many years. However, the concentration of animals into larger, more concentrated units has increased the visibility of the potential problems resulting from these major structural changes. The remainder of this report addresses the potential community health impacts of CAFOs.

Chapter 3.0 Air Quality Issues

Peter S. Thorne, Ph.D.
Professor, Department of Occupational and Environmental Health
The University of Iowa

This chapter will describe the agents that emanate from livestock facilities, waste storages and manure application sites associated with livestock production. This will include those agents of concern within barns and air contaminants beyond the barn. These may be on the farm in the vicinity of CAFOs or off the farm at locations or in communities adjacent to CAFOs. This chapter will also briefly describe the measurement approaches and the sources of data for these compounds. The toxic properties of these agents, their emission rates and the concentrations at which they appear are presented in subsequent chapters.

3.1 Sources of data

Air quality data for CAFOs are quite limited. There are relatively few monitoring programs for large-scale livestock production compared to other industries that are regulated. This is further complicated by the fact that the air emissions from CAFOs include a wide array of toxicants including gases, vapors, odoriferous compounds, particulates, and bioaerosols. There are no federally mandated monitoring programs in the United States and only a small number of states have instituted their own monitoring (see Chapter 9). Efforts to institute local controls have generally focused on siting, set backs and zoning rather than compliance with standards for hazardous air pollutants. In Europe, the situation is different. For instance, the Netherlands has established programs based on manure handling practices and for control of emissions from CAFOs. Initially these covered only intensive livestock producers, but now these regulations will extend to all farms. The European Union has issued a number of directives designed to limit emissions of ammonia, methane and odors.

The majority of the monitoring and exposure data available has come from academic researchers interested in characterizing the emissions either for studies of occupational and community health or for studies to address emission rates and efficacy of control approaches. Recently, citizens and citizen groups have begun setting up their own hydrogen sulfide monitoring as a means to provide exposure data to the debate over CAFOs. The swine industry has not engaged in monitoring of air emissions in the United States except when required by court settlements or regulatory action.

3.2 Particulate Matter

Particulate matter associated with CAFOs is composed of fecal matter, feed materials, skin cells, and the products of microbial action on feces and feed (Table 3-1). Components of feed include plant proteins, starches and carbohydrates; feed additives such as vitamins, minerals, amino acids and other supplements; and antibiotics. The most common approaches to measurement of particulate matter emissions are gravimetric sampling, nephelometry, or particle counting. Gravimetric sampling is performed by pre-weighing specialized air sampling filters using a precision microbalance, sampling in the test environment by pulling a measured amount of air through the filter, and then post-weighing the filters and correcting the weight gain for the change in the blanks. This corrected weight change is then divided by the volume of air that was pulled through the filter to determine the airborne dust concentration in mg per cubic meter of air. Different fractions of dust can be selectively sampled by changing the design of the air sampling device and the airflow rate through the device.

When dust is inhaled by humans or animals, a higher proportion of small particles than large particles will travel deep into the lung and be deposited. Thus, environmental health professionals often choose to collect fractions of the total suspended particulates (TSP) to gain more insight into the potential for toxic effects on the lung. Two such categories of smaller fractions are the inhalable dust fraction (50% of particulate mass less than 100 micron [μm]) and the respirable dust fraction (50% of particulate mass less than 3.5 μm). These terms are widely applied in the occupational health literature. Environmental health specialists who study community ambient air pollution more commonly measure two other fractions of particulate matter. These are called PM_{10} and $PM_{2.5}$. PM_{10} refers to particulate matter less than 10 μm in diameter and $PM_{2.5}$ is less than 2.5 μm in diameter. In general, finer particulate fractions contain a higher proportion of anthropogenic dust and lower levels of wind blown soil and plant pollens. Since lung problems associated with CAFOs include airway disease, it is important to consider inhalable particulate fraction and PM_{10}. While gravimetric sampling methods contribute the lion's share of the data on particulate matter concentrations, light scattering and particle counting devices are important as well. These latter methods provide real-time monitoring data and size-specific particle counting necessary for understanding pulmonary deposition and lung burdens.

Bioaerosols are a major component of the particulate matter from CAFOs. Bioaerosols are simply particles of biological origin that are suspended in air. These include bacteria, fungi, fungal and bacterial spores, viruses, mammalian cell debris, products of microorganisms, pollens, and aeroallergens (Table 3-1). Bacterial and fungal bioaerosols may be of infectious or non-infectious species. Bacterial products or components exist as bioaerosols and include endotoxins, exotoxins, peptidoglycans, lipoteichoic acids, and bacterial DNA bearing CpG motifs. Fungal products or components of note include conidia and microconidia, hyphal fragments, mycotoxins and glucans. Settings with very high bioaerosol concentrations include swine, poultry, and dairy confinement buildings; grain and feed mills, grain loading terminals, mushroom production facilities, composting facilities, and sawmills. Typical aerosol sizes for these bioaerosols in indicated in Table 3-2.

Table 3-1 Components of CAFO Particulate Matter

Feed dust	<u>Bioaerosols</u>
plant materials	Microorganisms
proteins	bacteria
starches	bacterial spores
carbohydrates	fungi
feed additives	fungal spores
vitamins	viruses
minerals	
amino acids	Products of bacteria
antibiotics	endotoxins
	exotoxins
Mammalian cell debris	peptidoglycans
	lipoteichoic acids
Aeroallergens	bacterial DNA bearing CpG motifs
plant pollens	Products of fungi
mite fecal allergens	conidia and microconidia
arthropod debris	hyphal fragments
	mycotoxins
	glucans

Table 3-2 Typical Sizes of Bioaerosols

Bioaerosols	Typical Sizes, µm
Tree/grass pollens	30 - 50
Fungi	20 - 100
Bacteria	2 - 20
Fungal conidia	5 - 15
Bacterial spores	0.5 - 3.0
Viruses	0.01 - 0.05
Droplet nuclei	5 - 10

Source: Thorne and Heederik, 1999b

Genera of bacteria found in air samples from swine barns include the Gram-negative organisms *Enterobacter, Acinetobacter, Enterococcus, Moraxella, Pseudomonas,* and *Escherichia coli,* and the Gram-positive organisms *Enterococcus, Staphylococcus, Streptococcus, Bacillus, Aerococcus,* and *Micrococcus* (Kiekhaefer et al 1995, Cormier et al. 1990). Gram-positive microorganisms (especially Enterococci) represent the majority of bacteria and gram-negative organisms are generally less than 25% of the viable bacteria (Clark et al 1983, Heederik et al 1991). The most commonly found fungi are the mold genera *Aspergillus, Scopulariopsis, Penicillium, Geotrichum, Mucor*, and *Fusarium*. Yeasts found in swine environments include *Candida, Cryptococcus, Toruopsis, Trichosporon, Rhodotorula,* and *Hansenula*. However, variations in housing conditions and feed ingredients can impact the gastric flora of the animals. The concentrations of non-culturable aerobic and anaerobic organisms in the particulate matter in swine barns is known to be 10 to 100-fold higher than the culturable organisms (Lange et al 1997b, Heederik et al 2002). However, the bacterial genera represented in these bioaerosols have not been adequately studied.

Much research has been conducted on methodology for assessment of bioaerosol concentrations in the agricultural environment. This body of work has been recently reviewed (Heederik et al 2002). Methods for assessment of culturable organisms rely on collecting bioaerosols using jet-to-agar samplers or using liquid impingers with dilution plating onto agar (Thorne and Heederik 1999a). Cultures are then allowed to grow in incubators and are enumerated to determine airborne concentrations. Individual colonies may be sub-cultured and identified. Impinger collection fluids may be cultured on a variety of media to quantify mesophilic bacteria, thermophilic bacteria, fungi and selective microbial groups (Thorne et al 1992, Kiekhaefer et al 1995, Cormier et al 1990, Lange et al 1997a, Kullman et al 1998). Since many of the airborne organisms are not culturable, it is necessary to employ non-culture based methods. These include use of direct count methods with DNA staining and epifluorescence microscopy, fluorescent in situ hybridization, and PCR techniques (Thorne et al 1992, Lange et al 1997b, Kullman et al 1998). Significant advances have arisen in the past few years in PCR-based techniques and these will advance the science of bioaerosol sampling in and around swine barns (Heederik et al 2002).

Endotoxin is a lipopolysaccharide (LPS) component of the outer cell wall of Gram-negative bacteria. Since Gm- organisms are ubiquitous in the environment, so is endotoxin. Endotoxin is a potent inflammatory agent that produces systemic effects and lung obstruction, even at low levels of exposure. Livestock confinement units present some of the highest concentrations seen anywhere. The concentration of endotoxin is best determined from liquid impingers or air sampling filters (Duchaine et al 2001) and analyzed using the *Limulus* amebocyte lysate (LAL) assay (Thorne et al 1997, Douwes et al 1995). The LAL bioassay is based on the exquisite sensitivity of an enzymatic clotting cascade in amebocytes taken from the hemolymph of horseshoe crabs (*Limulus polyphemus*) and related species (Thorne 2000). Samples are typically extracted in sterile, pyrogen-free water with 0.05% Tween-20 with continuous shaking. Extracts are centrifuged and supernatants are analyzed using the kinetic chromogenic LAL assay. To provide the highest quality analysis, a twelve-point calibration curve of standard endotoxin from *E. coli* 0111:B4 and four-point endotoxin determination for samples is performed (Thorne 2000). Assay reagent blank wells serve as reference and control. Quality assurance spiking assays are performed to assess matrix interference or enhancement. A number of studies have demonstrated refinements for use of this assay for agricultural environments (Thorne et al 1997, Douwes et al 1995, Gordon et al 1992, Hollander et al 1993, Duchaine et al 2001). Four studies have reported comparisons of endotoxin assay between laboratories (Thorne et al 1997, Reynolds et al 2001, Chun et al 2000, Chun et al 2001).

?(1-3)-glucans are cell wall components of fungi that have been associated with lung inflammation, although at exposure levels well above the levels of endotoxin required for comparable effects (Roy et al 1999). Studies of the past five years have provided evidence that glucans may also be important immunomodulators (Rylander et al 1999, Fogelmark et al 1997). ß(1? 3)-glucans are glucose polymers with variable molecular weight and degree of branching that may appear in triple helix, single helix or random coil structures (Williams 1994). ß(1? 3)-glucans originate from a variety of sources, including fungi, bacteria, and plants (Stone and Clarke 1992). They are water insoluble structural cell wall components of these organisms, but may also be found in extracellular secretions of microbial origin. Glucans may account for up to 60% of the dry weight of the cell wall of fungi, of which the major part is ß(1? 3)-glucan (Klis 1994).

There are currently three principal methods in use for the assay of ? (1-3)-glucans (Heederik et al 2001). Two are based upon the bioactivity of this molecule in the factor G-mediated *Limulus* coagulation pathway. These methods are extremely expensive and not feasible for large field studies. A polyclonal antibody-based immunoassay for ? (1-3)-glucans that is totally independent of the horseshoe crab hemolymph has also been developed (Douwes et al 1996). One laboratory in the Unites States has recently produced several monoclonal antibodies for glucans directed specifically against branched ? (1-3, 1-6)-glucans and ? (1-3)-glucans. This should facilitate future toxicology and exposure assessment studies for glucans.

3.3 Gases and Vapors

Hazardous gases and vapors are emitted from swine barns, lagoons, manure storage piles and from sites of manure land application. These compounds arise from the urine and feces, but especially from microbial degradation of liquid manure in storage or as manure compost. Table 3-3 lists volatile organic compounds; vapors and gases; and odoriferous volatile fatty acids, phenolic compounds and nitrogen-containing compounds. Many of these agents are sensory and respiratory irritants. In combination, they are associated with nasal, sinus, and eye irritation; coughing; wheezing; dyspnea and feelings of malaise (Schenker et al 1998).

While there are real time monitors available for some (e.g. Jerome meters for hydrogen sulfide) most compounds are determined using GC-MS or HPLC-MS methods on air samples collected in impermeable bags or by extraction or purging from collection media. Some vapors, such as ammonia, exist at significant concentrations in both the vapor phase as well as adsorbed to particulate matter. For quantification of these compounds, it is necessary to assay for both the solid and vapor phase. This can be accomplished with annular or honeycomb denuders that collect the vapor phase by reaction with citric acid and the particulate phase by analysis of material deposited on air sampling filters. Of the multitude of compounds in this mixture, those most commonly measured are ammonia, hydrogen sulfide and methane.

Table 3-3. Gases and Vapors Emanated from CAFOs

Volatile Organic Compounds
- acetaldehyde
- acetone
- acetophenon
- acrolein
- benzaldehyde
- benzene
- bis (2-ethylhexyl) phthalate
- 2-butanone
- carbon disulfide
- carbonyl sulfide
- chloroform
- crotonaldehyde
- ethyl acetate
- formaldehyde
- formic acid
- hexane
- isobutyl alcohol
- methanol
- 2-methoxyethanol
- naphthalene
- phenol
- pyridine
- tetrachloroethylene
- toluene
- triethylamine
- xylene

Vapors and gases
- ammonia
- hydrogen sulfide
- dimethyl sulfide
- hydrazine
- sulfur dioxide
- carbon dioxide
- carbon monoxide

Odoriferous microbial compounds
- volatile fatty acids including:
  - butyric and isobutyric acid
  - caproic and isocaproic acid
  - valeric and isovaleric acid
  - propionic and phenylpropionic acid
  - lauric acid
  - acetic and phenylacetic acid

Phenolic compounds
- phenol
- ethyl phenol
- cresols

Nitrogen-containing compounds
- ammonia
- amines
- pyridines
- indole
- skatole
- trimethylamine
- trimethyl pyrazine
- tetramethyl pyrazine

3.4 Odors

Odors are one of the most significant community concerns associated with CAFOs. The chemicals that evoke these odors can be an extreme nuisance and can induce adverse health effects with sufficient exposure. The breakdown of feed in the gut of the animals and of the manure after excretion produces odoriferous organic compounds. Bacteria attack organic matter in order to gain energy for life and growth. Bacteria will act on molecules in manure by dehydrogenating these compounds producing reduced oxygen species (Cheremisinoff and Young 1975). Sulfur in proteins is broken down to SO_4 ions. These and organic matter react under the influence of sulfate-reducing bacteria (e.g. *Vibrio desulfuricans*) to produce hydrogen sulfide:

$$SO_4^{-2} + \text{organic matter} \rightarrow S^{-2} + H_2O + CO_2$$

$$S^{-2} + 2H^{+} \rightarrow H_2S$$

In a similar fashion, when oxidized organic compounds are reduced to organic acids, mercaptans, skatoles or indoles they become orders of magnitude more odoriferous.

Some of the most objectionable compounds produced are the organic acids including acetic acid, butyric acids, valeric acids, caproic acids, and propanoic acid; sulfur containing compounds such as hydrogen sulfide and dimethyl sulfide; and nitrogen-containing compounds including ammonia, methyl amines, methyl pyrazines, skatole and indoles. Table 3-4 lists some smells associated with example compounds.

Table 3-4 Examples of Odor Qualities

Chemical Name	Smell
Hydrogen sulfide	rotten eggs
Dimethyl sulfide	rotting vegetables
Butyric, isobutyric acid	rancid butter
Valeric acid	putrid, fecal smell
Isovaleric acid	stinky feet
Skatole	fecal, nauseating
Indole	intense fecal

Source: Cheremisinoff and Young 1975

Methods are well established for characterization of the odor threshold of an air sample. (ASTM Standard Practice E679-91 Determination of Odor and Taste Thresholds by a Forced-Choice Ascending Concentration Series of Limits). Odor thresholds are quantified using an olfactometer and a panel of smellers. These panelists are non-smoking adults that are carefully selected and trained according to ASTM Special Technical Publication 758 Guidelines for Selection and Training of Sensory Panel Members. Eight panelists sniff a two-fold serially-diluted odor sample as it is discharged from one of three ports. The other two ports deliver clean air. The panelist must select which of the randomly assigned ports is the sample and declares whether the selection is based upon recognition, detection, or a guess. The panel then samples the odor at a two-fold higher concentration. Analysis of results from the panel utilizes the triangular forced-choice method in an ascending concentration series.

3.5 Environmental Pollution: Acidifying Emissions and Greenhouse Gases

It is recognized that ammonia emissions from the livestock sector contribute significantly to eutrophication and acidification of the environment. Acidification can put stress on species diversity in the natural environment. Reduction of ammonia emissions requires injection of liquid manure into soil and elimination of surface application. Covering of manure storages and livestock housing that controls emissions are also beneficial. CAFOs are known sources of greenhouse gases such as methane and nitrous oxide. These gases may contribute to global climate change and are the subject of national and international air pollution control strategies. Methane is produced during the digestive process by ruminants while nitrous oxide arises primarily from the microbial degradation of manure.

3.6 Summary

Potentially hazardous air pollutants arise from CAFOs and their associated manure storages and land application sites. These air emissions include coarse and fine particulates, bioaerosols, endotoxins, hydrogen sulfide, ammonia, volatile organic compounds, odoriferous microbial organic compounds, and greenhouse gases. While methods are established for monitoring concentrations of all these compounds, little monitoring has been done in the vicinity of CAFOs. However, occupational health studies have characterized exposures within animal houses. Quantifying odors has relied on olfactometry which uses panels of human subjects to determine odor thresholds. In addition to direct effects on humans, greenhouse gas emissions and volatilization and environmental deposition of ammonia are air quality concerns from CAFOs.

Abstract

This chapter is a review of research and peer-reviewed literature on the emission rates and emission models for dispersion of gases from CAFOs. Emissions originate from the housing ventilation air, manure storage units, and during land application of manure. Refereed publications were sought that identified ammonia, methane, hydrogen sulfide, particulate, bioaerosol, and volatile organic compound (VOCs, including "odor") emission from swine, dairy/cattle, and poultry production systems. The vast majority of published data is related to ammonia emission, and where available, the remaining components were cited and reported. A lack of data exists that reports downwind concentration of gases and particulates from CAFOs as a function of facility type and emission rate.

Dispersion models predict the relationship between concentrations at a receptor and emissions from a source. Appropriate dispersion models for use in predicting concentrations of compounds are reviewed, with reference to current and peer-reviewed literature reports. Dispersion models are generally found to poorly predict absolute concentrations, but are adequate for predicting trends and the expected relationship between reduced emissions and reduced downwind concentrations.

A series of tables is provided at the end of this chapter summarizing the reported emission rates of the above-mentioned components for swine, dairy/cattle, and poultry production systems. An overall summary of reported emission ranges for ammonia, from refereed publications, for ventilation air and manure storages is given below:

Species	Source	Ammonia	Units
Swine	**VA**	**5-311**	**g/AU-day**
	ST	**0.3-144**	**g/m2-day**
Dairy/Cattle	**VA**	**6-43**	**g/AU-day**
	ST	**0.3-18**	**g/m2-day**
Poultry	**VA**	**14-300**	**g/AU-day**
	ST (litter)	**3-5**	**g/m2-day**

VA=ventilation air, ST=storage, AU=animal unit (500 kg)

4.0. Introduction

This chapter summarizes published and refereed research data on gas and particulate emissions from swine, beef cattle, dairy cow, and poultry production systems. Emission refers to the rate at which gases or particulates are being emitted from either the housing unit, manure storage unit, or during land application events. This is in contrast to concentration-only measurements. Emission rates are determined by multiplying the concentration of a component by the volumetric rate at which a component at a given concentration is being emitted. This chapter reports published data, using units reported from each publication. At the end of this chapter, published emission rates are summarized into a table using common units. Research findings are organized by species, individual gases/particulates, and by the particular source, whether building, storage, or land application unit. Each species section is concluded with a summary of research results on published source emission levels versus downwind concentration. At the conclusion of all species-specific discussion, a section describing gas and particulate dispersion models is present. Concluding this chapter is a discussion on how different states address odor emissions and complaints. The terminology used in this chapter is defined below:

<u>Animal Unit:</u> Many emission quantities published are based on a per animal unit (AU) basis. Unless otherwise noted, one AU is equivalent to 500 kg body weight (1,100 lbs).

<u>Bioaerosol:</u> Includes the sub-class of viable particulates that has an associated biological component.

<u>Housing Unit:</u> Any facility used to house livestock or poultry incorporating either a mechanical or natural ventilation system for providing fresh-air exchange.

<u>Inhalable:</u> The class of particulates or bioaerosols having a mean aerodynamic diameter at or below 100 um (micrometers).

<u>Land Application Unit:</u> The process of applying animal manure to the soil.

<u>Manure Storage Unit:</u> Any structure used to store manure, including long-term storage inside the housing unit. Includes above- and below-ground structures.

<u>mg, ug, ng:</u> Respectively, milligrams (10^{-3}), micrograms (10^{-6}), and nanograms (10^{-9}).

<u>Particulate:</u> Includes the class of both inert and viable aerosols. Includes total, inhalable, and respirable fractions.

<u>ppm, ppb:</u> Respectively, parts per million and parts per billion.

<u>Respirable:</u> The class of particulates or bioaerosols having a mean aerodynamic diameter at or below 5 um.

Published emission data is presented in this chapter using original units reported from each citation. Where possible, emission rates from housing unit ventilation air were converted to grams of component per animal unit per day (g/AU-day) and presented in parenthesis after the cited levels. For reported manure storage emission rates, the published levels, where possible, were converted to grams of component per square meter of storage area per day (g/m2-day)

.

4.1. Swine System Emissions

4.1.1. Housing Unit Emissions

Ammonia

Aarnink *et al.* (1995) studied the ammonia emission patterns of nursery and finishing pigs raised on partially slatted flooring. They found that for nursery pigs, an average increase of 16 mg NH3/pig-day was measured and this increased to 85 mg NH3/pig-day for finishing pigs. The overall average ammonia emission measured was between 0.70 and 1.20 g NH3/pig-day for nursery pigs (19-33 g NH3/AU-day) and between 5.7 and 5.9 g NH3/pig-day for finishing pigs (42-43 g NH3/AU-day). They found an increase in ammonia emission during the summer months for nursery pigs due to higher ventilation rates but this same trend was not found for finishing pigs. They also found that removing the under-floor stored slurry reduced the ammonia emission by about 20 percent for a period of 10 hours, after which time the ammonia emission regained the pre-removal emission level.

Demmers *et al.* (1999) investigated the exhausted concentrations and emission rates of ammonia from mechanically ventilated swine buildings. They reported ammonia concentrations in a swine finishing house between 12 and 30 mg NH3/m3 with an average ammonia emission rate of 46.9 kg NH3/AU-yr (160 g NH3/AU-day).

Burton and Beauchamp (1986) studied the relationship between outside temperature, ventilation system response, in-house ammonia concentration, and the resulting emission of ammonia from the housing unit. They showed very clearly the inverse relationship of in-house ammonia concentration with outside temperature and the direct relationship of ammonia emission from the housing unit with outside temperature. This trend was attributed to the increased ventilation rates required during the summer to control inside climate temperatures for the housed animals. They summarized results over a one-year period and reported the monthly averages. February had the highest in-house concentration at 15 mg NH3-N/liter corresponding to the lowest emission rate at 0.9 kg NH3-N/day. August had the lowest in-house concentration of 4 mg NH3-N/liter and, correspondingly, the highest emission rate of 3.2 kg NH3-N/day, on average.

Ni *et al.* (2000) investigated the exhausted concentrations and emission rates of ammonia in and from a deep-pit swine finishing building with and without the presence of animals and with pits that were roughly half full (130 cm depth, 240 cm depth capacity). They investigated the gas release rates with and without the effect of heating the building through unit space heaters. Without the presence of animals, they measured ammonia concentrations between 6 and 15 ppm with emission rates between 40 and 58 mg NH3/m2-h (5-8 g NH3/AU-day). When the buildings were re-stocked with pigs, exhaust air concentrations of ammonia were on average 15.2 ppm with corresponding emission rates of 233 mg NH3/m2-h (40-50 g NH3/AU-day).

Groot Koerkamp *et al.* (1998) conducted an extensive study of ammonia emissions from swine housing facilities. They investigated both indoor ammonia levels and with simultaneous measurements of building ventilation rates, reported the resulting emission rate. In general, ammonia concentrations varied between 5 and 18 ppm, with average emission rates between 649 and 3751 mg NH3/AU-h (16-90 g NH3/AU-day). A more complete listing of the ammonia emission rates recorded as a function of maturity level and flooring is given below:

Table 4.1. Swine house ammonia emissions (Groot Koerkamp *et al,* 1998)

Species	Flooring Type	Low Average mg/AU-h (g NH3/AU-day)	High Average mg/AU-h (g NH3/AU-day)
Sows	Litter	744 (18)	3248 (78)
Sows	Slats	1049 (25)	1701 (41)
Nursery Pigs	Slats	649 (16)	1526 (37)
Finishing Pigs	Litter	1429 (34)	3751 (90)
Finishing Pigs	Slats	2076 (50)	2592 (62)

Hinz and Linke (1998) investigated the indoor concentrations and emissions of ammonia from a mechanically ventilated swine finishing facility during a grow-out period where pigs ranged between 25 and 100 kg. Interior ammonia concentrations during the grow-out varied from 10 to 35 ppm and these were inversely proportional to outside temperature. Emission rate of ammonia varied from 70 g NH3/hr (38 kg average pig weight) to 210 g NH3/hr (83 kg average pig weight) resulting in an average ammonia emission rate of 66 g NH3/AU-day.

Zahn *et al.* (2001b) studied the ammonia emission rate from both deep-pit and pull-plug swine finishing facilities during summer periods. He found that the ammonia emission rates were very similar for these two facility types and grouped the emission data into an overall average of 66 ng NH3/cm2-s (311 g NH3/AU-day).

Zhu *et al.* (2000) studied the daily variations in ammonia emissions from various mechanically and naturally ventilated swine housing systems. For a mechanically ventilated swine gestation facility, they measured internal ammonia concentrations between 9 and 15 ppm, with emission rates consistent at about 5 ug NH3/m2-s (2.2 g NH3/AU-day). For a mechanically ventilated farrowing facility, they measured internal ammonia concentrations between 3 and 5 ppm, with emission rates ranging between 20 and 55 ug NH3/m2-s (15-42 g NH3/AU-day). For a mechanically ventilated nursery facility, they measured internal ammonia concentrations between 2 and 5 ppm, with emission rates ranging between 20 and 140 ug NH3/m2-s (23-160 g NH3/AU-day). For a mechanically ventilated finishing facility, they measured internal ammonia concentrations between 4 and 8 ppm, with emission rates ranging between 20 and 55 ug NH3/m2-s (10-26 g NH3/AU-day). For a naturally ventilated finishing facility with pit exhaust fans, they measured internal ammonia concentrations between 7 and 15 ppm, with emission rates ranging between 60 and 170 ug NH3/m2-s (28-80 g NH3/AU-day).

Osada *et al.* (1998) investigated ammonia emission from a swine finisher over an eight week period comparing under-floor stored manure (reference) and under-floor manure removed weekly (treatment). They reported only slight differences in ammonia emission rates with the reference at 11.8 kg NH3/AU-yr (32 g NH3/AU-day) and the treatment at 11.0 kg NH3/AU-yr (30 g NH3/AU-day).

Hartung *et al.* (2001) investigated the effect of a mature and new biofilter on the ammonia emission rate from a swine finisher's ventilation air. They found that with an ammonia load from the ventilation air averaging 4475 mg NH3/m3-h, a reduction in ammonia emission of 15 to 36 percent was measured. This level of ammonia emission reduction was found to be highly dependent on airflow rate and therefore the retention time within the biofilter medium. For the biofilter tested, an airflow rate of 4000 m3/h through the filter bed resulted in a 60 percent ammonia emission reduction and this dropped to zero percent at an airflow rate of about 9000 m3/h.

Methane

Zahn *et al.* (2001b) studied the methane emission rate from both deep-pit and pull-plug swine finishing facilities during summer periods. He found that the methane emission rates were very similar for these two facility types and grouped the emission data into an overall average of 34 ng CH_4/cm^2-s (160 g CH_4/AU-day).

Osada *et al.* (1998) investigated methane emission from a swine finisher over an eight week period comparing under-floor stored manure (reference) and under-floor manure removed weekly (treatment). They reported only slight differences in methane emission rates with the reference at 19.7 kg CH_4/AU-yr (54 g CH_4/AU-day) and the treatment at 17.5 kg CH_4/AU-yr (48 g CH_4/AU-day).

Hydrogen Sulfide

Ni *et al.* (2000) investigated the exhausted concentrations and emission rates of hydrogen sulfide in a deep-pit swine finishing building with and without the presence of animals and with pits that were roughly half full (130 cm depth, 240 cm depth capacity). They investigated the gas release rates with and without the effect of heating the building through unit space heaters. They measured hydrogen sulfide concentrations ranging from 221 to 1492 ppb (parts per billion) with corresponding emission rates between 1.6 and 3.8 mg H_2S/m^2-h (0.22-0.49 g H_2S/AU-day). When the buildings were re-stocked with pigs, exhaust air concentration of hydrogen sulfide averaged 423 ppb with a corresponding emission rate of 9.4 mg H_2S /m^2-h (1.25 g H_2S/AU-day).

Zahn *et al.* (2001b) studied the hydrogen sulfide emission rate from both deep-pit and pull-plug swine finishing facilities during summer periods. He found that the hydrogen sulfide emission rates were very similar for these two facility types and grouped the emission data into an overall average of 0.37 ng H_2S/cm^2-s (1.7 g H_2S/AU-day).

Zhu *et al.* (2000) studied the daily variations in hydrogen sulfide emissions from various mechanically and naturally ventilated swine housing systems. For a mechanically ventilated swine gestation facility, they measured internal hydrogen sulfide concentrations between 500 and 1200 ppb, with emission rates consistent at about 2 ug H_2S/m^2-s (1 g H_2S/AU-day). For a mechanically ventilated farrowing facility, they measured internal hydrogen sulfide concentrations between 200 and 500 ppb, with emission rates consistent at about 5 ug H_2S/m^2-s (4 g H_2S/AU-day). For a mechanically ventilated nursery facility, they measured internal hydrogen sulfide concentrations between 700 and 3400 ppb, with emission rates ranging between 20 and 140 ug H_2S/m^2-s (23-160 g H_2S/AU-day). For a mechanically ventilated finishing facility, they measured internal hydrogen sulfide concentrations between 300 and 600 ppb, with emission rates consistent at about 10 ug H_2S/m^2-s (5 g H_2S/AU-day). For a naturally ventilated finishing facility with pit exhaust fans, they measured internal hydrogen sulfide concentrations between 200 and 400 ppb, with emission rates ranging between 5 and 15 ug H_2S/m^2-s (2-7 g H_2S/AU-day).

Trace Gases

Hartung and Phillips (1994) summarized average measured and reported concentrations of trace gases found in swine housing ventilation air. They did not provide corresponding ventilation rates from which to determine the emission rates of these trace gases. Zahn *et al.* (2001c) measured VOC concentrations in swine finishing facilities incorporating either deep-pit or pull-plug manure handling systems. The trace gases reported from Hartung and Phillips (1994) and those reported from Zahn *et al.* (2001c) are included in the table below. These VOCs are included as an identification of trace gases that might be expected in swine house air (Zahn *et al.*, 2001c list not complete).

Table 4.2. VOC components from swine house ventilation air

Measured In-House Trace Gas	Average Measured Concentration in Air mg/m3 (Hartung and Phillips, 1994)	Average Measured Concentration in Air mg/m3 (Zahn *et al.*, 2001c)**
Fatty Acids		
Acetic acid	0.189	0.281
Propionic acid	0.156	0.126
n-butyric acid	0.318	0.142
I-butyric acid	0.040	0.023
n-valeric acid	0.035	0.043
I-valeric acid	0.049	0.073
n-hexanoic acid	0.010	
I-hexanoic acid	0.004	
Heptanoic acid	0.003	Nd
Octoanoic acid	0.005	
Pelargonic acid	0.004	
Phenols and Indoles		
Phenol	0.023	0.009
p-cresol	0.039	0.085
Indole	0.0011	Nd
Skatole	0.0011	0.0005
Methylamines		
Dimethylamine	2	
Trimethylamine	2.2	
Other Gases		
Acetone	0.33	
Ammonia	8.5	9.6
Hydrogen sulphide	2	0.054
Methane	0.004	5.0
Total (nonmethane VOCs)	1.22	0.81

** list not complete from Zahn *et al.*, 2001c. Total reported nonmethane VOCs from both studies are based on complete listing.

Zahn *et al.* (2001c) did provide simultaneous ventilation rate measurements and therefore was able to assess VOC emissions. For the complete listing of identified VOCs, they reported a VOC emission rate of 89.9 g VOC/system-h.

Zhu *et al.* (2000) studied the daily variations in odor emissions from various mechanically and naturally ventilated swine housing systems. For each housing system studied, a deep-pit manure storage system was used, and each was pit-ventilated. They investigated odor strength from both the pit-fan exhaust-air and the air emitted from inside the building itself. From the pit-fan exhaust, odor strength was highest from the nursery facility ranging between 500 and 2400 OU (dilutions to threshold). The odor strength was lowest from the naturally ventilated finishing facility averaging between 200 and 400 OU. Odor strengths measured from inside the house were significantly lower than those measured from the pit-exhaust fans, with the highest measured levels from the nursery averaging between 250 and 900 OU. The lowest internal odor strength measurements were reported from the gestation facility averaging between 200 and 300 OU. For all five swine facilities monitored, with the exception of the nursery facility, the emission rate of odors ranged from about 5 to 20 OU m3/m2-s. For the nursery facility studied, the odor emission rate was significantly higher than the gestation, farrowing, or finishing facilities, averaging between 8 and 50 OU m3/m2-s (emitted OU strength multiplied by ventilation rate and divided by the floor area of the facility).

Hartung *et al.* (2001) investigated the effect of a mature and new biofilter on the odor emission rate from a swine finisher's ventilation air. They found that with an odor load from the ventilation air averaging 326 OU/m3-h, a reduction in odor emission of 78 to 81 percent was measured. This level of odor emission reduction was not found to be highly dependent on airflow rate. The biofilter experiments conducted resulted in an average air retention time through the filter medium of six seconds.

Particulates
Takai *et al.* (1998) conducted an extensive study of dust emissions from swine housing units. They investigated both indoor concentration levels of dust and the corresponding emission rates. They found significant differences in concentrations and emissions by housing type. The overall average indoor concentrations measured were 2.19 and 0.23 mg/m3 for inhalable and respirable dust concentrations, respectively. The average emission rate from the housing systems monitored were 762 and 85 mg/AU-h for the inhalable and respirable fractions, respectively (18 and 2 g particulates/AU-day). Seasonal effects were found to be significant for the inhalable dust emission rates from the pig houses monitored where, emissions were higher in summer periods, with indoor concentrations higher in winter than summer. There was no similar correlation found for the respirable fraction. A more complete table of results is presented below:

Table 4.3. Swine house particulate matter emissions (Takai et al, 1998)

		Inhalable Dust*		Respirable Dust	
Species	Flooring Type	Low Average Mg/AU-h	High Average mg/AU-h	Low Average mg/AU-h	High Average mg/AU-h
Sows	Litter	144 (3.5)	753 (18)	46 (1.1)	49 (1.2)
Sows	Slats	121 (2.9)	949 (22.8)	13 (0.3)	141 (3.4)
Nursery Pigs	Slats	687 (16.5)	1364 (32.7)	51 (1.2)	122 (2.9)
Finishing Pigs	Litter	561 (13.5)	890 (21.4)	69 (1.7)	73 (1.8)
Finishing Pigs	Slats	418 (10)	895 (21.5)	34 (0.8)	133 (3.2)

* levels in () are g particulates/AU-day.

Bioaerosols
Seedorf *et al.* (1998) conducted a comprehensive study of the emissions of endotoxin and mircroorganisms in the air fraction from pig housing facilities. They found average emission rates of inhalable and respirable endotoxin averaged 51 and 6 ug/AU-h, respectively (1.2 and 0.14 mg/AU-day). The table below gives a more complete listing of the average measured endotoxin emissions from various facilities:

Table 4.4. Swine house endotoxin emissions (Seedorf et al, 1998)

Species	N	Average Inhalable EE	Average Respirable EE	Maximum Inhalable EE	Maximum Respirable EE
Sows	43	37.4 (0.9)	3.7 (0.1)	961.6 (23)	68.7 (1.6)
Nursery Pigs	25	66.6 (1.6)	8.9 (0.2)	347.8 (8.3)	39.8 (1.0)
Finishing Pigs	39	49.8 (1.2)	5.2 (0.1)	299.7 (7.2)	56.1 (1.3)

N=number of buildings sampled, EE=endotoxin emission in ug/AU-h, values in () are mg/AU-day.

Microorganism emissions from these same facilities were categorized into total bacteria, enterobacteriaceae, and fungi. The results from this analysis are given in the table below, with results presented as the Log of the number of colony forming units (cfu) emitted per hour and per AU.

Table 4.5. Swine house microorganism emissions (Seedorf et al, 1998)

Species	N	Total	Enterobacteriacae	Fungi
			Log cfu /AU-h	
Sows	43	7.7	6.0	6.5
Nursery Pigs	25	7.1	6.9	5.8
Finishing Pigs	39	7.6	6.9	6.1

Endotoxin is a hazardous component of airborne particulates in CAFOs. It arises from the degradation of the cell wall of bacteria and is ubiquitous in the agricultural environment. Endotoxin is a potent inflammatory agent that produces systemic effects and lung obstruction, even at very low levels of exposure. It is consistently measured in high concentrations in CAFOs. Nine studies have reported endotoxin exposures in livestock confinement barns using rigorous quantitative methodology as summarized in the table below.

Table 4.6. Swine house interior endotoxin concentrations

Environment	Sites	Range, EU/m³	Mean, EU/m³	Reference
Swine Units	31	--	2400	Donham *et al*,1989
	21	2030 – 11300	4380	Duchaine *et al,* 2001
	350	56 – 15030	920	Preller *et al*,1995
	6	2190 – 24100	8080	Thorne *et al*,1997
	18	210 – 4200	900	Clark *et al*, 1983
Poultry Houses	6	200 – 4500	1360	Thorne *et al*, 1997
	7	1200 – 5000	3600	Clark *et al*, 1983
	25	1300 – 10900	--	Thelin *et al*, 1984
Dairy Barns	85	42 – 34800	742	Kullman *et al*, 1997

There have been few studies that have evaluated offsite transmission of endotoxin from CAFOs. One recent Iowa study (published only as an abstract) investigated in-barn and downwind endotoxin concentrations on 9 occasions over the course of 15 months (Thorne *et al.*, 2001). The study was conducted at one site with three hoop barns housing a mean total of 570 pigs and a conventional confinement site 15 miles away housing 1500 pigs. Grand mean in-barn endotoxin concentrations were 7230 EU/m^3 for the hoop barns and 9950 EU/m^3 for the conventional confinement facilities compared to upwind mean values of 17 EU/m^3 at both sites. Despite these high in-barn levels, there was a sharp diminution of airborne levels downwind of the barns. Endotoxin values 500 feet downwind had reached the 50 EU/m^3 level that is considered a no effect threshold (Dutch Expert Committee on Occupational Standards, 1998). However, it should be recognized that these facilities were small and a larger operation would be expected to produce higher levels of endotoxin. The endotoxin data from this study are summarized in table 4.7.

Table 4.7. Downwind concentrations of endotoxin (Thorne et al, 2001)

	Hoops		Conventional confinement	
	100 ft downwind	500 ft downwind	100 ft downwind	500 ft downwind
Mean, EU/m^3	837	51	155	44
Range, EU/m^3	22 – 3904	20 – 142	18 - 408	-143

4.1.2. Swine Manure Storage Unit Emissions

Ammonia

Aneja *et al.* (2001) studied the ammonia-nitrogen flux from lagoons in North Carolina and found that the emission rates were correlated with lagoon water temperature and aqueous ammonia concentration. They developed a correlation for ammonia nitrogen flux (NH3-N) as ln(NH3-N)=1.0788+0.0406*T+0.0015(NHx) where NH3-N is in ug N/m2-min, T is the lagoon surface temperature in Celsius, and NHx is the total ammonia-nitrogen concentration in mg N/liter.

Aneja *et al.* (2000) studied the seasonal variations in ammonia-nitrogen flux from an anaerobic lagoon in North Carolina and found maximum ammonia emissions during the summer (4017 ug N/m2-min) with minimum levels in the winter (305 ug N/m2-min). Mild weather emissions ranged from 844 (fall) to 1706 (spring) ug N/m2-min. These emission rates were correlated with lagoon surface temperature (measured 15 cm below the lagoon surface) as Log10(NH3-N)=2.1+0.048*T where NH3-N is in ug N/m2-min and T is the lagoon surface temperature in Celsius.

Zahn *et al.* (2001a) studied the efficiency of a polymer-based biocover on the reduction of gas emissions from a single-stage lagoon using micrometeorological techniques. Ammonia flux averaged 18 ng NH3/cm2-s (16 g NH3/m2-day) between summer and fall conditions.

Zahn *et al.* (2001b) studied the ammonia emission rates from 29 swine manure storage systems in Iowa (n=24), Oklahoma (n=2), and North Carolina (n=3). They found that the 29 manure storage systems could be grouped into four main "types", categorized by the total phosphorous and sulfur in the slurry and were able to show distinctions between these 29 storage systems into these four general manure storage "types". These four general types all exhibited similar gas and VOC emission characteristics, allowing grouping of emission results to be made. The four general types were, (1) housing units with long and short term under-floor manure storage configured as deep-pit or pull-plug systems, (2) earthen basin, concrete lined, or above-ground steel tanks, (3) lagoons without photosynthetic blooms, and (4) lagoons with photosynthetic blooms. A summary of the ammonia emission rates from these four types, based on averages within type, are given below:

Type	Description	Ammonia Flux Rate, ng NH3/cm2-s*
I	deep-pit, pull-plug	66 (57)
II	earthen, concrete-lined, steel tanks	167 (144)
III	lagoons without photosynthetic blooms	109 (94)
IV	lagoons with photosynthetic blooms	89 (77)

* values in () are g NH3/m2-day.

Hobbs *et al.* (1999) investigated the emission of odors and gases from stored swine manure with storage times between 0 and 112 days. They reported average daily emissions of ammonia at 4.35 g NH3/m2-day.

Sommer *et al.* (1993) conducted a series of controlled experiments to determine the ammonia emission from stored swine slurry. If the slurry was left uncovered, without allowing a crust to form, the ammonia emission rate was on average 4.3 g NH3-N/m2-day (5.2 g NH3/m2-day). If a crust was allowed to form (between 16-30 cm thick), the ammonia emission reduced to between 0.5 and 1.5 g NH3-N/m2-day (0.6-1.8 g NH3/m2-day). If this slurry was covered with chopped wheat straw at a thickness ranging from 15-23 cm, the ammonia emission was reduced to between 0.2 and 1 g NH3-N/m2-day (0.3-1.2 g NH3/m2-day). If this same slurry was capped with a lid, the ammonia emission reduced to between 0 and 0.3 g NH3-N/m2-day (0-0.4 g NH3/m2-day).

Methane

Zahn *et al.* (2001a) studied the efficiency of a polymer-based biocover on the reduction of gas emissions from a single-stage lagoon using micrometeorological techniques. Methane flux ranged from 134 ng CH4/cm2-s (116 g CH4/m2-day) in summer to 80 ng CH4/cm2-s (69 g CH4/m2-day) in fall.

Hobbs *et al.* (1999) investigated the emission of methane from stored swine manure with time between 0 and 112 days of storage. They reported average daily emissions of methane at 21.4 g CH4/m2-day respectively.

Zahn *et al.* (2001b) studied the methane emission rates from 29 swine manure storage systems, as described previously. A summary of the methane emission rates from the four type classifications, based on averages within type, are given below:

Type	Description	Methane Flux Rate, ng CH4/cm2-s*
I	deep-pit, pull-plug	34 (29)
II	earthen, concrete-lined, steel tanks	178 (154)
III	lagoons without photosynthetic blooms	218 (188)
IV	lagoons with photosynthetic blooms	200 (173)

* values in () are g CH4/m2-day

Hydrogen Sulfide

Zahn *et al.* (2001a) studied the efficiency of a polymer-based biocover on the reduction of gas emissions from a single-stage lagoon using micrometeorological techniques. Hydrogen sulfide flux ranged between 0.73 ng H2S/cm2-s (0.63 g H2S/m2-day) for the summer and 2.11 ng H2S/cm2-s (1.8 g H2S/m2-day) in fall.

Hobbs *et al.* (1999) investigated the emission of odors and gases from stored swine manure with time between 0 and 112 days of storage. They reported average daily hydrogen sulfide emissions of 66.6 g H2S/m2-day.

Zahn *et al.* (2001b) studied the hydrogen sulfide emission rates from 29 swine manure storage systems, as described previously. A summary of the emission rates from the four type classifications, based on averages within type, are given below:

Type	Description	Hydrogen Sulfide Flux Rate, ng H2S/cm2-s*
I	deep-pit, pull-plug	0.37 (0.32)
II	earthen, concrete-lined, steel tanks	1.1 (0.95)
III	lagoons without photosynthetic blooms	0.32 (0.28)
IV	lagoons with photosynthetic blooms	0.24 (0.21)

* values in () are g H2S/m2-day

Arogo *et al.* (2000) investigated the influence of water supply sulfate concentration on the emission of hydrogen sulfide from under-floor stored swine manure. They found a positive correlation between these two parameters in a controlled laboratory condition.

<u>Trace Gases</u>

Hobbs *et al.* (1999) investigated the emission of odors and gases from stored swine manure with storage times between 0 and 112 days. They measured and recorded several volatile organic compounds. Of these measured VOC's, acetic acid had the highest average emission at 1.49 g/m2-day. Phenols on average were emitted at 0.018 g/m2-day with indoles emitted at less than 0.001 g/m2-day. The cumulative odor emission rate was also reported at 802,483 OU/m2-min (odor threshold, OU, multiplied by release rate, m3/min, divided by surface area, m2).

Zahn *et al.* (2001b) studied the total VOC emission rates from 29 swine manure storage systems, as described previously, and summarized the VOC emission rate from the four type classifications, based on averages within type, as:

Type	Description	Total VOC Emission Rate (g VOC/system-h)
I	deep-pit, pull-plug	89.9
II	earthen, concrete-lined, steel tanks	394
III	lagoons without photosynthetic blooms	113.1
IV	lagoons with photosynthetic blooms	14.5

4.1.3. Swine System Emission Rates versus Downwind Concentrations

Seedorf *et al.* (1998) summarized downwind concentrations of endotoxin from swine facilities from work conducted by others:

Downwind Distance (m)	Endotoxin Concentration (ng/m3)
50	60
115	15

Seedorf *et al.* (1998) also summarized research of others on the simultaneous source emission and downwind concentration of microorganisms from swine facilities for both cold and mild weather ventilation conditions:

Downwind Distance (m)	Bacteria Concentration (log cfu/m3)	
	Winter	Spring
0 (source emission)	6.04	5.76
100	3.23	2.97

Zhu *et al.* (2000) studied the downwind concentrations of odor from five dairy/cattle facilities, 18 swine facilities, and five poultry facilities. These facilities ranged widely between manure handling and ventilation methods. Although individual building versus downwind odor strength data was not presented, insight into the downwind odor strength can be gained from this study. At 100 m from any of the sources investigated, the maximum odor strength measured was 270 OU (dilutions to threshold). At 200 m from any of the sources, the maximum odor strength measured was 70 OU, and this reduced to 50 OU at 300 m, and further reduced to 13 OU at 400-500 m downwind. All recordings were taken during daytime hours and the odor strength, reported as OU, was evaluated by personnel trained using a scale developed with n-butanol.

Cattle and Dairy System Emissions

4.1.4. Cattle and Dairy Housing Unit Emissions

Ammonia

Braam *et al.* (1997) investigated the influence of manure handling on the emission of ammonia from dairy cow housing. They investigated two new under-floor manure handling systems incorporating urine gutters with traditional slatted floor systems and found that ammonia emissions from dairy cow housing using slatted floor arrangements could be reduced by as much as 65 percent with special under-floor manure handling. If the under-floor slurry was designed as a sloping floor with a special gutter used to quickly remove urine from the slurry, ammonia emissions were reduced by as much as 50 percent. If in addition to this manure handling system, water was added 12 times per day at a rate of 6 liters/day-cow, the ammonia emission reduction was 65 percent, again relative to a under-floor pit with traditional slats.

Groot Koerkamp *et al.* (1998) conducted an extensive study of ammonia emissions from cattle housing facilities. They investigated both indoor ammonia levels and with simultaneous measurements of building ventilation rates, reported the emission rate. In general, ammonia levels inside the cattle buildings monitored were low, averaging 8 ppm, with average ammonia emission rates ranging between 315 and 1797 mg NH3/AU-h (7.6 and 43 g NH3/AU-day). A more complete listing of the ammonia emissions measured for various species and flooring type are given in the table below:

Table 4.8. Cattle house ventilation air ammonia emission (Groot Koerkamp et al, 1998)

Species	Flooring Type	Low Average mg/AU-h (g NH3/AU-day)	High Average mg/AU-h (g NH3/AU-day)
Dairy Cows	Litter	260 (6.2)	890 (21.4)
Dairy Cows	Cubicles	843 (20)	1769 (42.5)
Beef Cattle	Litter	431 (10.3)	478 (11.5)
Beef Cattle	Slats	371 (9)	900 (21.6)
Calves	Litter	315 (7.6)	1037 (25)
Calves	Slats	1148 (28)	1797 (43)

Jeppsson (1999) studied the influence of bedding material on the ammonia emission rate from cattle housing. Bedding consisting of chopped straw, long straw (ie unchopped), and chopped straw with a peat mixture (2:3 ratio) were tested. Bedding was added to each pen at a rate of 2.7 kg/animal-day over a six month period. They found that pens with chopped straw added to a peat mixture in a 2:3

ratio reduced the ammonia emission by nearly 60 percent relative to pens bedded with long straw. In total, the chopped straw/peat bedding resulted in an average ammonia emission rate of 319 mg/m2-h (8 g NH3/m2-day), while the pens with long straw resulted in an average ammonia emission rate of 747 mg/m2-h (18 g NH3/m2-day). They attributed this reduction to the ability of peat to absorb ammonia, lower the pH level, it's high carbon-to-nitrogen ratio, and it's ability to absorb water. Chopped straw alone, without the addition of peat, reduced the average ammonia emission rate to 547 mg/m2-h (13 g NH3/m2-day). For this study, cattle had access to an unbedded walkway with the reported ammonia emission from this area of the barn averaging 297 mg/m2-h (7.1 g NH3/m2-day).

Kroodsma *et al.* (1993) investigated the contributions of the slurry pit, feeding floor, and the influence of flushing on ammonia emission rates from free-stall dairy facilities. Overall, they reported that from all in-house contributions of ammonia emission, on average results were 1.0 to 1.5 kg NH3/cow-month produced, which equates to between 1344 and 2016 mg NH3/cow-h. They also studied the contributions of ammonia emission from different aspects of the dairy house, as summarized in the table below:

Table 4.9. Cattle house floor and slurry ammonia emission (Kroodsma et al, 1993)

Emission Source	Measured Ammonia Emission Rate mg NH3/m2-h (g NH3/m2-day)
Dirty Slatted Floor	400 (9.6)
Scraped Slatted Floor	380 (9.1)
Unstirred Slurry Below Slats	320 (7.7)
Stirred Slurry Below Slats	290 (7.0)
Dirty Solid Floor	670 (16)
Scraped Solid Floor	620 (15)
Flushed Solid Floor	210 (5)

These results point out the relative equal contributions from the flooring system itself and the stored slurry below the floor. Also, flushing manured floor surfaces can drastically reduce ammonia emissions, as shown. They tested many flushing regimes and found that flushing the floors at 60kPa nozzle pressure, for two seconds every two hours (50 liters water/cow-day), resulted in the best ammonia reduction levels, as reported above for the flushed solid floor.

Swierstra *et al.* (2001) studied the effectiveness of a specially grooved slatted flooring system for free-stall dairy housing with under-floor slurry storage. The flooring system tested had grooved channels with periodic perforations to quickly channel urine from the feeding floor and this was combined with frequent scraping (every two hours) of the slatted flooring to an opening that delivered manure to the under-floor pit area. This opening (to the under-floor pit) was closed during non-scraping events. This method of manure handling was compared with a conventional slatted flooring system based on ammonia emission rates. They consistently found that the ammonia emission rate was reduced by 46 percent compared with the conventional slatted floor system (11.7 g NH3/h vs 21.6 g NH3/h). On a per cow-day basis, these levels correspond to 28.1 g NH3/cow-day and 51.8 g NH3/cow-day. A follow-up field study confirmed this level of ammonia reduction.

Zhu *et al.* (2000) studied the daily variations in ammonia emission from a naturally ventilated dairy housing unit. During one day of monitoring, they measured a consistent 1 ppm of ammonia concentration inside the housing unit with a resulting emission rate averaging 4 ug NH3/m2-s (0.35 g NH3/m2-day).

Elzing and Monteny (1997) studied, in a controlled laboratory setting, the ammonia emission rate from manure and urine fouled slats and from the under-floor storage tank from dairy-cow manure. They found that peak ammonia emissions, from soiled slats covered with fresh manure and urine deposits, had a peak ammonia emission level at about two hours after deposition. The peak ammonia emission rate from the slats was positively correlated with both slat surface temperature and airspeed levels above the slats. They found that the combined slat and under-floor storage unit resulted in 10 g NH3 being emitted after 10 hours of fresh manure deposition on the slats and 12 g NH3 after 20 hours of fresh manure deposition on the slats. During these same periods of 10 and 20 hours, they reported that the contribution of this total ammonia emission from the under-floor storage unit was constant at 3.3 g NH3.

Methane

Kaharabata and Schuepp (2000) investigated emission of methane from dairy cows using a tracer-ratio method. They studied emissions from dairy cow housing and reported measured levels of 542 L CH4/day-cow.

Hydrogen Sulfide

Zhu *et al.* (2000) studied the daily variations in hydrogen sulfide emission from a naturally ventilated dairy housing unit. During one day of monitoring, they measured variations in internal concentrations between 4 and 26 ppb with resulting emission rates averaging roughly 3 ug H2S/m2-s (0.26 g H2S/m2-day).

Trace Gases

Zhu *et al.* (2000) studied the daily variations in odor emissions from a naturally ventilated dairy housing unit. During one day of monitoring, they measured a consistent internal odor strength of 50 OU (dilutions to threshold). The resulting odor emission rate was on average 2 OU m3/m2-s (odor strength, OU, multiplied by the estimated ventilation rate, m3/s, divided by the floor area of the housing unit, m2).

Particulates

Takai *et al.* (1998) conducted an extensive study of dust emissions from cattle housing. They investigated both indoor concentration levels of dust and the emission rates. They found significant differences in concentrations and emissions by housing type. The overall average indoor concentrations measured were 0.38 and 0.07 mg/m3 for inhalable and respirable dust concentrations, respectively. The average emission rate from the cattle housing systems monitored was 145 and 24 mg/AU-h (3.5 and 0.6 g/AU-day) for the inhalable and respirable fractions, respectively. Seasonal differences in concentration and emission of dust for cattle buildings for both inhalable and respirable fractions were not significant. A more complete table of results is presented below:

Table 4.10. Cattle house ventilation air particulate emission (Takai et al, 1998)

		Inhalable Dust*		Respirable Dust	
Species	Flooring Type	Low Average mg/AU-h	High Average mg/AU-h	Low Average mg/AU-h	High Average mg/AU-h
Dairy Cows	Litter	60 (1.4)	142 (3.4)	6 (0.1)	84 ((2.0)
Dairy Cows	Cubicles	21 (0.5)	338 (8.1)	13 (0.3)	54 (1.3)
Beef Cattle	Litter	36 (0.9)	135 (3.2)	6 (0.1)	26 (0.6)
Beef Cattle	Slats	78 (1.9)	144 (3.5)	5 (0.1)	29 (0.7)
Calves	Litter	64 (1.5)	190 (4.6)	14 (0.3)	40 (1.0)
Calves	Slats	63 (1.5)	192 (4.6)	14 (0.3)	22 (0.5)

* values in () are g/AU-day.

Bioaerosols

Seedorf et (1998) conducted a comprehensive study of the emissions of endotoxin and mircroorganisms from cattle housing facilities. They found average emission rates of inhalable and respirable endotoxin in cattle buildings of 9 and 1 ug/AU-h, respectively. The table below gives a more complete listing of the average measured endotoxin emissions from various facilities:

Table 4.11. Cattle house ventilation air endotoxin emission (Seedorf et al, 1998)

		Average	Average	Maximum	Maximum
Species	N	Inhalable EE*	Respirable EE	Inhalable EE	Respirable EE
Cows	31	2.9 (0.07)	0.3 (0.007)	11.4 (0.28)	1.9 (0.05)
Beef	18	3.7 (0.09)	0.6 (0.01)	22.8 (0.55)	9.3 (0.22)
Calves	17	21.4 (0.50)	2.7 (0.06)	90.1 (2.18)	44.8 (1.08)

* EE=endotoxin emission in ug/AU-h. Values in () are mg/AU-day.

Microorganism emissions from the facilities studied in Seedorf *et al.* (1998) were summarized in terms of total bacteria, enterobacteriaceae, and fungi. The results from this analysis are given in the table below, with results presented as the Log of the number of colony forming units (cfu) emitted per hour and per AU.

Table 4.12. Cattle house ventilation air microorganism emission (Seedorf et al, 1998)

		Total	Enterobacteriacae	Fungi
Species	N		Log cfu /AU-h	
Cows	31	6.8	6.2	6.0
Beef	18	6.7	6.2	5.9
Calves	17	7.3	6.1	6.5

4.1.5. Cattle and Dairy Manure Storage Unit Emissions

Ammonia

Kellems *et al.* (1979) conducted experiments to investigate ammonia emission from cattle slurry as the proportions of feces, urine, and water changed. They found clear trends in ammonia emission rates with various proportions. From the urine fraction only, the ammonia emission rate was 426 ug NH3/h, representing the worst-case scenario. From the feces fraction only, 3.2 ug NH3/h was emitted. With a 1:1 ratio of feces and urine, the emission rate of ammonia was 120 ug NH3/h.

Dewes (1999) studied ammonia emission characteristics of liquid and solid cattle manure over the initial 16 days of storage time. Over this short initial time period, solid manure with 15 kg of straw added per animal per day had the highest emission rate of ammonia at 6300 ug NH3-N/h-kg of manure with liquid manure having the lowest emission rate of ammonia at 663 ug NH3-N/h-kg of manure. Projections were made for longer storage periods and conclusions were made that after a storage period of 28 days, the ammonia emission rate would be greatest with manure stored as a liquid. However, it was also concluded that solid manure systems that use heaped piles can result in higher ammonia emission rates versus liquid manure systems since the emitting area for a stored pile is large.

Sommer *et al.* (1993) conducted a series of controlled experiments to determine the ammonia emission from stored cattle slurry. If the slurry was left uncovered, without allowing a crust to form, the ammonia emission rate was on average 4.5 g NH3-N/m2-day (5.5 g NH3/m2-day). If a crust was allowed to form, at 7 cm thickness, the ammonia emission reduced to 1.3 g NH3-N/m2-day (1.6 g NH3/m2-day). If this same slurry was capped with a lid, the ammonia emission reduced to between 0.2 and 0.4 g NH3-N/m2-day (0.25-0.5 g NH3/m2-day).

Methane

Kaharabata and Schuepp (2000) investigated emission of methane from dairy cows using a tracer-ratio method. They studied emissions from the feedlot and reported average emissions of 631 L CH4/day-cow.

Poultry System Emissions

4.1.6. Poultry Housing Unit Emissions

Ammonia

Demmers *et al.* (1999) investigated the exhausted concentrations and emission rates of ammonia from a mechanically ventilated poultry building. They reported ammonia concentrations between 1 and 37 mg/m3. Emission rates of ammonia averaged 18.6 kg NH3/AU-yr (51 g NH3/AU-day).

Wathes *et al.* (1997) studied extensively the emission of ammonia from broiler and layer facilities. They reported average emissions of ammonia at 9.2 g NH3/AU-h (221 g NH3/AU-day). This ammonia emission rate was consistent across both layer and broiler facilities. A complete table of their findings is presented below:

Table 4.13. Poultry house ventilation air ammonia emission (Wathes et al, 1997)

Poultry Type	Season	Average Ammonia Emission g NH3 /AU-h (g NH3/AU-day)
Caged Layers	Winter	8 (192)
Broilers	Winter	9 (216)
Caged Layers	Summer	12.5 (300)
Broilers	Summer	9 (216)

Groot Koerkamp *et al.* (1998) conducted an extensive study of ammonia emissions from poultry housing facilities. They investigated both indoor ammonia levels and with simultaneous measurements of building ventilation rates, reported the emissions. In general, ammonia levels inside the buildings ranged between 5 and 30 ppm with the average emission rate of ammonia between 602 and 10892 mg NH3/AU-h (14 and 261 g NH3/AU-day). A more complete listing of the ammonia emissions measured for various species and flooring types is given in the table below:

Table 4.14. Poultry house ventilation air ammonia emission (Groot Koerkamp et al, 1998)

Species	Flooring Type	Low Average mg/AU-h (g/AU-day)	High Average Mg/AU-h (g/AU-day)
Laying Hens	Litter	7392 (177)	10892 (261)
Laying Hens	Cages	602 (14)	9316 (224)
Broilers	Litter	2208 (53)	8294 (199)

Zhu *et al*. (2000) studied the daily variations in ammonia emission from a mechanically ventilated broiler house using litter bedding. During one day of monitoring, they measured internal concentrations of ammonia between 9 and 13 ppm with a resulting ammonia emission rate averaging between 4 and 20 ug NH3/m2-s (7-33 g NH3/AU-day).

Methane

Wathes *et al*. (1997) studied the emission rate of methane from broiler and layer facilities. They reported average methane emissions of 0.85 g CH4/AU-h (19 g CH4/AU-day) for caged layers and 0.25 g CH4/AU-h (0.6 g CH4/AU-day) for broilers. A summary table of reported methane emissions is given below:

Table 4.15. Poultry house ventilation air methane emission (Wathes et al, 1997)

Poultry Type	Season	Average Methane Emission g CH4 /AU-h (g CH4/ AU-day)
Caged Layers	Winter	0.80 (19)
Broilers	Winter	0.25 (6)
Caged Layers	Summer	0.90 (22)
Broilers	Summer	0.25 (6)

Hydrogen Sulfide

Zhu *et al*. (2000) studied the daily variations in hydrogen sulfide emission from a mechanically ventilated broiler house using litter bedding. During one day of monitoring, they measured internal concentrations of hydrogen sulfide between 40 and 150 ppb with a resulting hydrogen sulfide emission rate averaging less than 2 ug H2S/m2-s (3.3 g H2S/AU-day).

Trace Gases

Misselbrook *et al*. (1993) studied the relationship between odor emission and intensity for broiler house air. They determined a relationship using a 0-6 point intensity scale versus the concentration of odors emitted from broiler houses. The intensity scale used is given below:

Intensity (I)	Description
0	No odor
1	Very faint odor
2	Faint odor
3	Distinct odor
4	Strong odor
5	Very strong odor
6	Extremely strong odor

They found a relationship that described 84 percent of the variability in their data where I=2.35 (Log_{10} C) + 0.30 where C is the dilution to threshold concentration of odor. They further summarized their data to give indications of the odor intensity with the dilution threshold concentration as given below:

Intensity	Broiler House Air Odor Concentration (OU/m3)
0	0-1.2
1	1.2-3.3
2	3.3-8.8
3	8.8-23.4
4	23.4-62.6
5	62.6-167
6	> 167

From this study, and from cited work of others, they concluded that an odor intensity at or below an intensity of 2 (faint odor) may be considered acceptable, which further implies that for broiler house ventilation air the odor concentration should be below about 3.3 OU/m3.

Zhu *et al.* (2000) studied the daily variations in odor emissions from a mechanically ventilated broiler house with litter bedding. During one day of monitoring, they measured a consistent internal odor strength of about 100 OU (dilutions to threshold). The resulting odor emission rate was less than 2 OU m3/m2-s (determined by multiplying the odor threshold, OU, by the ventilation rate, m3/s, and dividing through by the floor surface area of the housing unit, m2).

Particulates

Wathes *et al.* (1997) studied the emission of dust from broiler and layer facilities. They reported average inhalable and respirable dust emissions of 1.0 g/AU-h and 0.17 g/AU-h (24 and 4 g/AU-day) for caged layers and 6.7 g/AU-h and 0.79 g/AU-h (161 and 19 g/AU-day) for broilers, respectively. A summary table of emissions is given below:

Table 4.16. Poultry house ventilation air particulate emission (Wathes et al, 1997)

Poultry Type	Season	Inhalable Dust g/AU-h (g/AU-day)	Respirable Dust g/AU-h (g/AU-day)
Caged Layers	Winter	0.9 (22)	0.24 (5.8)
Broilers	Winter	5.2 (125)	0.60 (14.4)
Caged Layers	Summer	1.1 (26)	0.09 (2.2)
Broilers	Summer	8.2 (197)	0.88 (21.1)

Takai *et al.* (1998) conducted an extensive study of dust emissions from poultry housing facilities. They investigated both indoor concentration levels of dust and the emission rates to the atmosphere. They found significant differences in concentrations and emissions by housing type. The overall average indoor concentration was 3.60 and 0.45 mg/m3 for inhalable and respirable dust concentrations, respectively. The average emission rate from the various poultry housing systems was 3165 and 504 mg/AU-h (76 and 12 g/AU-day) for the inhalable and respirable fractions, respectively. Seasonal effects were found to be significant for the inhalable dust emission rates with emissions higher in summer periods, and indoor concentrations higher in winter than summer. There was no similar correlation found for the respirable fraction. A more complete table of results is presented below:

Table 4.17. Poultry house ventilation air particulate emission (Takai et al, 1998)

		Inhalable Dust*		Respirable Dust	
Species	Flooring Type	Low Average mg/AU-h	High Average mg/AU-h	Low Average mg/AU-h	High Average mg/AU-h
Laying Hens	Cages	398 (9.6)	872 (21)	24 (0.6)	161 (3.9)
Broilers	Litter	1856 (45)	6218 (149)	245 (5.9)	725 (17.4)

* values in () are g/AU-day.

<u>Bioaerosols</u>

Wathes *et al.* (1997) studied the emission of endotoxin from broiler and layer facilities. They reported average emissions of endotoxin between 1 and 45 ug/AU-h (0.024 and 1.1 mg/AU-day) with very strong seasonal effects, with summer emissions 3 to 45 times higher for caged layers and broilers, respectively. A summary table of endotoxin emissions is given below:

Table 4.18. Poultry house ventilation air endotoxin emission (Wathes et al, 1997)

Poultry Type	Season	Average Endotoxin Emission g/AU-h (g/AU-day)
Caged Layers	Winter	10 (240)
Broilers	Winter	< 1 (<24)
Caged Layers	Summer	30 (720)
Broilers	Summer	45 (1080)

Hinz and Linke (1998) investigated the indoor concentration and emission of endotoxin from a naturally ventilated broiler house. Endotoxin was measured in the broiler with reported levels ranging between 0.05 and 0.45 ug/m3 with no apparent seasonal trends, unlike the trends observed for inhalable dust.

Seedorf *et al.* (1998) conducted a comprehensive study of the endotoxin emissions from poultry housing facilities. They found average emission rates of inhalable and respirable endotoxin in poultry facilities, averaging 678 and 43 ug/AU-h (16 and 1 mg/AU-day), respectively. The table below gives a more complete listing of the average measured endotoxin emissions from various facilities:

Table 4.19. Poultry house ventilation air endotoxin emission (Seedorf et al, 1998)

Species	N	Average Inhalable EE	Average Respirable EE	Maximum Inhalable EE	Maximum Respirable EE
Layers	43	538.3 (13)	38.7 (0.9)	5247.1 (127)	342.5 (8.3)
Broilers	19	817.4 (20)	46.7 (1.1)	6836.3 (165)	294.6 (7.1)

EE=endotoxin emission in ug/AU-h. Values in () are mg/AU-day.

Microorganism emissions from the facilities studied were summarized in terms of total bacteria, enterobacteriaceae, and fungi. The results from this analysis are given in the table below, with results presented as the Log of the number of colony forming units (cfu) emitted per hour and per AU.

Table 4.20. Poultry house ventilation air microorganism emission (Seedorf et al, 1998)

Species	N	Total	Enterobacteriacae Log cfu /AU-h	Fungi
Layers	43	7.1	7.1	6.0
Broilers	19	9.5	6.1	7.8

4.1.7. Poultry Manure Storage Unit Emissions

Ammonia

Brewer and Costello (1999) investigated the emission of ammonia from broiler house litter, comparing new bedding consisting of either rice hulls or rice hulls mixed with pine shavings and re-used bedding of the same. On average, new bedding resulted in an average ammonia emission of 149 mg NH3-N/m2-h (4.3 g NH3/m2-day) with a maximum emission of 314 mg NH3-N/m2-h (9.1 g NH3/m2-day). When the bedding was re-used for subsequent grow-out periods, the average ammonia emission increased to 208 mg NH3-N/m2-h (6.0 g NH3/m2-day) with a maximum emission of 271 mg NH3-N/m2-h (7.9 g NH3/m2-day).

4.2. Emissions During Land Application of Livestock Manure

Ammonia

Svensson (1994) investigated the factors that affect ammonia volatilization and thus emission from land applying swine and cattle manure. He pointed out that the major factors influencing ammonia emission were (1) meterorological, (2) soil/manure characteristics, and (3) the application technique. For meteorological factors, wind speed, air temperature, and thermal stratification near the soil surface were most important. Regarding soil/manure characteristics, soil temperature, soil pH, soil porosity, and soil water content were most important. Finally, the application technique was noted as having a large impact on ammonia emission rates. Svensson (1994) conducted a series of controlled experiments to quantify the influence of these factors, mainly by recording the equilibrium ammonia concentration above the soil after a land application event. This equilibrium ammonia concentration was then used to determine the relative potential of ammonia emission rates from land application of both cattle and pig slurry. Soil temperature was found to be a critical factor. At soil temperatures of 24 C, the equilibrium ammonia concentration was over three times that for soil temperatures at 14 C (18 versus 5 ppm ammonia). Manure solids content was also found to be an important contributor to ammonia emission. A pig slurry of 5.4 percent solids had an equilibrium ammonia concentration of about 4 ppm, and this increased to 23 ppm ammonia for pig slurry at 14.4 percent solids. Application technique had the largest effect on the equilibrium ammonia concentration above the soil surface after spreading. If the slurry was injected, the average equilibrium ammonia concentration one hour after land applying was less than 1 ppm. If this same slurry was surface applied with no follow-up coverage, the equilibrium ammonia concentration one hour after land applying rose to 39 ppm. Svensson (1994) further investigated the influence of land application technique using pig urine only. If this "slurry" was broadcast spread with no follow-up cover, ammonia was emitted at about 700 g NH3/hectare-h during the first four hours. If this same slurry was broadcast spread with immediate covering *via* harrowing, the ammonia emission reduced to about 120 g NH3/hectare-h over the same time period, representing an 83 percent reduction. Clearly, injecting or *immediate* covering of slurry has a substantial reducing effect on ammonia emission.

Trace Gases

Misselbrook *et al.* (1993) studied the relationship between odor emission and intensity for land applied swine manure. They determined a relationship between a 0-6 point intensity scale and the concentration of odors emitted from land applied slurry. Their intensity scale used is given below:

Intensity (I)	Description
0	No odor
1	Very faint odor
2	Faint odor
3	Distinct odor
4	Strong odor
5	Very strong odor
6	Extremely strong odor

They found a relationship that described 68 percent of the variability in their data with $I=1.61(\mathrm{Log}_{10} C) + 0.45$ where C is the dilution to threshold concentration of odor. They further summarized their data to give indications of the odor intensity with the dilution threshold concentration as given below:

Intensity	Pig Slurry Odor Concentration (OU/m3)
0	0-1.1
1	1.1-4.5
2	4.5-18.8
3	18.8-78.9
4	78.9-331
5	331-1390
6	> 1390

From this study, and from cited work of others, they concluded that an odor intensity at or below an intensity of 2 (faint odor) may be considered acceptable, which further implies that for pig slurry the odor concentration should be on average below about 4.5 OU/m3. For a barely perceptible odor, indicated by an Intensity level of 1, the odor concentration should be on average below about 1.1 OU/m3.

Pain *et al.* (1991) investigated the concentrations and emissions of odors from land applied pig and cattle slurry. They investigated the emission rates of odors as a function of the land application method, and found odor emission rates (OU/s-m3 of slurry applied) of 8600 if the slurry was immediately plowed under versus 53700 for surface applied slurry, representing an 84 percent reduction in odor emission rates. For all experiments conducted, peak emissions occurred within one hour after spreading, and exponentially decayed rapidly to a level of about 10 percent the initial emission rate six hours after spreading. They stated that waiting 3-6 hours after surface applying before incorporating the slurry gave no benefit to the odor load experienced.

4.3. Dispersion Models

Predicting downwind concentrations of air pollutants released from concentrated animal feeding operations (CAFOs) is difficult because the emissions vary over time and they tend to be emitted from a variety of source types within a small area. This section provides a brief overview of the state of the science of the issue with focus on 1) classic methods for predicting pollutant concentrations downwind of a source and 2) recent reports in the peer-reviewed literature.

The Gaussian Plume model is the classic method of predicting downwind concentrations of air pollutants released from a single source. The model is based on a statistical model of diffusion from an origin. Its most important assumption is that of steady state conditions from a single source. The model assumes a constant state of meteorological conditions and emission rates. Given this assumption, however, the model can be used to examine how factors such as turbulent dispersion in the vertical and horizontal directions, wind speed, atmospheric stability, and emission rates will affect concentrations of the pollutant downwind. See figure below.

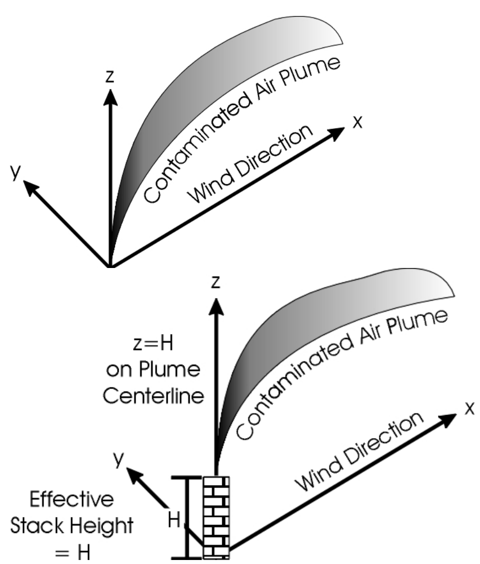

Figure 4.1. Coordinates of the Gaussian Plume model. The top figure describes a ground-level emission and the bottom figure describes a stack point-source emission.

The general equation for the concentration of pollutants can be derived as:

$$C(x,y,z) = \frac{Q}{2\pi\sigma_y\sigma_z}\exp\left(-\frac{y^2}{2\sigma_y^2}\right)\exp\left(-\frac{(z-H)^2}{2\sigma_z^2}\right)$$

where C is the concentration (mass/volume); x is the distance downwind of the source; y is the horizontal distance perpendicular to the x direction; z is altitude; Q is the emission rate (mass/time); σ_y and σ_z are the dispersion coefficients in the horizontal and vertical directions, respectively; and H is the effective stack height of the plume.

The Gaussian plume model is a reasonable screening level approach for estimating the concentration of pollutants released from a source. It can be modified to incorporate reflection or absorption of the pollutants by the ground and reactions in the atmosphere. This model is useful in examining the effect of atmospheric stability and in estimating the point of maximum downwind concentrations. Use of the Gaussian plume model can be useful in addressing questions about downwind concentrations of air pollutants from CAFOs such as:

- What level of improvement in air concentrations is predicted with a reduction in the emission rate?
- What wind directions and atmospheric stabilities will result in higher concentrations?
- What affect would installation of a stack exhaust have on downwind concentrations?
- How do meteorological conditions affect the diurnal and seasonal variability of air concentrations?
- What is the relationship between decreasing concentrations and distance from the source?

4.3.1 EPA Dispersion Models

There are a number of U.S. EPA approved computer models that are based on the Gaussian plume approach, with specific adaptations for local terrain, non-constant emissions, ground level and small area sources, and atmospheric deposition. As noted above, the Gaussian Plume models are especially useful as screening tools, designed to quickly address basic hypotheses about the relationship between sources and downwind concentrations.

Several dispersion models approved by the EPA have been evaluated for their use in association with confinement operations. The Industrial Source Complex Short Term (ISCST3) model is commonly used to model the dispersion from industrial point-sources. This model and two others: the AMS/EPA Regulatory Model (AERMOD), and the non-steady state CALPUFF model were evaluated for their effectiveness in modeling emissions from feedlot facilities (Earth Tech, 2001). The sophistication of the AERMOD and CALPUFF models give them certain advantages such as: flexibility for defining the area source geometry (AERMOD); and a realistic simulation of multi-facility impact assessment (CALPUFF). However, the ISCST3 model was chosen as the best model for evaluation of a single facility primarily because of its ease of use and familiarity. This model has been used in the past for modeling emissions from agricultural sources because, in addition to modeling plumes from tall stacks, it can also account for ground-level sources as would be the case for gases emitted from a manure pit (Gassman, 1992). Modifications to this model have also been made to increase the accuracy of its use for hydrogen sulfide and ammonia by the application of specific dispersion coefficients for these gases (Rege and Tock, 1996).

4.3.2. Livestock System Based Dispersion Models

Dispersion models have been used to predict downwind concentrations of ammonia from CAFO facilities. Quinn *et al.* (2001) tested several atmospheric dispersion models. They predicted air concentrations close (<100 m) to the CAFO source with some success. They tested a computational fluid dynamics (CFD) model linked to a modified diffusion model. The latter approach best reasonably fit the data although it underestimated concentrations for the majority of the points. The modeling was most successful in predicting the decrease in concentration with distance for near (<100m) sites. It should be noted that the success of this study is due, in part, to the design of the study. In this study, ammonia gas was released in known quantity, so the modeling effort benefited from use of a quantitative emission source.

Dispersion of odorous compounds has been considered using a modified Gaussian plume model. In one of the earlier papers on this subject, Carney and Dodd (1989) compared a modified Gaussian plume model used for odor dispersion with actual data from a number of sources, including a 450-sow swine facility, and determined that modeling adequately predicted actual plume dispersion. However, Li et al. (1994) found that the Gaussian model was inadequate for odor prediction from a 200-sow facility. The model's predicted plumes were too wide compared to those in the field and the model's emission rates were unreasonably high. Furthermore, Heinemann and Wahanik (1998) studied the application of this model to the dispersion of odors from a composting facility and found that instantaneous measurements taken during field samples may differ considerably from model predictions because of the large averaging time used by the model. Gassman (1992) reviewed odor modeling using the Gaussian-plume method and stated that the method was adequate when used on a relative basis for comparing differences between different scenarios, but did not recommend this method for finding absolute odor concentrations.

One of the ultimate utilities of odor-dispersion modeling is its use for estimating odor concentrations for the purpose of establishing setback distances and dilution ratios (Jacobson *et al.*, 2001; Zhu *et al.*, 2000b). However, researchers recognize that the use of dispersion models for this purpose will involve considerable field validation, which includes an understanding of the effects of various weather conditions on model accuracy and odor intensity. Previous field validation studies have demonstrated that the INPUFF-2 dispersion model simulated odor intensity in agreement with field odor measurements and may be the best model for the purpose of establishing odor setback distances (Zhu *et al.*, 2000b; Jacobson *et al.*, 2000).

4.3.3 Uncertainties and Recommended Uses of Models for CAFO Emissions

The Gaussian plume model and its modifications assume an emission source that is singular or made up of specific single sources: a point source, line source, or homogeneous area sources. Emissions from CAFOs are none of these. Animal operations in Iowa are increasingly compacted, and some facilities include an integration of the animal life-cycle from farrow to finish as well as outside manure storages (See Figure 4.2). There are a variety of potential gas and particulate emission sources. Possible sources may include farrowing/nursery barns, finishing barns, outside storages and fields where manure is applied. When barns are ventilated with single fans, the sources may be modeled as point sources, but outside storage units are clearly more like area sources. Barns with a series of ventilation fans behave as something in between area and point sources. Modeling emission sources from such a variety of source types makes achievement of an accurate prediction difficult. In addition, the emission rates often vary throughout the day, with local climate, and as the need for ventilation changes. For these reasons, Gaussian plume models will not excel at predicting actual pollutant concentrations downwind from a source or sources.

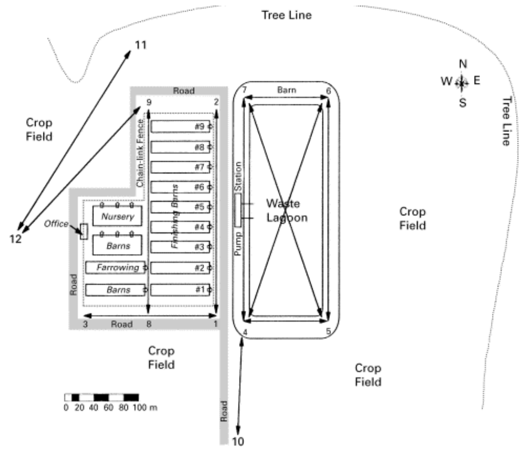

Figure 4.2. Integrated industrial swine production facility. From Childers *et al.*, 2001, Atmos. Environ. (35) 1923-1936.

Atmospheric dispersion models have limited utility for predicting absolute concentrations of atmospheric particles and gaseous compounds released from concentrated animal facilities. This limitation is primarily because the magnitude and variability in the emission sources that are difficult to quantify. Therefore, models cannot be used in lieu of direct measurements.

Noting the difficulties above, models still have essential uses in controlling and interpreting downwind concentrations of air pollutants released from CAFOs. First of all they successfully address how changes in the emission source, meteorology, and time of day or year affect concentrations (see bulleted questions above). Use of models for these purposes is a valuable and well-accepted mechanism for abatement of air pollutants. Models can be successfully used to predict the effect of emission reductions on ambient air concentrations. For example, models are a routine component of state implementation plans (SIPs) for reduction of criteria pollutants (U.S.EPA, 2002). State environmental agencies use models to estimate the relationship between local emission sources and measured concentrations of air pollutants. Using these findings, state agencies issue permits to emitters limiting emissions or requiring specific air pollution control devices or procedures. It is reasonable that states would also use this strategy to issue permits for CAFO emissions.

Dispersion models are useful as screening methods for predicting trends and percent changes in concentrations of atmospheric compounds released from CAFOs. Factors that may aggravate downwind conditions and that can be addressed with dispersion models include: trends caused by meteorological conditions, relative changes in source strengths, and dilution factors with distance away from the source. If direct measurements of emissions or concentrations very close to the facility are made, then dispersion models can be used to estimate dilution of the atmospheric compounds as a function of distance from the facility. Use of dispersion models to predict relative decreases in air concentrations as a result of decreases in emission rates is one of the most powerful uses of the models.

4.4. Evaluating Community Exposures to Odor

One method for evaluating the influence of CAFOs on surrounding residences is to review odor complaint records and the methods used for evaluating these complaints. Several states have procedures in place for documenting and evaluating odor complaints, as discussed in this section.

There is not a consistent method used in addressing odor complaints from animal feeding operations in the United States. Not all states have odor standards to address odor complaints. Some states use an arbitrary odor scale. Some states use dilution-to-threshold for odor evaluation. Others states use hydrogen sulfide as a surrogate method to measure odors. In Iowa, one of the most frequent complaints from livestock operations is odor. Since Iowa has no regulations pertaining to odors, some field offices do not record odor complaints.

Between July 1994 to October 2001, Iowa had 306 odor complaints. North Carolina Department of Air Quality (DAQ) started keeping a database for odors in February 1999. North Carolina has reported 415 separate complaints with a follow-up inspection of all complaints. As of December 2001, DAQ in North Carolina confirmed the presence of "objectionable odors" at 6 complainant locations involving 11 farms. Most of the complaints reported in Iowa and North Carolina were from swine facilities. Missouri has a state odor standard for industrial emission which will also be applied to the Class 1A CAFO's beginning January 2002.

4.4.1. Methods of evaluation of complaints

Some states do have odor standards or regulations governing odor emissions from industry, livestock or both. The methods on how complaints are addressed ranges from lay observers, to trained observers going to the site from a regulatory agency to simply registering the complaints from an individual. Several states and municipalities have odor standards.

The methods used to evaluate odor complaints range from a person to a group of people going to the location of the complaint and observing the source, strength of odor at the location, or measuring a surrogate odorous gas concentrations. There is limited data available on odor complaints from livestock.

Methods of evaluation complaint evaluation by states

Methods of odor evaluation are not consistent among states. The methods range from no protocol to arbitrary methods, to odor threshold measurement, to using hydrogen sulfide as a surrogate method of measurement. The length of time for evaluation and protocol for evaluation also differs.

No protocol

Some states do not regulate odors and therefore do not have an approved procedure for evaluating odor complaints. Iowa currently does not have an odor standard; therefore, does not have an adopted protocol for measuring odors. The livestock odor complaints in Iowa basically go unverified, since there are no standards. Within Iowa some municipalities have standards which use the scentometer to evaluate odors.

Arbitrary protocol

Some states use an arbitrary odor scale to evaluate odor strength with 0 being no odor and a higher number being a very strong odor. North Carolina uses an arbitrary scale of 0 to 5 with 0 being no odor and 5 being very odorous. This method often uses a team approach of more than one person taken to the site for investigation. Average values from the panel are used to evaluate odor strength.

Odor Threshold

The scentometer made by Barnebey and Sutcliffe is the primary method used when the protocol uses dilution-to threshold techniques for evaluating odors. Table 1 shows (Sweeten, 1990) a list of states that uses this method as a standard. The accepted standard level of odor threshold varies from state to state as shown in the table. Also the location of measurement differs between standards used, i.e., on site, property line, or neighbor's residence.

Hydrogen sulfide

Hydrogen sulfide concentrations are sometimes used as a substitute for odor evaluation. This standard is used in both Minnesota and Nebraska. Minnesota has a state hydrogen sulfide standard at 30 ppb not to be exceeded more than twice per 5 days in a 30-minute time period at the property line. Minnesota allows for a time period of 21 days during the year when this standard of 30 ppb is exempt. Nebraska has a similar standard of 100 ppb that cannot be exceeded more than 30 minutes. Both of these states give the counties jurisdiction for siting livestock facilities and the allowable odor level is left up to the county.

4.4.2. Odor Complaint Evaluation Discussion by State

Iowa

The Iowa Department of Natural Resources (DNR) Compliance and Enforcement Bureau consists of six field offices that are located throughout the state. Each field office is responsible for conducting routine inspections of agricultural facilities and handling complaints from the public in their designated counties. Animal feeding operations, or AFOs, are the source of many types of complaints, including well contamination, waste runoff, improper disposal of dead animals, and many others. Although the field offices receive a variety of complaints, one of the most frequent causes of complaints is odor. Animal feeding operations generate odors from several sources, such as the buildings where animals are housed, waste treatment systems such as lagoons or earthen basins, and the spreading of manure. More specifically, odors can occur from:

- stockpiling manure,
- untimely disposal of dead animals,
- improper compost pile management,
- spilling manure on roads or highways,
- spreading manure on snow, and
- spreading manure without injection.

Citizens that have complaints are encouraged to call the field office in their area. Odor complaints taken at field offices are not referred to the Air Quality Bureau or central offices. Although similar in nature, the complaint forms vary for each field office. Each contains the following information:

- the date the complaint was received,

- basic information on the complainant,
- basic information on who the complaint is against,
- program area (such as wastewater, air, solid waste, etc.),
- a statement of the complaint, and
- action/resolution.

The program area section lists different areas in which to classify the compliant, but varies in content and detail for each form. Some forms list the DNR employee to whom the complaint was referred, and others assign each complaint a complaint number. After a complaint form is filled out, each complaint gets logged in a spreadsheet. Again, although similar in nature, the categories listed in the spreadsheet vary for each field office. Several issues arose while completing this study:

- Most odor complaints go unrecorded at the field offices. There is no written protocol established for receiving and recording incoming odor complaints because the DNR does not regulate odor.
- Many odor complaints are never called in. Once citizens learn that there are no odor regulations, they realize the DNR may not be able help them, so they don't place the call.
- Citizens may call about odor and an additional problem, and the complaint gets logged under the additional problem.

Odor complaint records involving confined animal feeding operations in the state of Iowa were evaluated from 7/1/94 to the present (10/15/01). There were 306 total complaints, which fell into the following livestock categories: 86.9% swine, 5.6% cattle, 3.9% poultry, 3.6% horse, and <1% ostrich.

Several field office staff made the statement that most complaints occur during spring and fall due to manure application. This may also be attributed to the amount of time people spend outdoors.

There is a lack of consistency in recording, processing, and responding to odor complaints in Iowa. Since Iowa has no regulations pertaining to odor, some field offices do not record complaints when odor is the primary concern. There is no written protocol established for receiving and recording incoming odor complaints. The complaint form should be standardized for each field office as well as the central offices, and the database system where complaint records finally end up should also be standardized. A well organized complaint system for the state of Iowa would allow simple queries that could quickly determine how many times a facility has been referred, or how many times a certain individual has called in a complaint.

<u>Missouri</u>

The state of Missouri has an odor standard for industrial emissions using the scentometer. Missouri's odor standard states that no person may cause, permit, or allow the emission of odorous matter in concentrations and frequencies or for durations that odor can be perceived when one (1) volume of odorous air is diluted with seven (7) volumes of odor-free air for two (2) separate trials not less than fifteen (15) minutes apart within the period of one (1) hour. One exception of this standard was livestock production units. Class 1A CAFOs; however, was added to the list of regulated odors. A Class 1A livestock operation has a population of greater than 4,900 head of dairy cows; 17,500 head of finishing hogs; or 210,000 layer hens. Missouri has 20 Class 1A CAFOs. All 1A CAFOs operating on or after January 1, 1999, shall prepare and implement an odor control plan.

These plans must be submitted no later than July 1, 2000. After January 1, 2002, no Class 1A Concentrated Animal Feeding Operation (CAFOs) may cause, permit or allow the emission of odorous matter in concentrations and frequencies or for durations that the odor can be perceived when one (1) volume of odorous air is diluted with five and four-tenths (5.4) volumes of odor-free air for two separate trials not less than fifteen minutes apart within the period of one hour. This odor evaluation shall be taken at a site not at the installation and will be used as a screening evaluation. A positive screening evaluation for odor shall require an odor sample to be taken and evaluated by olfactometry. There were no odor complaint charts found for the state of Missouri.

North Carolina

North Carolina uses an arbitrary scale of 0 to 5 for panel members to evaluate odor complaints on site. Zero is no odor detected. A 5 is considered a very strong odor. Normally, two or more observers go to the complainant site to determine if an odor problem exists. This sometimes requires evaluation during night-time conditions.

The Department of Air Quality (DAQ) in North Carolina is maintaining a database of complainants and complaint locations. The DAQ database was begun February 23, 1999. The following information was gathered from the database:

- There have been 255 individual complainants/complaint locations listed in their database. There was a DAQ staff follow-up site visit in each case.
- There were 415 separate complaints listed in the database from the above complainants.
- As of (December, 2001), DAQ regional inspectors have confirmed the presence of "objectionable odors" at 6 complainant locations involving 11 farms.
- The Director has required the submission of 6 BMPs per regulations for 5 of the 6 complainant locations.
- For those sites where the presence of objectionable odors was confirmed, it took between 7 and 14 visits by DAQ staff to confirm the presence of the objectionable odor in response to a complaint. Each odor determination investigation typically requires 2 or more DAQ staff and most objectionable odor conditions occur outside of normal business hours.
- The odor complaints were greatest in 1999, lesser in 2000 and 2001 (Saunders, 2001).
- Most complaints are from smaller units that fall below the required size for odor management plans (Saunders, 2001).

Odor Management Plans are required under DAQ, 2D.1802(d), for swine operations based upon steady state live weight (SSLW). The regulations have the following schedule for submittal.

- January 15, 2001, number of farms with SSLW of more than 4 million pounds required to submit odor management plan response to DAQ;7 farms.
- July 15, 2001, number of farms with SSLW of more than 2 million pounds but less than 4 million pounds required to submit odor management plan response to DAQ;78 farms.

Table 4.21. Summary of Odor Standards in the United States (Sweeten,1990)

State or Political Division	Regulatory Limit			
	Residential	Commercial	Industrial	Other

Table 4.26. Particulate Emission Summary

Species	Species Phase	Notes	Emission Source	Partic.ulate Emission	Reported Units	Reference Source	Reference Year	**VA** g particulates/AU - day
Pigs	Sows	on bedding, inhalable	VA	144 – 753	mg/AU-h	Takai et al	1998	3.5 - 18
Pigs	Sows	on slats, inhalable	VA	121 – 949	mg/AU-h	Takai et al	1998	2.9 - 22.8
Pigs	Nursery	Inhalable	VA	687 - 1,364	mg/AU-h	Takai et al	1998	16.5 - 32.7
Pigs	Finishing	on bedding, inhalable	VA	561 – 890	mg/AU-h	Takai et al	1998	13.5 - 21.4
Pigs	Finishing	on slats, inhalable	VA	418 – 895	mg/AU-h	Takai et al	1998	10 - 21.5
Pigs	Sows	on bedding, respirable	VA	46 – 49	mg/AU-h	Takai et al	1998	1.1 - 1.2
Pigs	Sows	on slats, respirable	VA	13 – 141	mg/AU-h	Takai et al	1998	0.3 - 3.4
Pigs	Nursery	Respirable	VA	51 – 122	mg/AU-h	Takai et al	1998	1.2 - 2.9
Pigs	Finishing	on bedding, respirable	VA	69 – 73	mg/AU-h	Takai et al	1998	1.7 - 1.8
Pigs	Finishing	on slats, respirable	VA	34 – 133	mg/AU-h	Takai et al	1998	0.8 - 3.2
Dairy		on bedding, inhalable	VA	60 – 142	mg/AU-h	Takai et al	1998	1.4 - 3.4
Dairy		free-stall, inhalable	VA	21 – 338	mg/AU-h	Takai et al	1998	0.5 - 8.1
Beef		on bedding, inhalable	VA	36 – 135	mg/AU-h	Takai et al	1998	0.9 - 3.2
Beef		on slats, inhalable	VA	78 – 144	mg/AU-h	Takai et al	1998	1.9 - 3.5
Calves		on bedding, inhalable	VA	64 – 190	mg/AU-h	Takai et al	1998	1.5 - 4.6
Calves		on slats, inhalable	VA	63 – 192	mg/AU-h	Takai et al	1998	1.5 - 4.6
Dairy		on bedding, respirable	VA	6 – 84	mg/AU-h	Takai et al	1998	0.1 - 2
Dairy		free-stall, respirable	VA	13 – 54	mg/AU-h	Takai et al	1998	0.3 - 1.3
Beef		on bedding, respirable	VA	6 – 26	mg/AU-h	Takai et al	1998	0.1 - 0.6
Beef		on slats, respirable	VA	5 – 29	mg/AU-h	Takai et al	1998	0.1 - 0.7
Calves		on bedding, respirable	VA	14 – 40	mg/AU-h	Takai et al	1998	0.3 - 1
Calves		on slats, respirable	VA	14 – 22	mg/AU-h	Takai et al	1998	0.3 - 0.5
Poultry	Caged layers	winter, inhalable	VA	0.9	g/AU-h	Wathes et al	1997	22
Poultry	Caged layers	summer, inhalable	VA	1.1	g/AU-h	Wathes et al	1997	26
Poultry	Broilers	winter, inhalable	VA	5.2	g/AU-h	Wathes et al	1997	125
Poultry	Broilers	summer, inhalable	VA	8.2	g/AU-h	Wathes et al	1997	197
Poultry	Caged layers	winter, respirable	VA	0.24	g/AU-h	Wathes et al	1997	5.8
Poultry	Caged layers	summer, respirable	VA	0.09	g/AU-h	Wathes et al	1997	2
Poultry	Broilers	winter, respirable	VA	0.6	g/AU-h	Wathes et al	1997	14
Poultry	Broilers	summer, respirable	VA	0.88	g/AU-h	Wathes et al	1997	21
Poultry	Caged layers	Inhalable	VA	398 – 872	mg/AU-h	Takai et al	1998	9.6 - 21
Poultry	Broilers	on litter, inhalable	VA	1,856 - 6,218	mg/AU-h	Takai et al	1998	45 - 149
Poultry	Caged layers	Inhalable	VA	24 – 161	mg/AU-h	Takai et al	1998	0.6 - 3.9
Poultry	Broilers	on litter, inhalable	VA	245 – 725	mg/AU-h	Takai et al	1998	5.9 - 17.4

Table 4.27. Bioaerosol Emission Summary

Species	Species Phase	Notes	Unit	Bioaerosol Emission	Reported Units	Reference Source	Reference Year	VA mg /AU-day	VA Log CFU/AU -day
Pigs	Sows	average, inhalable endotoxin	VA	37.4	ug/AU-h	Seedorf et al	1998	0.9	
Pigs	Nursery	average, inhalable endotoxin	VA	66.6	ug/AU-h	Seedorf et al	1998	1.6	
Pigs	Finishing	average, inhalable endotoxin	VA	49.8	ug/AU-h	Seedorf et al	1998	1.2	
Pigs	Sows	average, respirable endotoxin	VA	3.7	ug/AU-h	Seedorf et al	1998	0.09	
Pigs	Nursery	average, respirable endotoxin	VA	8.9	ug/AU-h	Seedorf et al	1998	0.2	
Pigs	Finishing	average, respirable endotoxin	VA	5.2	ug/AU-h	Seedorf et al	1998	0.1	
Dairy		average, inhalable endotoxin	VA	2.9	ug/AU-h	Seedorf et al	1998	0.07	
Beef		average, inhalable endotoxin	VA	3.7	ug/AU-h	Seedorf et al	1998	0.09	
Calves		average, inhalable endotoxin	VA	21.4	ug/AU-h	Seedorf et al	1998	0.5	
Dairy		average, respirable endotoxin	VA	0.3	ug/AU-h	Seedorf et al	1998	0.007	
Beef		average, respirable endotoxin	VA	0.6	ug/AU-h	Seedorf et al	1998	0.01	
Calves		average, respirable endotoxin	VA	2.7	ug/AU-h	Seedorf et al	1998	0.06	
Poultry	Caged layers	winter, endotoxin	VA	10	g/AU-h	Wathes et al	1997	240000	
Poultry	Caged layers	summer, endotoxin	VA	30	g/AU-h	Wathes et al	1997	720000	
Poultry	Broilers	winter, endotoxin	VA	< 1	g/AU-h	Wathes et al	1997	< 24000	
Poultry	Broilers	summer, endotoxin	VA	45	g/AU-h	Wathes et al	1997	1080000	
Poultry	Caged layers	average, inhalable endotoxin	VA	538.3	ug/AU-h	Seedorf et al	1998	13	
Poultry	Broilers	average, inhalable endotoxin	VA	817.4	ug/AU-h	Seedorf et al	1998	20	
Poultry	Caged layers	average, respirable endotoxin	VA	38.7	ug/AU-h	Seedorf et al	1998	0.9	
Poultry	Broilers	average, respirable endotoxin	VA	46.7	ug/AU-h	Seedorf et al	1998	1.1	
Pigs	Sows	average, total bacteria	VA	7.7	Log CFU/AU -h	Seedorf et al	1998		185
Pigs	Nursery	average, total bacteria	VA	7.1	Log CFU/AU -h	Seedorf et al	1998		170
Pigs	Finishing	average, total bacteria	VA	7.6	Log CFU/AU -h	Seedorf et al	1998		182
Dairy		average, total bacteria	VA	6.8	Log CFU/AU -h	Seedorf et al	1998		163
Beef		average, total bacteria	VA	6.7	Log CFU/AU -h	Seedorf et al	1998		161
Calves		average, total bacteria	VA	7.3	Log CFU/AU -h	Seedorf et al	1998		175
Poultry	Caged layers	average, total bacteria	VA	7.1	Log CFU/AU -h	Seedorf et al	1998		170
Poultry	Broilers	average, total bacteria	VA	9.5	Log CFU/AU -h	Seedorf et al	1998		228

5.1 Introduction

A schematic of the fate and transport of air emissions from Confined Animal Feeding Operations (CAFOs) is given by Figure 1. Many sources contribute to the overall fugitive emissions from such operations: the animals themselves, their manure, manure applied to farm fields nearby, and waste lagoons. Emissions can be as particles or gases, and they may serve as reactants for aerosol formations (micron and submicron size solid and liquid suspensions).

Particles emitted from CAFOs that may cause problems include odorants, dusts, animal dander and other allergens. Generally, these are dispersed rapidly in the atmosphere by mixing processes and are deposited to the land surface.

Gases are also of concern. These may include odorants, hydrogen sulfide (H_2S), ammonia (NH_3), methane (CH_4) and other trace gas constituents. Some of these persist in the atmosphere for hours or days, and they may be transported hundreds of kilometers (Table 1). Ammonia and sulfur compounds from CAFOs participate in reactions that can form secondary particles and aerosols in the atmosphere. These may limit visibility, cause health effects to sensitive individuals, and be precursors of acid rain at a regional scale. Secondary particles include ammonium sulfate $(NH_4)_2SO_4$, ammonium bisulfate $(NH_4)HSO_4$, and ammonium nitrate NH_4NO_3.

Large amounts of manure at feedlots can undergo partial anaerobic degradation by bacteria to form gases such as methane (CH_4) and nitrous oxide (N_2O). These are potent greenhouse gases at a global scale, and they contribute a significant fraction of Iowa's greenhouse gas emissions to the global atmosphere.

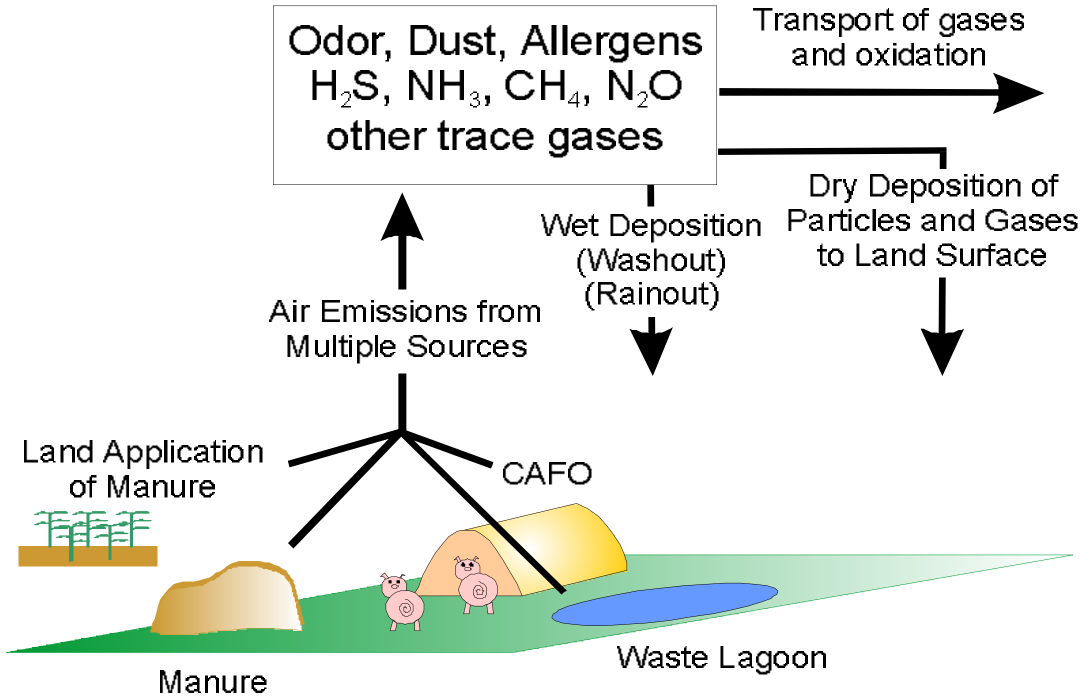

Figure 1. Fate and Transport of Air Emissions Associated with Confined Animal Feeding Operations

Table 1. Transport of Air Emissions Associated with Confined Animal Feeding Operations

	Local Scale		Regional to Global Scale	
	Short Range Transport (<10 km)	Fate Processes	Medium-to-Long Range Transport (10-1000 km)	Fate Processes
Particles	Odor (particles) Dust (animal Dander) Allergens	Dispersion Dry Deposition	Secondary Particle Formation (e.g., $(HN_4)_2SO_4$, NH_4NO_3, $(NH_4)HSO_4$, Aerosols)	Dispersion Dry Deposition Washout Rainout
Gases	Odor (gases) Dimethyl sulfide (DMS) Mercaptans	Dispersion Rapid Rxn.	Hydrogen Sulfide (H_2S) Carbon Disulfide (CS_2) Ammonia (NH_4) Sulfur oxides (SO_x) Methane (CH_4) Nitrous Oxide (N_2O)	Dispersion Rxn. with hydroxyl radicals Washout Dry Deposition

A simplified stoichiometric equation for the anaerobic digestion of manure is:

$$\underset{\text{“manure”}}{C_5H_7O_2NS_{0.5}} + 3.025\ H_2O \xrightarrow{\text{anaerobes}} 2.5125\ CO_{2(g)} + 2.4875\ CH_{4(g)} + NH_{3(g)} + 0.05\ H_2S_{(g)}$$

Four primary gases are formed including carbon dioxide, methane, ammonia, and hydrogen sulfide. These are the major constituents emanating from CAFOs, but they are not necessarily the most problematic. Hydrogen sulfide and ammonia are toxic to humans. However, odorants, dust, and allergens may cause greater nuisance problems for nearby citizens and communities.

The above chemical reaction may occur wherever manure is handled in large quantities. Piles of manure below CAFO gratings and in penned areas, manure that is improperly knifed (mixed) into soil on agricultural fields, and anaerobic waste lagoons can all produce these gases.

5.2 Sulfur Compounds

Confined animal feeding operations (CAFOs) produce significant amounts of reduced sulfur compounds (H_2S, mercaptans, carbon disulfide, dimethyl sulfide DMS, and others) from anaerobic microbial action on fecal matter on a local scale. Reduced forms of sulfur in the atmosphere are oxidized by hydroxyl radicals. For H_2S and DMS the reaction is reasonably fast with lifetimes in the troposphere (lower atmosphere) of 4.4 days and 0.6 days, respectively (Warnek, 1988). Thus, they can be transported tens or even hundreds of kilometers from the animal feeding operation prior to oxidation. A series of free radical reactions occurs for H_2S in the presence of hydroxyl radicals, formaldehyde, or ozone in the atmosphere.

$$\cdot OH + H_2S \rightarrow H_2O + HS\cdot$$

$$HS\cdot + HCHO \rightarrow H_2S + HCO\cdot$$

or

$$HS\cdot + O_3 \rightarrow HSO + O_2$$

The $HS\cdot$ radical does not build-up in the atmosphere, and it is thought that formaldehyde and ozone react with $HS\cdot$. Likewise, dimethyl sulfide (DMS) undergoes a series of free radical reactions beginning with the ubiquitous hydroxyl radical $\cdot OH$.

$$\cdot OH + CH_3SCH_3 \rightarrow CH_3S(OH)CH_3$$

$$CH_3S(OH)CH_3 + O_2 \rightarrow (O_2\text{ - DMS - }OH)\text{ complex}$$

$$\text{complex} \rightarrow \underbrace{CH_3(SO_3)H}_{MSA} + CH_3\cdot$$

Methane sulfonic acid (MSA) is a major product of the reaction between hydroxyl radicals and DMS. It is a condensable product that helps to form aerosol particles in the atmosphere (cloud condensation nuclei). But these reactions would occur far from the confined animal feeding operation at a regional or global scale.

Carbon disulfide (CS_2) also reacts rapidly with hydroxyl radicals in the atmosphere and has a lifetime of ~12 days which transports it hundreds of kilometers from the source (Warnek, 1988). Of course, the concentration dissipates quickly due to mixing (dispersion), dry deposition, and washout by precipitation.

$$\cdot OH + CS_2 \rightarrow SCSOH$$
$$SCSOH + O_2 \rightarrow COS + SO_2 + H$$

Carbonyl sulfide (COS) is slow to be oxidized. Its lifetime in the atmosphere is on the order of 44 years (Warnek, 1988). Carbonyl sulfide is transported and mixed at trace concentrations on a global scale.

$$\cdot OH + COS \rightarrow CO_2 + H_2S$$

Sulfur oxides can also be emitted from CAFOs , and/or they may form as an oxidation product of reduced sulfur emissions from CAFOs. Both gas and aqueous phase reactions are important in the oxidation of sulfur dioxide in the atmosphere. Oxygen and hydroxyl radicals can oxidize SO_2 to SO_4^{2-} in the gas phase, and humidity in the air (H_2O) can convert SO_3 to acidic aerosol particles.

$$SO_2 + \cdot OH \rightarrow HOSO_2 \xrightarrow{O_2} SO_3 + HO_2(\text{superoxide})$$
$$SO_3 + H_2O \rightarrow H_2SO_4 \text{ (aerosol)}$$

Aqueous phase reactions for SO_2 include reaction with ozone O_3 and hydrogen peroxide H_2O_2; both can be important depending on the concentrations of ozone and hydrogen peroxide in clouds.

$$SO_2 + H_2O \rightarrow SO_3^{2-} + 2H^+$$
$$SO_3^{2-} + O_{3(aq)} \rightarrow SO_4^{2-} + O_2$$
$$SO_3^{2-} + H_2O_{2(aq)} \rightarrow SO_4^{2-} + H_2O$$

Lifetimes for the above reactions in clouds are on the order of 1-50 days. Clouds process a tremendous amount of air and water vapor. They serve as a concentrating vortex for particles and gases that react with SO_2. These are all long-range transport processes that take place far from the original CAFO operation.

Most CAFO sulfur emissions are in the form of reduced sulfur species and SO_2. Sulfur falls back to earth (continents and oceans) in the form of $SO_{2(g)}$ (dry deposition), sulfate aerosols (H_2SO_4, $(NH_4)_2SO_4$ NH_4NO_3, $MgSO_4$, $CaSO_4$ in dry deposition), and sulfate ions (H_2SO_4 and $CaSO_4$ in wet deposition). Sulfate aerosols and cloud condensation nuclei play an important role as a negative feedback effect to global warming by increasing the earth's albedo on a global scale. $SO_{2(g)}$ results in H_2SO_4 (sulfuric acid) and acid deposition. However, emissions from CAFOs are very small compared to coal-fired power plants, smelters, industrial emissions, and even volcanoes. In Figure 2, CAFOs contribute negligible amounts of hydrogen sulfide H_2S, DMS, COS, and CS_2 to the global atmosphere; these gases are in turn oxidized to $SO_{2(g)}$ and eventually to sulfate, both of which are deposited to land and oceans.

Ammonia $NH_{3(g)}$ is a weak base that reacts with water to form ammonium and hydroxide ions in CAFO air. This increases the pH of water vapor in CAFO settings and helps to neutralize sulfuric acid from SO_2 emissions (Figure 3). When water is evaporated from the atmosphere, one of the principal salts that form as aerosols and causes decreased visibility is ammonium sulfate $(NH_4)_2SO_4$.

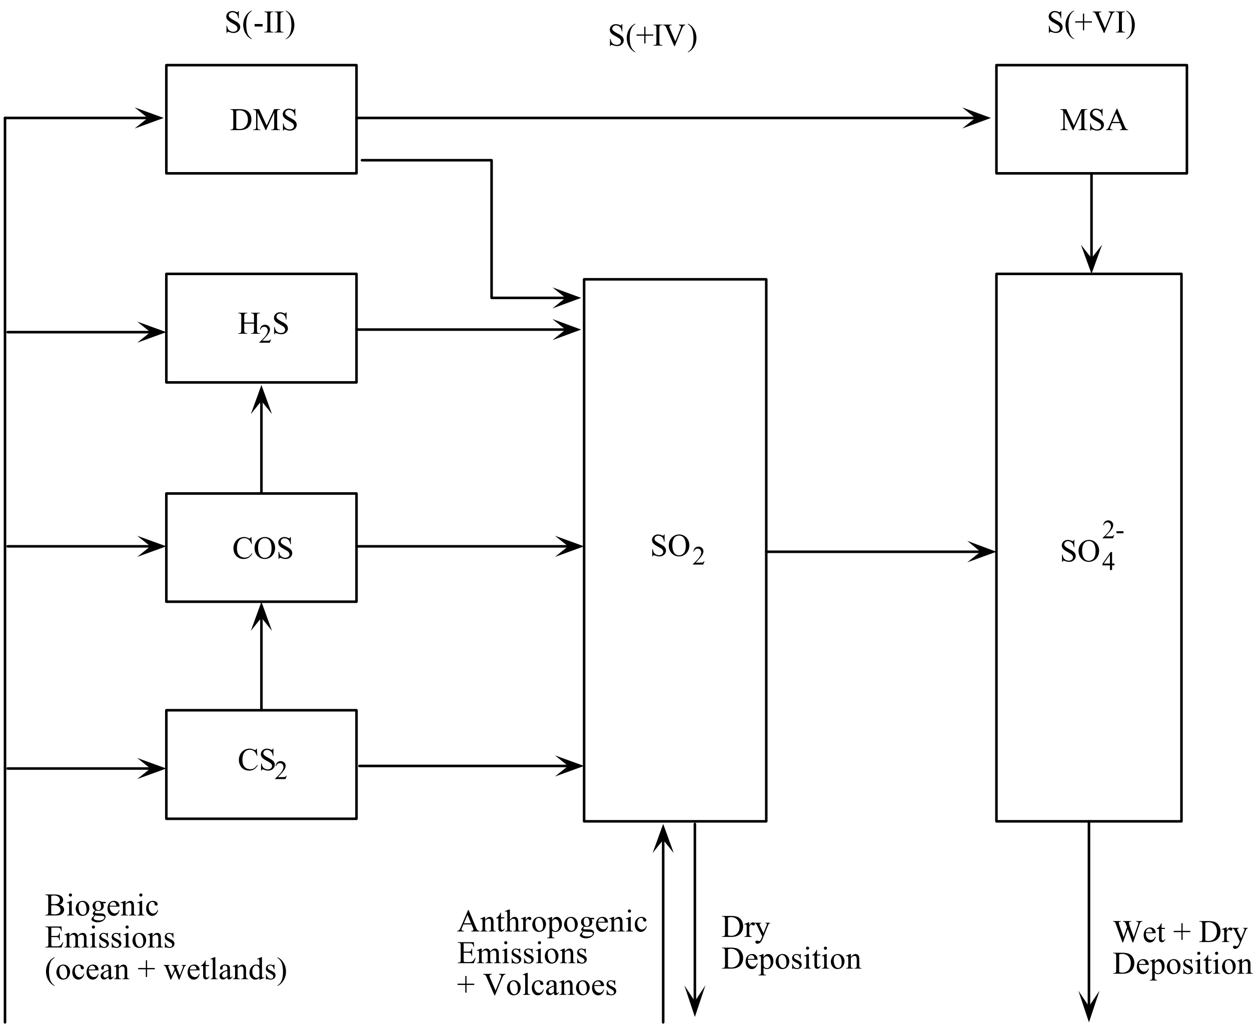

Figure 2. Global Reactions and Transport of Sulfur Species in the Atmosphere

The atmosphere is a small reservoir for sulfur species, only 4.6 x 10^{12} g-S resides in the atmosphere resulting in a mean residence time of only 4.9 days. SO_2 travels 500-2000 km by long range transport, but it does not accumulate in the atmosphere.

Table 2. Global Sulfur Budget[a] to and from the Atmosphere (from Schnoor, 1996)

Sources and Sinks	Tg-S yr^{-1}

[a]10^{12} g S yr^{-1} = 1 million metric tonnes = Tg-S yr^{-1}
[b]CAFO sources are negligible on a global scale

5.3 Methane and Nitrous Oxide, Greenhouse Gas Emissions

Trace gases in the atmosphere include methane (CH_4), and nitrous oxide (N_2O), a small amount which emanates from CAFO sources. Methane and nitrous oxide are potent greenhouse gases with radiative effects 25 and 200 times greater than carbon dioxide, respectively. The global budget for N_2O is the least well known, especially regarding its sinks. Sources include industrial emissions and incomplete combustion of fossil fuels, 1 Tg-N_2O/yr, and biomass burning ~1 Tg-N_2O/yr. Natural ecosystems emit 3-9 Tg-N_2O/yr as an intermediate oxidation state (leakage) from the nitrogen cycle. Fertilized fields are thought to emit up to ten times more N_2O/m^2 than nature. Thus, emissions of N_2O from farm fields receiving large amounts of manure application could be a significant source of N_2O emissions on a global basis. Deforestation and the opening of the soil nitrogen cycle after clear-cutting may account for another large source and, in addition, surface ocean waters could be emitting N_2O because they are ~4% supersaturated with N_2O. Since N_2O is increasing in the atmosphere at only 0.2%/yr, it is thought that there must be a large sink in the soil (oxidation-reduction reactions to $N_{2(g)}$ or $NO_{x(g)}$). Atmospheric sinks for N_2O include a slow oxidation with singlet oxygen to form NO.

Methane is another trace greenhouse gas that occupies 1.7 ppm by volume of the atmosphere. Anthropogenic sources of methane rival natural sources with flooded rice agriculture and ruminant animals as the largest sources (Table 2). Wetlands, including CAFOs and waste lagoons, emit large amounts of methane due to methanogenic conditions in anaerobic sediments and soils (Paterson, 1993). Methane reacts with hydroxyl radicals in the atmosphere as the principal sink. Eventually methane oxidizes to form CO_2, but the reactions are slow. Table 3 is a compilation of some trace gas reactions for carbon species in the atmosphere including methane assuming pseudo-steady state approximations. Methane reacts with ·OH to form formaldehyde, HCHO; and formaldehyde undergoes photolytic oxidation to form carbon monoxide, which eventually yields carbon dioxide. Methane has a long residence time in the atmosphere (5-10 years). Natural emissions of non-methane hydrocarbons (NMHC) are also important sources of formaldehyde and carbon monoxide to the atmosphere. They enter the photolytic cycle and participate in the formation of ozone and smog. NMHCs are primarily C_{10} and higher alkenes that are emitted by vegetation, such as terpene and isoprene. They are responsible for the haze found in the Smokey Mountains of Appalachia.

[a]CAFO sources are a moderate and increasing portion of methane emissions on a global scale.

Greenhouse gas emissions from agriculture compose about 21% of emissions from all sources in Iowa (Table 4). Capturing methane by anaerobic digestion of manure at large feedlots (CAFOs with more than 5000 animals) could reduce methane emissions by 700,000 tons CO_2 equivalents per year in Iowa, about 1% of total greenhouse gas emissions (Ney et al., 1996). Most of this reduction would be possible at large hog lots where 102,000 tons CH_4 per year (~250,000 tons CO_2 equivalents per year) are emitted due to the management of pig manure (Table 5).

Table 4. Greenhouse Gas Emissions from Iowa Agriculture and Total Emissions, Base Year 1990.

Iowa Source of Greenhouse Gas	Gas	Emissions (tons CO_2 equivalent/yr) 1990
Fossil Fuel Combustion On-farm	CO_2	2,540,000
Fertilizer use	N_2O	4,480,000
Manure Management	CH_4	2,590,000

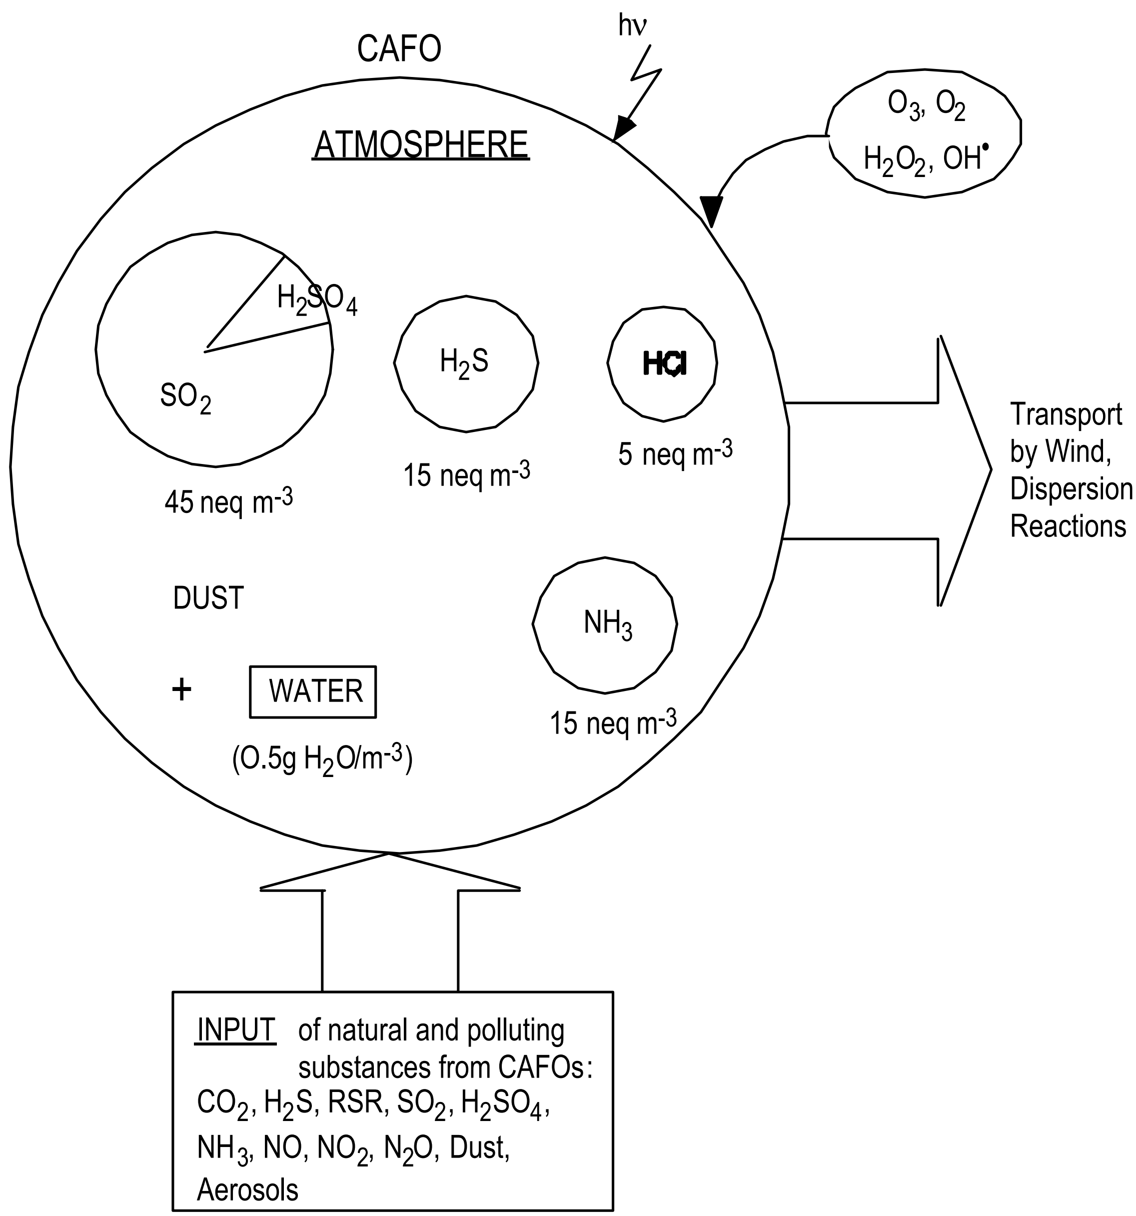

Figure 3. Air Emissions (Inputs) and Formation of Gas Composition in Vicinity of CAFOs.

Rain clouds process a considerable volume of air over relatively long distances and thus are able to absorb gases and aerosols from a large region. Because fog is formed in lower air masses, fog droplets are efficient collectors of pollutants close to the earth's surface. The influence of local emissions (such as NH_3 and H_2S from CAFOs) is reflected in the local fog composition. Fog waters typically contain total ionic concentrations of 0.5-15 meq/ℓ. Remarkably different pH values can be observed in fog. In addition to neutral fogs (pH 5-7) – some of which have very high anion concentrations – other fogs contain acidity (Sigg and Stumm, 1989). Ammonia emissions from feedlots may cause alkaline fog waters. As the fog evaporates, it can decrease visibility (haze) by formation of aerosols, especially ammonium nitrate and ammonium sulfate aerosols.

5.4 Wet and Dry Deposition

Wet deposition occurs when pollutants fall to the ground or water surface by rainfall, snowfall, or hail/sleet. *Dry deposition* is when gases, particles, and aerosols are intercepted by the earth's surface in the absence of precipitation. Wet deposition to the surface of the earth is directly proportional to the concentration of pollutant in the rain, snow, or ice phase.

Wet deposition flux is defined by equation (1) below

$$F_{wet} = IC_w \tag{1}$$

where F_{wet} is the areal wet deposition flux in $\mu g/cm^2$-s, I is the precipitation rate in cm/s (as liquid H_2O), and C_w is the concentration of the pollutant associated with the precipitation in $\mu g/cm^3$. Wet deposition is measured with a bucket collector and a rain gauge. The rain gauge is placed at the receptor site and provides an accurate measure of precipitation rate, I. The wet bucket collector is open only during the precipitation event, and its contents are analyzed for pollutant concentration, C_w.

The concentration of pollutants in wet deposition is due to two important effects with quite different physical mechanisms:

- aerosol particle scavenging
- gas scavenging

Aerosols begin their life cycle after nucleation and formation of a submicron hygroscopic particle, e.g., $(NH_4)_2SO_4$, which hydrates and grows very quickly due to condensation of water around the particle. At this stage, it is neither solid nor liquid, but merely a stable aerosol with a density between 1.0-1.1 g/cm^3. Mass quantities of air are processed by clouds, creating updrafts which cleanse the air of pollutants. Cloud droplets are very small, on the order of 10 μm in diameter. Typically one million cloud droplets are needed to comprise a 1 mm diameter raindrop. Assuming an average spacing of 1 mm between cloud droplets, condensation of 10^6 cloud droplets into a 1 mm raindrop would scavenge enough air for a washout ratio of 10^6.

$$W = \frac{C_w}{C_{ae}} \tag{2}$$

where C_w is the concentration of the pollutant in precipitation water in $\mu g/cm^3$, C_{ae} is the concentration of the pollutant associated with aerosol droplets in air in $\mu g/cm^3$, and W is the washout ratio for aerosols, dimensionless (cm^3 air/cm^3 precipitation).

Details of the physics of the scavenging process are beyond the scope of this report, but reference texts include Schwartz and Slinn (1992), and Pruppacher *et al.* (1983), and Eisenreich (1981). Because clouds process such large quantities of air and pull-up polluted air from the surface, washout is caused predominantly by in-cloud processes. Washout ratios for particles are typically on the order of 10^5-10^6. In other words, they are removed rapidly by cloud processes and/or rained-out efficiently. *Rainout* sometimes refers to below-cloud processes, whereby pollutants are scavenged as raindrops fall through polluted air.

Washout for gas scavenging operates by a different mechanism than aerosol particle scavenging. Here, Henry's law is applicable because chemical equilibrium for absorption processes in the atmosphere is on the time scale of one second. Gas scavenging, therefore, is reversible, while aerosol scavenging is an irreversible process. Ammonia is quite efficiently scavenged by washout processes and absorbed into the aqueous phase of water vapor or precipitation where it forms ammonium ions, NH_4^+. Hydrogen sulfide is less efficiently scavenged.

If we express Henry's constant K_H in units of M atm^{-1}, the following equations apply for Henry's law and the washout ratio.

$$C_w = K_H \, p_{atm} \tag{3}$$

$$W = \frac{C_w}{C_g} = K_H RT \tag{4}$$

where C_w is the concentration in the water phase (M), p_{atm} is the atmospheric partial pressure (atm), W is the washout ratio (dimensionless, i.e., ℓ H_2O/ℓ gas), C_g is the concentration in the gas (mol/ℓ gas) and RT is the universal gas law constant times temperature (24.46 atm/M at 25°C).

Some estimates for washout ratios of ammonia gas and selected pesticides are presented in Table 6. Henry's constants are provided in Schwarzenbach *et al.* (1993). In general, washout ratios are large for soluble and polar compounds, intermediate for semi-volatiles (such as DDT, dieldrin, dioxin, and PCBs), and low for volatile organic chemicals. Semi-volatile pollutants are an interesting case because these gases can be transported long distances and recycled many times before being deposited in polar regions by a "cold-trap" effect. Although washout ratios of gases by snow are smaller than by rain, there can be appreciable liquid water contained in snow that absorbs gases. Adsorption of gases to snowflake surfaces can also be significant.

The washout ratio does not give enough information to calculate the mass of pollutant in a column of air that is actually "washed-out" by rain, but such information is provided in reference texts such as Schnoor (1996).

Dry deposition takes place (in the absence of rain) by two pathways.

- aerosol and particle deposition
- gas deposition

There are three resistances to aerosol and gas deposition: 1) aerodynamic resistance, 2) boundary layer resistance, and 3) surface resistance. Aerodynamic resistance involves turbulent mixing and transport from the atmosphere (~ 1 km elevation) to the laminar boundary layer in the quiescent zone above the earth's surface. Boundary resistance refers to the difficulty of pollutant transport through the laminar boundary layer, and surface resistance involves the physical and chemical reactions that may occur at the surface of the receptor (sea surface, vegetation, snow surface, etc.). Dry deposition velocity encompasses the electrical analog of these three resistances in series

$$V_d = \frac{1}{r_a + r_b + r_s} \quad (5)$$

where V_d is defined as the dry deposition velocity (cm/s), r_a is the aerodynamic resistance, r_b is the boundary layer resistance, and r_s is the resistance at the surface.

Table 6. Estimates of Washout Ratios for Selected Gases, 25˚C (Schnoor, 1996)

Chemical	Henry's Constant K_H, M-atm^{-1}	Washout Ratio $W = K_H RT^*$
ammonia	63	1,500
aldrin	100	2,450
benzene	0.18	4.4
benzo(a)pyrene	830	20,300
CCl_4	0.042	1.0
dioxin	20	490
DDT	105	2,570
dieldrin	89	2,200
di-n-butyl phthalate	780	19,000
methane	0.0015	0.037
naphthalene	2.3	56
parathion	2,630	64,000
trichloroethene	0.093	2.3
toluene	0.15	3.7
2,2',5,5'-PCB	3.5	86

* RT = 24.46 atm/M at 25˚C

The deposition velocity is affected by a number of factors including relative humidity, type of aerosol or gas, aerosol particle size, wind velocity profile, type of surface receptor, roughness factor, atmospheric stability, and temperature. V_d increases with wind speed because sheer stress at the surface causes increased vertical turbulence and eddies. A summary of dry deposition measurements and a comparison of collector surfaces are given by Davidson and Wu (1990).

For aerosol particles, the deposition velocity is dependent on particle diameter. A minimum deposition velocity (~10^{-2} cm/s) exists for fine aerosol particles in the size range from 0.1-1.0 μm. Larger particles are deposited much more rapidly.

In reality, aerosols change constantly due to changes in relative humidity; they evaporate or condense into water continually. The mass median diameter (MMD) is a measure of the particle size distribution. Milford and Davidson (1985) showed a general power-law correlation for the dependence of V_d on particle size

$$V_d = 0.388\ MMD^{0.76} \quad (6)$$

where V_d is the deposition velocity in cm/s and MMD is the mass median diameter of the particle in μm. Table 5 is a compilation of dry deposition velocities for chemicals of interest from Davidson and Wu (1990).

In general, gases that react at the surface (e.g., H_2S, SO_2, HNO_3, HCl, and O_3) tend to have slightly higher deposition velocities, on the order of 1.0 cm/s. HNO_3 vapor has a very large deposition velocity because there is no surface resistance -- it is immediately absorbed and neutralized by vegetation and/or water. Some gases such as NO_x display higher V_d values in daylight because vegetation transpires at that time, and gas exchange through the stomata serves to increase the concentration gradient and the flux at the leaf surface.

The receptor surface is critical. Deposition velocities in Table 7 are mostly to natural earth surfaces. Surrogate surfaces tend to underestimate the actual dry deposition because of differences in reactivity at the surface, differences in surface area, and aerodynamic differences around the collector. Natural vegetation and trees are relatively efficient interceptors of gases and particles based on specific surface areas. SO_2 dry deposition velocity for a coniferous forest may be several times higher than for an open field or a snow field. Buffer strips of trees around CAFOs could intercept and remove some of the gases and particles by dry deposition.

Table 7. Dry Deposition Velocities for a Number of Aerosol Particles and Gases

Pollutant	V_d, cm/s^{-1} Typical Range	V_d, cm/s^{-1} Typical Median	Conditions
$SO_2(g)$	0.3-1.6	0.95	to natural vegetation
	0.04-0.22	0.13	to snow field
SO_4^{2-}	0.01-1.2	0.55	submicron aerosols in field (micrometeorological)
	0.01-0.5	0.26	to surrogate surfaces
NO_3^-	0.1-2.0	0.7	aerosol particle deposition
NH_4^+	0.05-2.0	0.8	aerosol particle deposition
$HNO_{3(g)}$	1-3	1.4	gas, no surface resistance
$NO_{x(g)}$	0.01-0.5	0.05	night, closed stomata
	0.1-1.7	0.6	day, open stomata
Cl^-	1-5	2	particles, MMD = 1-4 μm
$HCl_{(g)}$	0.6-0.8	0.7	sorption by dew
$O_{3(g)}$	0.01-1.5	0.4	by measured gradients
Pb	0.1-1.0	0.26	aerosol particle deposition from autos MMD < 1 μm
Crustal metals (Ca, Mg, K, Fe, Mn)	0.3-3.0	1.5	associated w/coarse particles MMD = 1-4 μm
Enriched (anthropogenic metals-Ag, As, Cd, Cu, Zn, Pb, Ni)	0.1-1.0	0.3	assoc. w/fine particles, enriched MMD < 1 μm
Fine Particles	0.1-1.2	0.4	submicron particles

6.1 Abstract - Toxicology

Valid evaluation of the health effects of airborne substances released from animal production units should be based on the important and well-established toxicological principles of dosage and response. Dosage is the most important factor that determines response to poisons. Toxicity is the quantitative amount of toxicant required to produce a defined effect, but the hazard or risk of toxicosis depends not only on the inherent toxicity of the agent, but on the probability of exposure to the toxicant under conditions of use. Acute, subacute, and chronic toxicity are different chronological quantitations of chemical toxicity and are determined by relative dosage and time of exposure. Many factors can alter animal or human response to toxicants, including those inherent in the toxicant, the organism, the environment and the combinations of these major factors. Toxicological evaluation depends heavily on determination of exposure and evidence for the contribution of interacting factors that can alter toxicity. Quantitative expressions of toxicity and exposure are essential for thorough toxicological evaluation and prognosis.

Response to exposure by airborne toxicants is likely to involve the respiratory system because it is a portal of entry. Study of CAFO issues suggests consideration of the mechanisms of injury by volatile agents and particulates, as well as understanding the potential effects of both acute and chronic exposure. Respiratory system effects are manifest in relatively limited ways (bronchoconstriction, pulmonary edema, asthma, carcinogenesis), and careful attention must be given to evidence for cause and effect from among a wide range of insults and levels of exposure. Similar considerations are important for systemic effects that are manifested in other parts of the body.

Laboratory animals are often as experimental models of human disease to help establish the mechanism of action and the correlation between exposure levels of airborne toxicants and clinical response. Clinical response to these pollutants depends not only on the concentration of the specific compound, but also the frequency and duration of exposure.

Studies of aerial ammonia in laboratory animals have demonstrated dose-effect and duration-effect patterns for damage to the respiratory tract similar to that observed in humans. Acute exposures to moderate concentrations of ammonia irritate the upper respiratory tract. Prolonged or repeated exposures to lower levels of ammonia produce inflammation and lesions of the respiratory tract. Exposures to high concentrations of ammonia result in severe damage to the upper and lower respiratory tract and alveolar capillaries.

Controlled studies with hydrogen sulfide in laboratory animals have shown that levels of 500 ppm or greater are likely to be lethal, similar to the response observed in humans. Exposure to sub-lethal levels of hydrogen sulfide have produced progressive effects ranging from increased respiratory rate, to pulmonary edema, to histopathological changes in the nasal cavity and lung tissue.

Endotoxins, glucans, and microorganisms maybe important components of bioaerosols associated with animal production units. Inhalation of these compounds have been shown to produce respiratory system effects including airway constriction and obstructive breathing pattern, inflammatory tissue responses, and overt infection of lung tissue.

6.1 Toxicology

6.10 Overview of Toxicology

Toxicology is the study of poisons, and their effects on living organisms. This includes an understanding of sources of poisons, circumstances of exposure, their effects, diagnosis and treatment and the application of management or educational strategies to prevent poisoning. More than many of the specialties in veterinary medicine, toxicology is based on the important principle of dose and response. Response is dependent not only on presence of a potential toxicant but on the amount of exposure as well.(Osweiler, 1996) With emphasis in this report on accountability of Concentrated Animal Feeding Operations (CAFOs) for substances released from animal production units, there is increasing need to be aware of and apply the dosage and response principle to best estimate the need for regulation or remediation.

Determinants of exposure that affect dosage may be more than simply the gross amount of material with access to animals or man. Rather, the effective dosage at a susceptible receptor site determines the ultimate response. Thus, environmental factors that influence exposure, species differences in organisms within an exposure area, vehicle differences that affect absorption, specific drug or chemical interactions that potentiate response, and organ dysfunction that limits elimination may all be factors which influence the ultimate dosage and the outcome of exposure. (Osweiler, 1996)

Toxicological Principles Of Evaluation For Cafo Issues

A **poison** or **toxicant** is any natural or synthetic solid, liquid or gas that when introduced into or applied to the body can interfere with homeostasis of the organism or life processes of cells of the organism by its own inherent qualities, without acting mechanically and irrespective of temperature. For CAFOs, toxicants considered are natural products that would normally be handled by ecological assimilation, but may be locally in unnatural or excessive concentration. Knowledge of the chemical nature and specific effects of toxicants and their combinations is the only certain way to assess hazard from such exposure. Suggestions about potential adverse effects of natural products from livestock waste may be gained from comparative experimental studies, from know effects of substances at high concentrations within CAFOs, and from well-controlled and properly interpreted epidemiological studies. This chapter will review the known biological effects of compounds identified in CAFOs, and will also present evidence gained from epidemiological studies.

Toxicological conventions should be followed in assessment of risk to different populations. **Toxicity** is the quantitative amount or dosage of a poison that will produce a defined effect. For example, the acute lethal dosage of hydrogen sulfide to swine could be described as a **concentration** in air, e. g. 1,000 parts-per-million or as the equivalent amount on a body weight basis. Toxicity values do not describe the biological effects, but only the quantitative amount (dosage) required to produce a defined effect (e.g. death, respiratory distress, immune suppression, etc). **Dosage** is the correct terminology for toxicity expressed as amount of toxicant per unit of body weight. Commonly accepted dosage units are mg/kg body weight or moles or micromoles of agent/per kg body weight. In comparative toxicology, relative effects in large and small animals relate dosage to the body surface area, which is approximately equal to (body weight) $^{2/3}$. This relationship, and others relevant to interspecies comparisons, should always be considered when comparing laboratory or farm animal toxicity data against risk for humans. Generally, as animals increase in weight, the body surface area increases proportionally less, and this may affect the rate of metabolism, excretion and receptor interaction with toxicants. For many toxicants, larger animals will be poisoned by relatively lower body weight dosages than are smaller mammals. (Eaton and Klaassen, 2001; Osweiler, 1996)

From a public health and diagnostic toxicology perspective it is essential to know what exposure level will not cause any adverse health effect. This level is usually referred to as the "no observed adverse effect level" (NOAEL). (Eaton and Klaassen, 2001) Usually a NOAEL in laboratory animals is based on chronic exposures ranging from ninety days to two or more years depending on the species. The inhalation toxicity for gases or aerosols, including particulates, is often expressed as the concentration of material (i.e. the weight of compound per volume or weight of air). The no-effect level is the largest dosage or concentration that does not result in detrimental effects. In industrial hygiene, the concept of protecting human health from exposure is quantified to an assumed normal work day exposure and given a value called the Threshold Limit Value (TLV), which includes a safety factor between exposure allowed and concentrations where adverse effects may be expected.

Response to Toxicants

Toxicant evaluation is usually classified according to chronological scale that accounts for both dosage and response. **Acute toxicity** refers to effects of a single dose or multiple doses measured during a twenty-four-hour period. Toxic effects apparent over a period of several days or weeks are classified as **subacute**. **Subchronic** toxicity refers to toxic effects that occur between 30 days and ninety days exposure. **Chronic** effects are those produced by prolonged exposures of three months to a lifetime. Chronic effects are affected by the cumulative tendencies of the toxicant. The ratio of the acute to chronic LD_{50} dosage is called the **chronicity index**. (Eaton and Klaassen, 2001) Compounds with strong cumulative properties have larger chronicity index. The potential for individual products from CAFOs to cause cumulative effects should include evaluation of their cumulative potential or chronicity index. Conversely, organisms may develop **tolerance** for a compound such that repeated exposure increases the size of the dose required to produce lethality. For example, the single dose LD_{50} of potassium cyanide in rats is 10 mg/kg, while rats given potassium cyanide for ninety days are able to tolerate a dosage of 250 mg/kg without lethality.

Toxicity and Risk

The concept of risk or hazard is important to toxicology. While toxicity defines the amount of a toxicant that produces specific effects at a known dosage, hazard or risk is the probability of poisoning under the conditions of expected exposure or usage. Compounds of high toxicity may still present low hazard or risk if exposure to the toxicant is limited. CAFO risk evaluation should include estimation of dosage at remote or off site locations, and measurement or estimation of exposure at such locations is essential. Factors discussed in previous chapters relating to dispersion and dilution in the environment are essential in estimating the risk for a compound, even if it is of high inherent toxicity. Moreover, binding of toxicant gases to particulates may either reduce or increase their toxic properties so that risk is a function of all factors and interactions.

Factors That Affect Response To Toxicants

Many factors inherent in the toxicant, the animal or the environment can alter a toxicity value determined under defined experimental conditions. The toxicity of a compound may vary with the route of exposure. Usual routes of exposure to environmental agents are oral, dermal and inhalation. Gases are absorbed directly through pulmonary membranes, but aerosols including dusts may be deposited in lower airways or lungs if they are in a range between 0.1 and 5.0 um. Systemic retention occurs when macrophages laden with particles gain access to the pulmonary lymphatic drainage. Retention of inhaled particles in the gastrointestinal tract can occur when large particles trapped by cilia and mucus in the nasopharynx and trachea are swallowed. (Eaton and Klaassen, 2001)

Many environmental and physiological factors can influence the toxicity of compounds, and such factors, or others possibly unknown, can substantially influence response to toxicants. Accurate evaluation of CAFO risk to both on-site and off-site persons must consider multiple factors and their interactions to properly support regulatory and remedial activity. Some examples of factors that alter response to toxicants are presented in Table 1

TABLE 1. SELECTED FACTORS THAT MAY ALTER RESPONSE TO TOXICANTS	
Alteration or Change	**Mechanism or Example**
Changes in chemical composition or salts of inorganic agents	Toxicity of metals may be altered by valence state. Sodium salts are more water soluble than parent compounds, promoting absorption.
Instability or decomposition of chemical	Volatile compounds can decompose or change to more toxic form upon exposure to sunlight, as with nitrogen and nitrogen oxides.
Ionization	Generally, compounds that are highly ionized are poorly absorbed and thus less toxic. The pH of the source of pit gases may influence ionization of some products.
Vehicle effects	Non-polar and lipid soluble vehicles usually increase toxicity of toxicants by promoting absorption and membrane penetration.
Protein binding	Binding to serum albumin is common for many drugs and toxicants, limiting the bioavailability of the agent and reducing toxicity.
Chemical or drug interactions	Chemicals may directly bind, inactivate or potentiate another. One chemical may also induce microsomal enzymes to influence the metabolism of another.
Biotransformation	Prior exposure to the same or similar chemical may induce increased metabolic activity of microsomal mixed function oxidases (MFOs). Foreign compounds activated by MFOs can then be conjugated by Phase II metabolism and excreted. If toxicants are activated by MFO activity, then toxicity may be increased. Liver disease, very young or very old animals, and specific breeds or strains of animal can alter ability of MFO to begin metabolism followed by Phase II

	detoxification of foreign compounds.
Liver disease	Reduced synthesis of conjugating or binding agents (glutathione, metallothionein), essential proteins and coagulation factors may alter response to absorbed chemicals.
Nutrition and diet	Vitamin C and vitamin E can aid in scavenging of free radicals and repair of cellular protective mechanisms.

Respiratory System Response to Injury

Response of airways and lung to injury is dose dependent and expressed in chronological terms as acute, subacute or chronic. Response of the respiratory tract to toxicants is manifest in relatively few ways in response to many different chemicals, and a few specific mechanisms of injury are known. (Haschek and Rousseaux, 1998; Witschi, 2001)

Mechanisms of Respiratory System Injury

Respiratory damage depends on relatively few recognized molecular and cellular mechanisms that account for a wide variety of toxicant exposures. Many recognized effects are related to the oxidative burden imposed on the respiratory tract. (Witschi, 1997) This includes generation of unstable and reactive free radicals that lead to oxidative chain reactions and subsequent cellular damage or destruction. Cellular injury then results in release of microsomes and flavoproteins, neutrophils, moncytes and macrophages that can sustain the conversion of molecular oxygen to reactive oxygen metabolites. Many of these effects are an excessive response to what is a normal respiratory defense mechanism against microorganisms and low- or high-molecular-weight antigenic materials. Immunologic consequences are triggered when foreign materials in the respiratory tract sensitize the lung or airways to further exposure of the same material. (Witshci, 2001). Further consequences of oxidative damage or covalent binding in the pulmonary systems can result from damage and cross linking of DNA with potential subsequent development of carcinogenesis. The consequences of these mechanisms can be acute or chronic respiratory damage and the physiological dysfunction that accompanies each.

Acute Respiratory Injury

Acute airway damage in the transport passages (nasopharynx, trachea, bronchi, bronchioles) is reflected as bronchoconstriction and/or excess or reduced mucus and ciliary function. (Haschek and Rousseaux, 1998; Witschi, 2001). Response to irritants in nasal passages can cause acute or chronic rhinitis or, at higher concentrations, pause in respiration which develops as a reflex protective mechanism. Autonomic nervous system response to irritants is associated with acute reflex contraction of trachea and bronchi, resulting in decreased airway diameter and increased resistance to air flow. This results in wheezing, coughing, dyspnea and reduced exercise tolerance. This response is most likely triggered by irritant gases with moderate water solubility. Effects of short-term exposure resolve quickly when the irritant gas is no longer present and if no permanent cellular damage has occurred; long-term exposure may lead to chronic effects.

Acute lung damage can result in two major effects on lung tissue. Toxic pulmonary edema, which is characterized by alveolar or interstitial fluid accumulation and a thickened alveolar-capillary interface results in reduced oxygen and carbon dioxide exchange. Highly water-soluble irritant gases, including ammonia and hydrogen sulfide, which reach the lung parenchyma can damage cellular membranes and allow fluid leakage leading to pulmonary edema. Inflammatory response and cellular accumulation may accompany the edema and, if severe, result in prolonged changes including fibrogenesis. Acute alveolar endothelial damage and necrosis stimulates Alveolar Type II cell proliferation. These cells are physically thicker than Type I cells, and as immature replacements of Type I cells (alveolar endothelium) markedly reduce oxygen and carbon dioxide exchange (Witschi, 2001).

Chronic Respiratory Injury

Chronic response to injury may come from excessive and prolonged acute injury or from low-level or subclinical damage. In either event, manifestation is commonly as fibrosis or other chronic inflammatory change, emphysema, asthma or carcinogenesis.

Fibrosis is the result of excessive production of collagen in lung parenchyma and can occur at the alveolar, alveolar duct and bronchiolar levels. Type I and III collagen constitute approximately 90 percent of lung collagen. Increases in collagen, especially Type I, increase stiffness of the lung and reduce compliance, with severe fibrosis resulting in reduced vital capacity and reduced exercise tolerance.

Emphysema is characterized by "abnormal enlargement of the airspaces distal to the terminal bronchiole, accompanied by destruction of the walls, without obvious fibrosis". (Snider et al, 1985) Emphysema arises from interference with or lack of alpha$_1$-antiprotease, leading to loss of pulmonary elastin and subsequent alveolar wall breakdown. This leads to reduced alveolar surface and hyperinflation of alveoli and lungs with excessive compliance.

Asthma is characterized by increased airway activity with excessive contraction of large airways in response to irritants. Effects may be initiated by exposure to antigens or by chemicals that serve as haptens, with contributing influences by inflammatory cells and cytokines (Barnes et al 1998). Effects are mild to severe dyspnea, which can be acute, recurring and influenced by inhalation of a variety of pollutants (Witschi, 2001).

Respiratory carcinogenesis, especially lung cancer in humans is common and associated with environmental, industrial and personal exposures to a variety of chemicals. For most lung cancers, there is likely a dose-response relationship but clinical disease is often manifested later in life after long-term exposure. Animal studies are helpful in definition of mechanisms and in selected dose-response considerations. However, animal studies are important to intepret carefully in the context of significant differences in laboratory animal susceptibility and for the dosages used in experimental studies compared to ambient exposures of human populations (Hahn, 1997; Malkinson, 1998).

Systemic Effects of Airborne Toxicants

Airborne toxicants can affect systems other than or in addition to the respiratory tract. Lung is an efficient absorption organ and readily transports volatile compounds to the systemic circulation. Neurological and immune system consequences may occur secondary to inhalation exposure. A limited amount of xenobiotic metabolism is possible in lung, so that some bioactivation of toxicants can occur upon first pass pulmonary absorption. Effects of absorbed volatile agents will depend on the eventual target organs and susceptible receptors. These specific effects in target tissues and organs will be discussed in detail in subsequent sections of this chapter.

6.1.1 Toxicology of ammonia

Experimental studies indicate that the concentration of aerial ammonia which is acutely lethal to laboratory animals is dependent on the duration of the exposure. The lethal concentration of ammonia in rats and mice increases 5-10 times as the duration of exposure decreases from 16 hours to several minutes (Hilado et al. 1977; Kapeghian et al. 1982; Weedon et al. 1940). Exposure frequency also appears to be an important factor in determining lethality. Continuous exposure to 653 ppm of ammonia for 25 days resulted in nearly 64% lethality in rats, whereas intermittent exposure to nearly twice this concentration was tolerated for 42 days (Coon et al. 1970). It also appears that male rats are more sensitive than female rats to the lethal effects of aerial ammonia (Appelman et al. 1982).

Studies in laboratory animals have demonstrated dose-effect and duration-effect patterns for damage to the respiratory tract similar to that observed in humans. Acute exposures to moderate concentrations of ammonia ($\leq$1000 ppm) irritate the upper respiratory tract, whereas exposures to high concentrations ($\geq$4000 ppm) result in severe damage to the upper and lower respiratory tract and alveolar capillaries (Coon et al. 1970; Kapeghian et al. 1982; Mayan and Merilan 1972; Richard et al. 1978a,b; Schaerdel et al. 1983). Prolonged or repeated exposures to lower levels of ammonia ($\geq$150 ppm) produce inflammation and lesions of the respiratory tract (Broderson et al. 1976; Coon et al. 1970).

No overt symptoms of neurological disorders were reported in guinea pigs or monkeys that were exposed to up to 1105 ppm ammonia for 6 weeks (Coon et al. 1970). However, acute exposure to low levels of ammonia (100 ppm) has been shown to depress free-access wheel running behavior in rodents (Tepper et al. 1985). This may represent avoidance of sensory or upper airway irritation, but these same effects can be seen after injection of ammonium salts.

6.1.2 Toxicology of hydrogen sulfide

Controlled studies using dogs, rats, mice, and rabbits exposed acutely to high concentrations of hydrogen sulfide gas for various periods of time have shown that levels of 500 ppm or greater are likely to be lethal, similar to the response observed in humans exposed to high levels (Beck, 1979; Elovaara, 1978; Higuchi and Fukamachi, 1977; Haggard, 1922; Lopez,1987,1988a,1988b,1989; Kage, 1992; Khan, 1990; Prior, 1988, 1990; Savolainen, 1980; Smith and Gosselin, 1964; Tansy,1981).

In addition to an increase in respiration rate that was noted in rats exposed to 100-200 ppm hydrogen sulfide for 1 hour (Higachi and Fukamachi, 1977), a number of histological and biochemical changes were noted in the respiratory tissues and fluids of rats acutely exposed to 200, 300 or 400 ppm hydrogen sulfide for 4 hours (Lopez, 1987; Green,1991). Histopathological changes were reported in the nasal cavity of rats exposed to greater than 200 ppm hydrogen sulfide for 4 hours (Lopez, 1988b). Moderate-to-massive pulmonary edema was evident in rats exposed to 375 ppm hydrogen sulfide for 4 hours (Prior, 1990), and slight pulmonary congestion was found in rats exposed to 75 ppm hydrogen sulfide for 1 hour (Kohno, 1991). Significant decreases in numbers of viable pulmonary alveolar macrophages were noted in the lung lavage fluid of rats exposed for 4 hours to 400 ppm hydrogen sulfide (Khan, 1991).

The effects of intermediate-duration exposures to hydrogen sulfide have been examined in rats, mice, and pigs. Respiratory effects were not observed in two strains of rats exposed to hydrogen sulfide at concentrations up to 80 ppm 6 hours/day, 5 days/week, for 90 days (CIIT 1983b, CIIT

1983c). In contrast to rats, inflammation of the nasal mucosa described as minimal to mild was observed in mice exposed to hydrogen sulfide at 80 ppm (CIIT 1983a). Respiratory effects were not observed at 30.5 ppm. No mortality was noted during 90-day studies in which rats and mice were exposed for 6 hours/day, 5 days/week, to up to 80 ppm hydrogen sulfide (CIIT 1983b, 1983c). (CIIT 1983a).

Guinea pigs exposed daily to 20 ppm of hydrogen sulfide for 11 days developed fatigue, somnolence, and dizziness (Haider, 1980). Neurochemical analyses revealed decreased cerebral hemisphere and brain stem total lipids and phospholipids. Lethargy was observed in rats following exposure to 400 ppm of hydrogen sulfide for 4 hours (Lopez, 1988b).

Rats were exposed to average concentrations of 100-200, 200-300, 300-400, or 400-500 ppm hydrogen sulfide; at 200-300 ppm, a decreased response rate in a discriminated avoidance task was observed (Higuchi and Fukamachi, 1977). Except at the highest concentrations tested, the response rates and percent avoidances recovered rapidly when ventilation with clean air was provided, although even at 400-500 ppm, they were almost normal the following day. When these same animals were tested for Sidman-type conditioned avoidance response at response-shock intervals of 10 or 30 seconds, an inverse relationship between hydrogen sulfide concentration and response rate was noted; this effect dissipated when exposure stopped (Higuchi and Fukamachi 1977). Excitement was observed when mice were exposed to 100 ppm of hydrogen sulfide for 2 hours at 4-day intervals (Savolainen, 1980). Exposure also resulted in decreased cerebral ribonucleic acid (RNA), decreased orotic acid incorporation into the RNA fraction, and inhibition of cytochrome oxidase. An increase in the glial enzyme marker, 2',3'-cyclic nucleotide-3'-phosphohydrolase, was seen. Neurochemical effects have been reported in other studies. Decreased leucine uptake and acid proteinase activity in the brain were observed in mice exposed to 100 ppm hydrogen sulfide for 2 hours (Elovaara, 1978). Inhibition of brain cytochrome oxidase and a decrease in orotic acid uptake were observed in mice exposed to 100 ppm hydrogen sulfide for up to 4 days (Savolainen, 1980).

The intermediate-duration effects of hydrogen sulfide on neurological function were examined by the measurement of motor and sensory nerve conduction velocities of the tail nerve or morphology of the sciatic nerve but, no neurotoxic effects were observed in rats exposed to 50 ppm hydrogen sulfide for 5 days a week, for 25 weeks (Gagnaire, 1986).

Neurologic function and neuropathology were evaluated in rats exposed to 0,10.1, 30.5, or 80.0 ppm hydrogen sulfide for 6 hours/day, 5 days/week, for 90 days (CIIT, 1983c). Although absolute brain weights were decreased (5%) in rats exposed to 80 ppm hydrogen sulfide in this study, there were no treatment-related effects on neurological function or neuropathology. In addition, no signs of neurotoxicity were noted in a similar study in which mice and rats were exposed to 0, 10.1, 30.5, or 80.0 ppm hydrogen sulfide for 90 days (CIIT, 1983a, CIIT, 1983b).

6.1.3 Toxicology of bioaerosols

Endotoxin

The bioaerosol constituent present in swine barns that has been most studied is endotoxin. Endotoxin is a lipopolysaccharide (LPS) component of the outer cell wall of Gram negative (Gm-) bacteria. Endotoxin has been shown in both humans (Schwartz et al 1995, Jagielo et al 1996, Deetz et al 1997) and animals (Schwartz et al 1994, Jagielo et al 1996, Thorne et al 1998, Thorne 2000) to be a potent pro-inflammatory agent through its ability to activate the innate immune system. Endotoxin is an amphipathic molecule consisting of a phospholipid fraction, called lipid A, bound to a polysaccharide. The polysaccharide has two components: the O-antigen and the core polysaccharide (Rietschel et al 1996). In swine CAFOs, endotoxin most likely includes pieces of other membrane materials in association with LPS. The biological activity of endotoxin rests largely with the lipid A fraction. Once inhaled, endotoxin will interact with macrophages or soluble CD14 inducing signal transduction via the TLR-4 receptor (Medzhitov et al 1997, Faure et al 2000, Gao et al 1998). Through multiple transcription factors (Gao et al 1998), the initiation of transcription of several genes coding for inflammatory mediators can trigger the production of pro-inflammatory cytokines. The cytokines most associated with inhalation of endotoxin are Interleukin (IL)-1, tumor necrosis factor (TNF)a, IL-6, IL-8 (humans), and MIP-2 (mice) (Thorne et al 1998, Deetz et al 1997). Recent evidence suggests a regulatory role for IL-10, IL-12 (Shnyra et al 1998), and interferon ? (IFN?) (Kline et al 1998). An aggressive response to endotoxin exposure results in a cascade of events producing airway narrowing and an obstructive breathing pattern (Pauwels et al 1990). Chronic inhalation exposure in mice has been shown to induce airway remodeling and collagen formation (George et al 2001).

Glucans

Studies of the past five years have provided evidence that glucans may also be important immunomodulators (Rylander 1999, Fogelmark et al 1997). ß(1? 3)-glucans are glucose polymers with variable molecular weight and degree of branching that may appear in triple helix, single helix or random coil structures (Williams 1994). ß(1? 3)-glucans originate from a variety of sources, including fungi, bacteria, and plants (Stone and Clarke 1992). They are water insoluble structural cell wall components of these organisms, but may also be found in extracellular secretions of microbial origin. Glucans may account for up to 60% of the dry weight of the cell wall of fungi, of which the major part is ß(1? 3)-glucan (Klis 1994). Recently it has been suggested that ß(1? 3)-glucans play a role in bioaerosol induced inflammatory responses and resulting respiratory symptoms (Williams 1994, Rylander et al 1992, Fogelmark et al 1994).

Microorganisms

Infectious microorganisms may present an occupational hazard when inhaled (Thorne 2001, Douwes et al 2002). Fortunately, airborne transmission of zoonotic pathogens at sufficient doses to cause disease appears to be uncommon in CAFOs. The most notable infectious bioaerosol in agricultural occupational environments is *Mycobacterium tuberculosis* (Schenker et al. 1998). However, this arises from transmission from person-to-person. Tuberculosis occurs with high prevalence among immigrant farm laborers. More germane to CAFOs in Iowa is concern over the emergence of antibiotic resistant pathogenic organisms that may arise under the influence of antibiotics added to feed.

Non-infectious microorganisms are a more significant problem in CAFOs by virtue of the enormously high concentrations at which they occur. There has been limited study of the effects of inhaled bacteria and fungi in laboratory animal models of human disease. Most of the studies in the literature have used a lung infection model to study host defense against lung pathogens or to assess the efficacy of antimicrobial therapies. However, a few studies are informative. McCray et al (1999) demonstrated severe inflammation with neutrophilic infiltration to the lungs of mice following 4 hr inhalation exposure to *Pseudomonas aeruginosa* at a concentration of 3.3×10^8 CFU/m^3. This study used bacterial lung burdens that resemble those attainable in CAFOs. The bacteria were cleared from the lungs within 24 hours and the inflammation resolved by 72 hours after exposure. Thorne and Gassman studied the relative potency of inhaled Gram-negative organisms and Gram-positive organisms for lung inflammation in mice (Gassman et al 2000). This study demonstrated that the Gram-negative bacteria: *Enterobacter agglomerans* and *Pseudomonas aeruginosa* were orders of magnitude more potent that the Gram-positive organisms: *Bacillus magaterium* and *Micrococcus luteus* at initiating inflammation. In this study, markers of inflammation included influx of neutrophils to the lung and increased concentration of interleukin-6 (IL-6) and tumor necrosis factor (TNFa). It was concluded that the endotoxin derived from the Gram-negative organisms was the cell component primarily responsible for the inflammation.

Fungi and fungal conidia are also found airborne in CAFOs. Fungi have been studied primarily as allergens and as sources of mycotoxins. There is no reported evidence of animal or human health problems due to mycotoxin delivery arising from inhalation of fungal spores for the common fungi found in CAFOs. Studies of allergen potency for fungi found in CAFOs have focused on human studies rather than on animal models.

Chapter 6.2. Animal Health Effects

The preponderance of scientific studies on the effects of air contaminants and emissions on animal health has been conducted in and around swine facilities. Air contaminants can be divided into gases, particulates, bioaerosols, and toxic microbial by-products. Excess ammonia has been associated with lowered average number of pigs weaned, arthritis, porcine stress syndrome, muscle lesions, abscesses, and liver ascarid scars. Particulates (dust) have been related to reduced growth in growing pigs and turbinate pathology. Bioaerosols have been associated with lowered feed efficiency, decreased growth, and increased morbidity and mortality due to respiratory disease and abscesses. There are few scientific studies regarding the health effects and productivity problems of air contaminants on cattle and other livestock. Ammonia and hydrogen sulfide are the two most important inorganic gases affecting the respiratory system of cattle raised in confinement facilities. These gases affect the mucociliary transport and alveolar macrophage functions of the respiratory system lessening its protective responses.

6.2.1 Ammonia - Livestock Health Effects

At concentrations usually found in livestock facilities (<100 ppm), the primary impact of aerial ammonia is as an irritant of the eye and respiratory membranes; and as a chronic stressor that can affect the course of infectious disease as well as directly influence the growth of healthy young animals (Lillie, 1972; Curtis, 1983).

A series of experiments at the University of Illinois measured the effects of various levels of aerial ammonia on young pigs. The rate of gain of young pigs was reduced by 12% during exposure to aerial ammonia at 50 ppm, but no lesions were observed in the respiratory system. At both 100 and 150 ppm aerial ammonia, rate of gain was reduced by 30% and tracheal epithelium and nasal turbinates showed lesions consitent with a tissue irritant (Drummond et al., 1980). Aerial ammonia at 50 and 75 ppm reduced the ability of healthy young pigs to clear bacteria from their lungs (Drummond et al., 1978). At 50 and 100 ppm, aerial ammonia exacerbated nasal turbinate lesions in young pigs infected with *Bordetella bronchiseptica,* but did not add to the infection-induced reduction in the pig's growth rate (Drummond et al., 1981a). In another study, 100 ppm aerial ammonia reduced the rate of gain by 32%; while effects of 100 ppm ammonia and concurrent ascarid infection were additive to where the rate of gain was reduced by 61% (Drummond, et al., 1981b). In a study of 28 swine farms in Sweden, a higher incidence of arthritis, porcine stress syndrome lesions, and abscesses had a positive correlation with levels of aerial ammonia in the facilities (Donham, 1991)

It has recently been recommended that the maximum long-term ammonia exposure limit for swine should be less than 20 ppm as both pathological data (Hamilton, 1996) and immunological data (Urbain, 1994) suggest that exposure to ammonia concentrations of 10 to 15 ppm reduce resistance to infection (Jones, 1997). British workers utilized operant conditioning techniques giving pigs the choice between ambient ammonia levels of 0, 10, 20, and 40 ppm to demonstrate that pigs have an aversion to atmospheres containing even relatively low levels of ammonia (Jones, 1997).

Ammonia has been considered as the most significant air pollutant in cattle barns as its irritating effect on the respiratory epithelium appears to directly reduce the number of ciliated cells and thus decrease the efficiency of mucociliary transport (Marschang, 1973). Ammonia concentrations within cattle facilities varied greatly from 80 to 2001 mg/h per animal depending on the type of housing (concrete floors vs slatted flooring, ventilated vs closed), bedding, age of animals, environmental conditions, waste storage system employed, frequency of cleaning, and ration (Koerkamp et al, 1998; Wathes et al, 1998; Pitcairn et al, 1998; Gurk et al, 1997). At concentrations less than 100 ppm and in a poorly ventilated facility, ammonia appears to affect pulmonary function in cattle. Five mechanisms protect the lungs from invasion of foreign materials: cellular and humoral immunity, mucociliary transport, macrophage function, cough reflex, and nasopharyngeal filtration. Of these defensive mechanisms, mucociliary transport and alveolar macrophage functions are most severely affected by ammonia and possibly hydrogen sulfide (Lillie and Thompson, 1972).

In poultry, ammonia is considered the most harmful gas in broiler chicken housing (Carlile, 1984). Ambient ammonia levels of 50 ppm for prolonged periods irritate respiratory airways and predispose chickens to respiratory infections with the added risk of secondary infections; and development of lesions of keratoconjunctivitis of the eye is associated with ambient ammonia levels of 60 ppm (Hauser, 1988). A reduced rate of bacterial clearance from the lungs was measured in turkeys exposed to 40 ppm aerial ammonia (Nagaraja, 1984). Excessive mucous production, matted cilia, and deterioration of normal mucociliary apparatus was found in turkeys exposed to ammonia concentrations as low as 10 ppm for 7 weeks (Nagaraja, 1983).

6.2.2 Hydrogen Sulfide - Livestock Health Effects

Hydrogen sulfide is a potentially lethal gas produced by anaerobic bacterial decomposition of protein and other sulfur containing organic matter. This colorless gas with the distinctive odor of rotten eggs is heavier than air and may accumulate in manure pits, holding tanks, and other low areas in a facility. The sources of hydrogen sulfide presenting the greatest hazard in an agricultural setting are liquid manure holding pits which are commonly under slatted floors of livestock facilities. Although most of the continuously produced hydrogen sulfide is retained within the liquid of the pit, the gas is rapidly released into the ambient air when the waste slurry is agitated to suspend solids prior to being pumped out. While the concentration of hydrogen sulfide usually found in closed animal facilities (<10 ppm) is not harmful, the release of this gas from manure slurry agitation may produce concentrations up to 1000 ppm or higher (Lillie, 1972; Carson, 1998; Donham, 2000).

Hydrogen sulfide is an irritant gas producing local inflammation of the moist membranes of the eye and respiratory tract. The irritant action of hydrogen sulfide is fairly uniform throughout the respiratory tract, although the deeper pulmonary structures suffer the greatest damage often producing pulmonary edema (Curtis, 1983).

Differences between mammalian species susceptibility to toxic concentrations of hydrogen sulfide are small, as demonstrated by the following reported acutely toxic levels of hydrogen sulfide: goat – 900 ppm; guinea pig – 750 ppm; dog – 600 ppm; rat – 500 ppm (Sayer, 1923). However, chickens were found to be less sensitive to hydrogen sulfide than mammals, with exposures of 4,000 ppm not resulting in immediate death (Klentz, 1978).

Early experiments examining various levels of acute hydrogen sulfide gas exposure in pigs reported the following associated clinical effects; 50 to 100 ppm - nothing significant; 250 ppm – distress; 500 to 700 ppm – semicomatose; 1000 ppm – intermittent spasms, cyanosis, unconsciousness, convulsions, death (O'Donoghue, 1961). At low levels of hydrogen sulfide exposure, no effect was measured on rate of body weight gain or respiratory tract structure in young pigs breathing air containing 8.5 ppm hydrogen sulfide for 17 days (Curtis, 1975)

6.3.3 Particulates

Particulates are derived from two primary sources: pigs and feed. The primary particulate component from the pigs is dried fecal material. After drying fecal material becomes aerosolized by movement of the pigs and air currents. This dust is very fine, and up to 40% is inhalable (Donham, 2000). Dried fecal material is heavily contaminated with microbes and microbial by-products. Animals and workers in nursery and farrowing facilities would be exposed to greater concentrations of fecal dust than would those in finishing facilities where feed dust would predominate (Donham, 2000).

6.3.4 Bioaerosols and Endotoxins

Air quality, as defined in ventilation parameters, influences the aerosol spread of potential viral and bacterial pathogens that colonize the respiratory epithelium. However, rarely does one find pathogens in the air. They generally are less viable and found in fewer numbers relative to the nonpathogens and saprophytes (Donham, 2000). Bacteria, fungi, and yeast heavily contaminated the atmosphere of swine confinement facilities. Total microbial concentration (cfu per cubic meter) range from 100,000 – 10,000,000 (Donham, 2000). Maximum concentration for swine health is approximately 430,000 (Donham, 2000).

Of recent importance is the concentration of endotoxin detected in the atmosphere of confinement facilities. Endotoxin is a phospholipid-polysaccharide macromolecule that comprises the cell wall of Gram-negative bacteria. It is released when the integrity of the cell wall is disturbed. A typical range for endotoxin in the atmosphere of a confined building is 150 -1000 units (Donham, 2000). Maximum concentration for swine health has been approximated at 150 units. Endotoxin is a highly inflammatory substance and is believed to play a major role in respiratory disease of workers (Donham, 2000).

6.3 Human Health Effects

While other public health impacts, which include human exposures to polluted water or antibiotic resistant microorganisms that may arise from CAFOs, are not being addressed in this chapter, occupational exposures to CAFO environments will be reviewed and discussed because of their relevance to human response to CAFO air emissions.

The lung contains the largest epithelial surface in the body, consisting of more than 100 square meters of surface area in the average adult male (compared with approximately 2 square meters of skin). The average adult male inhales up to 15 kg of air daily, and children inhale proportionately more for their size. Because of this high surface area and high volume of air exchanged, the lung is capable of absorbing vast quantities of inhaled substances. Defense mechanisms of the lung, including the cough reflex, mucociliary transport, and the innate immune system are efficient at combating inhaled particulate matter and microorganisms. Gases, vapors, and aerosols (of "respirable" size, approximately 1-10 microns in diameter) are readily inhaled and absorbed.

Health effects associated with inhalation of toxins and bioaerosols are manifold. Medical problems commonly associated with inhaled agents include respiratory diseases (asthma, hypersensitivity pneumonitis, industrial bronchitis), cardiovascular events (sudden death associated with particulate air pollution), and neuropsychiatric conditions (due to odor as well as delayed effects of toxic inhalations).

Most studies of human exposures to airborne agricultural hazards have focused on occupational exposures in agricultural settings. With the rise of large, industrial CAFOs as the preeminent form of livestock production and their associated higher production of gases, vapors, and fumes, these exposures now have the potential to affect larger numbers of individuals, including members of the neighboring community not involved in agriculture or related industrial livestock production. Few studies have directly examined the health effects of proximity or exposure to CAFOs in the community, thus extrapolations must be considered from well-documented effects of these toxins in laboratory settings and occupational exposure studies. Donham and colleagues (1977) first reported that workers in swine confinement facilities described significantly more respiratory symptoms than non-exposed workers; subsequent studies have confirmed this symptomatology and have also documented increased risks of respiratory infections, progressive declines in pulmonary function, and poisoning from hydrogen sulfide in this occupational group.

For many reasons, standards for community exposures to the toxic agents released from CAFOs must be stricter than that for occupational exposures. First of all, community members may include subgroups of especially susceptible individuals, for example the elderly, children, and those with pre-existing impairments. Secondly, community members may be exposed continuously to released substances rather than for a workshift or less; this is especially true for those who do not work outside the home, and for pre-school children. Moreover, exposed community members may not have chosen to live in proximity to a CAFO, whereas occupationally exposed individuals have some choice in their employment. Thus, ambient exposure levels arising from CAFOs, including ammonia and hydrogen sulfide, must be significantly lower than occupational levels; notwithstanding, many components of the CAFO environment, e.g. bioaerosols including endotoxins and glucans, have no current recommended or mandated occupational exposure limits.

6.3.1 Studies of Adverse Health Effects from Specific Exposures found in CAFO Emissions

It is important to examine the literature regarding adverse health effects arising from individual chemicals and mixtures of chemical compounds, often referred to as odorants, exposures known to be components of emissions from CAFOs. The following is a summary of available, published findings from clinical, experimental and epidemiological observations for several categories of these exposures. The concentration of exposure is not always known or measured, but there have been several studies of individual chemical exposures that have documented both concentrations and durations of exposure, some at very low levels. The vast majority of these observations come from occupational, experimental, and non-CAFO community exposures, many of which were made among selected populations of workers or healthy volunteer subjects. Regulatory agencies have used many of these findings, taking into account uncertainty and susceptibility factors, in making their recommendations regarding exposure limits for exposed communities (See Chapter 8.0).

6.3.1.1. Ammonia

Ammonia is both a component of animal waste and released in waste treatment processes. Well recognized as a human toxin, the current OSHA PEL for ammonia is a TWA of 50 ppm (also its odor threshold), although ACGIH and NIOSH recommend a lower TWA of 25 ppm. Concentrations of greater than 100 ppm have been regularly reported in poultry confinement operations (Mulhausen et al, 1987). The EPA has found that animal agricultural operations are responsible for almost three fourths of ammonia air pollution in the United States (Harris et al, 2001), although numerous other industries are associated with inhalation exposure to ammonia. EPA has recommended as reference concentration for chronic inhalation of ammonia of 1.4 ppm. ATSDR has recommended a long-term MRL of 300 ppb for community exposures (See Chapter 8.0 for detailed discussion).

Water-soluble, ammonia is rapidly absorbed in the upper airways, with the result of damaging upper airway epithelia. Moderate concentrations (50-150 ppm) can lead to severe cough and mucous production; higher concentrations (>150 ppm) may cause scarring of the upper and lower airways (Close et al, 1980; Leduc et al, 1992). A consequence of these inflammatory responses, in some cases, is reactive airways dysfunction syndrome (RADS) and associated persistent airway hyperresponsiveness (Bernstein and Bernstein, 1989; Flury et al, 1983). At higher concentrations, sufficient ammonia may bypass the upper airways to cause lower lung inflammation and pulmonary edema (Close et al, 1980; Sobonya, 1977). Massive exposure to ammonia can be fatal, including in the agricultural sector, a consequence to disruption of tanks of anhydrous ammonia (Sobonya, 1977). These fatalities, as well as the chronic lung disease seen following as little as two minutes of exposure to high concentrations of ammonia gas may result in the development of bronchiolitis obliterans (de la Hoz et al, 1996; Kass et al, 1972; Sobonya, 1977; Walton, 1973), restrictive lung disease (de la Hoz et al, 1996), and bronchiectasis (Leduc et al, 1992).

In addition to pulmonary disease, exposure to ammonia also leads to irritation of the eyes, sinuses, and skin. Exposure to 100 ppm ammonia for short (30 second) duration leads to nasal irritation and increases in nasal airway resistance (McLean et al, 1979). When increasing concentrations of ammonia are delivered by spontaneous respiration, severe nasal irritation develops at 134 ppm after 5 minutes; some individuals report symptoms as low as 32 ppm (Keplinger et al, 1973). Clinical sinusitis has been reported following accidental exposure to ammonia as well (Brautbar, 1998). Chemical burns to the skin and eyes are also commonly seen following high-concentration ammonia exposures (Latenser and Loucktong, 2000).

Although the most serious adverse effects of ammonia inhalation are usually seen with concentrations of ammonia that have been associated with fatal exposures (in the range of 500 ppm), evidence exists that lower concentrations of ammonia can reach the alveoli and may be adsorbed to respirable particulates, as may be seen in complex bioaerosols such as those found in the agricultural setting resulting in a research-recommended occupational exposure limit of 7 ppm (See Section 6.3.2.2). Similar occupational exposures to ammonia (9 ppm) have been studied among soda ash workers (Holness et al, 1989) who reported increased symptoms of coughing, wheezing, nasal complaints, eye irritation, throat irritation, and skin complaints; however, no changes in lung function were observed when measured over a working shift. It was noted that this was a cross-sectional study of a small population and that selection bias may have therefore occurred.

6.3.1.2. Hydrogen Sulfide

Hydrogen sulfide is one of the most important of the gases arising from the storage, handling, and decomposition of animal wastes. Smelling like rotten eggs, this gas that is recognized as both an irritant and an asphyxiant, is a prominent component of odorants released from CAFOs. Current OSHA PEL for H_2S are 10 ppm (with STEL of 15 ppm), while NIOSH has recommended a time weighted average occupational exposure limit of 10 ppm. For community exposures, EPA has recommended a reference concentration for long-term exposure of 7 ppb (See Chapter 8.0 for full discussion).

Levels as high as 1,000 ppm have been reported (Donham and Gustafson, 1982) following the perturbation of manure lagoons, and levels greater than 100 ppm are considered immediately hazardous to life and health. Exposure to these elevated levels of H_2S can cause rapid loss of consciousness, and H_2S has been implicated in a number of deaths when encountered in confined environments in agricultural settings. The primary mode of absorption of H_2S is through inhalation (Bhambhani et al, 1996a).

One particular hazard is that, although the odor threshold is quite low (less than 1 ppm), at levels over 6 ppm the intensity of the smell only modestly increases; above 150 ppm, exposure to hydrogen sulfide may actually reduce the sense of smell, hindering the olfactory detection of high concentrations of the gas and making H_2S monitoring equipment mandatory in occupational settings (van Aalst et al, 2000). The toxic effects of hydrogen sulfide are based on its property as a chemical asphyxiant; it binds to the mitochondrial enzyme cytochrome oxidase, blocking oxidative phosphorylation and ATP production. This leads to anerobic metabolism and the development of lactic acidosis (Nichols and Kim, 1982).

Experimental exposure studies have been carried out examining the effects of inhalation of low levels of H2S on healthy volunteers (Bhambhani et al 1996a, 1996b, 1997). Inhalation of 5 ppm of H_2S by exercising men leads to a significant decrease in the concentration of citrate synthase, a marker of aerobic metabolism, in muscle biopsy tissue, although no increases in lactic acidosis were noted (Bhambani et al, 1996b). Levels of 10 ppm cause no change in physiologic measures of pulmonary function (Bhambani et al, 1996a), but do cause a significant decline in maximal oxygen update (VO2max) and an associated increase in blood lactate in exercising men and women (Bhambani et al, 1997). Jappinen and colleagues (1990) exposed a group of asthmatics (severe asthmatics were eliminated from the study) to 2 ppm of hydrogen sulfide for 30 minutes. Three complained of headache and two were found to have increased airway resistance, but there was no change in other lung function values or associated symptoms. Members of a Mobile Monoriting Team of the Texas Natural Resource Conservation Commission (TNRCC) evaluated hydrogen sulfide concentrations downwind from an oil refinery and reported 0.09 ppm 30-minute averages over a period of five hours (Texas Natural Resources Conservation Commission, 1998). Six staff members reported eye and throat irritation, headache, and nausea. These experimental studies indicate consistent patterns of adverse health effects after short, low concentrations of exposure to hydrogen sulfide.

Epidemiological studies of workers exposed to hydrogen sulfide exposure include pulp mill workers who reported increased respiratory symptoms (irritation and cough), as well as increased headache and migraine; it was noted that these workers were also exposed to other sulfur compounds including sulfur dioxide and mercaptans (Partti-Pellinen et al, 1996). Jappinen and colleagues (1990) studied pulp mill workers thought to be exposed to hydrogen sulfide levels usually below a maximum permitted concentration of 10 ppm and reported no significant changes in lung function and airway hyperresponsiveness at the end of the workday, compared with control values. Hessel and colleagues (1997) studied oil and gas workers at undefined, but probably moderately high, exposures to hydrogen sulfide (as some of the workers lost consciousness); nearly third of the workers reported symptoms.

Several additional epidemiological studies of community residents exposed to low levels of hydrogen sulfide have been reported. A U.S. Public Health Service study of a general population exposed to levels in excess of 0.3 ppm reported adverse health effects including shortness of breath, eye irritation, nausea, and loss of sleep (United States Public Health Service, 1964). Jaakkola and colleagues (1991) studied chronic community exposure to hydrogen sulfide and TRS (total reduced sulfur) compounds (hydrogen sulfide annual means of 0.006 ppm and daily means of 0.07 ppm) and found that both asthma and chronic bronchitis were slightly more prevalent, that eye and nasal symptoms were found significantly more often, and that these symptoms were dose-related. They concluded that the WHO standard of 0.1 ppm (24 hour average) did not protect against these adverse health effects. Jaakkola and colleagues (1991) also studied the respiratory infection rate among infants exposed to ambient hydrogen sulfide levels of 0.001 ppm, and at half-hour maximal exposures of 0.125 ppm, and reported that exposed infants had higher rates of respiratory infection, but that combined effects of other air pollutants may have been contributing factors. Haahtela and colleagues (1992) studied community residents exposed to peak exposures of hydrogen sulfide of 0.095 ppm (four hour average) and 0.025 and 0.030 ppm over two days of exposure, compared to control days, with four hour exposures ranging between 0.00007 and 0.002 ppm. Cough, throat irritation, and eye symptoms were observed significantly more often during the peak exposure period. The author concluded that the WHO guideline of 0.10 ppm for a 24 hour average did not provide adequate protection from adverse health effects. Rossi and colleagues (1993) studied the occurrence of asthma attacks in relation to air pollution events (hydrogen sulfide levels ranged from the highest 1 hour mean of 0.011 ppm and daily 24 hour means of 0.002 ppm), and reported significant associations between the frequency of asthma attacks at an emergency room and nitrogen sulfides, sulfur dixoxide, total suspended particulates, and hydrogen sulfide. Partti-Pellinin and colleagues (1996) studied a general population exposed to TRS levels of up to 0.1 ppm over a 24-hour period. Based on a self-administered questionnaire, the authors concluded that the exposed community reported more cough, respiratory infections, and headaches than the reference community, and also that headaches, depression, tiredness, and nausea were more often reported on days when the 1 hour or daily mean TRS levels exceeded 0.028 ppm (both communities were exposed to similar levels of sulfur dioxide). These community studies of hydrogen sulfide and TRS exposures are especially useful because they report measured low levels of exposure and associated adverse health effects. However, as is the case with community exposures to CAFOs, these are invariably mixed exposures to hydrogen sulfide and other chemicals, some of which may contribute to the adverse health effects described in these studies. Campagna and colleagues (2001) studied the effects of ambient hydrogen sulfide and TRS levels on hospital visits for respiratory diseases among children and adults in Dakota City and South Sioux City, Nebraska. While peak levels of hydrogen sulfide were as high as 1,375 mean levels over an entire day were much lower. An increase in asthma hospital visits was seen a day following peak TRS exposures among children and an increase in hospital visits for all respiratory disease was seen following peak exposures for both TRS and hydrogen sulfide.

Finally, Xu and colleagues (1998) has reported a retrospective epidemiological study of spontaneous abortion among a large cohort of female workers in a petrochemical plant in Beijing, China. Among women exposed only to hydrogen sulfide (concentrations were not reported because of the retrospective nature of the study), a rate of spontaneous abortion of 12.3% was observed and a significant association with hydrogen sulfide exposure was reported (OR, 2.3, CI 1.2-4.4).

Chronic low-level exposure is associated with anosmia, the loss of ability to detect odors. At higher levels, hydrogen sulfide exposure causes loss of consciousness, shock, pulmonary edema, coma and death. Survivors of hydrogen sulfide poisoning are reported to commonly have neuropsychiatric defects which may be permanent; a recent study by Kilburn of University of Southern California has demonstrated that even exposure to low concentrations of hydrogen sulfide leads to significant neuropsychologic abnormalities, including impaired balance, visual field performance, color discrimination, hearing, memory, mood, and intellectual function (Kilburn, 1997). These effects may be due to anoxic encephalopathy.

6.3.1.3. Particulates

The air in CAFOs is contaminated with high concentrations of particulates, approximately one quarter of which is protein; about one third of suspended dust is considered respirable (< 10 microns in diameter, PM10). Occupational and environmental studies have demonstrated an average of 2-6 mg/m^3 dust concentrations, and levels up to 20 mg/m^3 may be encountered. National ambient air standards for PM10 are an annual average of 50 mcg/m^3 with a 24-hour average of 150 mcg/m^3. Of these, particles between 4 and 10 microns are deposited in the airways and smaller particles (< 2.5 microns) progress into and may be absorbed by the terminal bronchiols and alveoli. Particles which settle in the upper airways are associated with asthma and bronchitis; smaller particles may be absorbed and have systemic effects including, in studies of urban air pollution, increased rates of cardiac death. In addition to direct inflammatory response to inhaled allergens, dust can also convey inflammatory and/or irritating gases or chemicals (such as ammonia, hydrogen sulfide, or endotoxin) deeper into the lung, thereby enhancing their toxic effects.

Although certain mineral particulates, such as silica dioxide, lead to characteristic pulmonary inflammatory and scarring conditions known as pneumoconioses, even inhalation of seemingly inert dust particles appear to have adverse long-term consequences. In a number of occupational settings, cumulative exposure to dust particles in the respiratory range is one of the most important causes of persistent respiratory symptoms and progressive declines in lung function (Healy et al, 2001; Ulvestad et al, 2001); and this has also been reported in non-occupational settings (Dockery and Pope, 1994; Dockery et al, 1993; Pope et al, 1995, Lippmann et al, 2000).

6.3.1.4. Bioaerosols

An important component of the environment released from CAFOs is microbiologic in origin. Swine manure contains up to 10^8 coliform bacteria/gram, and CAFOs contain these organisms in airborne and respirable particles; total organism load may exceed 10^{10} cfu/m^3 at times. Some of the microorganisms that are present in the CAFO environment are human pathogens, creating a potential risk of infection for those exposed to these agents. Dust in CAFOs and other agricultural settings, contains far more than merely viable organisms. Microbial products of medical importance include antigens, glucans, and endotoxins.

Exposure to protein antigens derived from plants, animals, and microbes are known to cause a variety of medical problems. Inhalation of thermophilic bacteria, commonly found in moldy hay and other damp locations, leads to a condition known as hypersensitivity pneumonitis, a respiratory condition characterized by granulomatous inflammation of the lung, restrictive physiology, and progressive dyspnea. Associated with detection of antibodies to these organisms in the blood, hypersensitivity pneumonitis (also known as "farmer's lung" in agricultural settings), is found among agricultural workers and others occupationally exposed to these agents (Skorska et al, 2000).

Asthma may also be caused or exacerbated by exposure to conditions common in CAFOs. Atopic asthma is caused, in susceptible individuals, by sensitization to and subsequent inhalation of allergens, agents that can lead to asthma in previously non-sensitized individuals. Those with a previous diagnosis of asthma may have their asthma triggered in a non-specific way by exposure to the dust and irritant-inducing agents arising from the CAFO environment. CAFOs contain, among other compounds, high concentrations of grain dust, dust mites, animal dander, pollen grains, molds and fungal spores, and dried fecal particles, each of which may induce or exacerbate asthma. Proximity to CAFOs, and periodic/seasonal agricultural activities (e.g., agriculture chemical and manure applications), are frequently cited by rural asthma patients as exposures resulting in asthma exacerbation making asthma control more difficult.

Endotoxins are lipopolysaccharide complexes that are products of gram-negative bacterial cell walls. Ubiquitous in the environment, they are present in high concentrations in agricultural settings such as grain elevators, feed barns, and CAFOs. Endotoxins are important components of exposures responsible for the adverse health effects following inhalation of organic agricultural dust. Acute effects of endotoxin inhalation include symptoms of cough, chest tightness, and dyspnea and alterations in pulmonary function characterized most typically by a decline in FEV1; over a working shift and overtime; systemic effects include fever, rigors, myalgia, arthralgia, and other "flu-like" symptoms. Although no occupational standards currently exist for endotoxin in the United States, Dutch Expert Committee on Occupational Standards of the National Health Council has proposed a limit of 50 EU/m^3 (4.5 ng/m^3) over an 8-hour exposure period (Heederik and Douwes, 1997).

Kline and colleagues (1999) evaluated the responses of 72 normal, non-smoking, non-atopic, non-asthmatic volunteers who were exposed to graded doses of endotoxin by inhalation in a clinical exposure facility. Each subject first inhaled 0.5 mcg of endotoxin then underwent spirometry prior to inhaling a greater concentration of endotoxin. Cumulative levels of endotoxin inhalation consisted of 0.5, 1.5, 3.5, 6.5, 11.5, 21.5, 41.5 mcg. The protocol was terminated for decline in FEV1 to < 90% of baseline or a total of 41.5 mcg. Among study participants, a wide range of sensitivity to the bronchospastic effects of inhaled endotoxin was found; some individuals demonstrated a 20%

decline in FEV1 following inhalation of as little as 1.5 mcg whereas others were resistant to these effects and did not even decline by 10% following inhalation of over 41.5 mcg. In a separate study, asthmatic individuals were found to have an enhanced degree of symptoms and bronchospasm following inhalation challenges compared with normal control subjects (Kline et al, 2000). Other studies have also found that inhalation exposure to endotoxin and endotoxin-containing grain dust leads to the development of bronchospasm and airway inflammatory responses (Blaski et al, 1996; Jagielo et al, 1996; Michel et al, 1989; Michel et al, 1996; Michel et al, 1997; Schwartz et al, 1995a).

Most of the reports of community, occupational, and ambient effects due to endotoxin exposure are related to inhaled endotoxin; this is clearly different than the case of patients suffering from gram-negative infections, who are typically exposed to endotoxin via the blood stream. The greatest effect of inhaled endotoxin is on airway inflammation and the induction of bronchial hyperresponsiveness, both characteristic of asthma. Interestingly, some recent studies have demonstrated a protective effect of endotoxin exposure relative to the development of allergic disease. Von Mutius and colleagues (2000) recently reported that environmental endotoxin exposure of farmers' children protects them from the development of atopy; Gereda and colleagues (2000), in a study of urban homes, found that home levels of endotoxin inversely correlated with likelihood of allergen sensitization in infants. In a similar vein, Gehring and colleagues (2001) found that environmental exposure to endotoxin protected infants from the development of atopic eczema. These effects of endotoxin on early-life development of allergic responsiveness may be due to the deviation away from a Th2-type response to allergens and towards a Th1-type response, however alternate explanations are possible.

Exposure of adults, however, (and infants and children in some studies) appears to be clearly detrimental with regards to airway function and asthma. In contrast to the studies showing protective effects of endotoxin on the development of disease among infants, Park and colleagues (2001) reported that infants with at least one asthmatic/allergic parent were placed at increased risk of developing wheezing when their home environment contained higher levels of ambient endotoxin. Douwes and colleagues (2000), in a community study of household dust, found that endotoxin content of dust was associated with increased peak flow variability among asthmatic children. Michel and colleagues (1991) reported that asthmatic patients with higher levels of home endotoxin exposure develop more symptoms and require more intensive treatment than those from homes with lower levels of endotoxin. In a separate study, the same group confirmed that asthma severity correlates with endotoxin exposure (Michel et al, 1992). In a study conducted in Brazil, Rizzo and colleagues (Rizzo et al, 1997) found that endotoxin (but not dust mite) content of dust significantly correlated with symptom scores in asthmatic children.

Controlled laboratory studies of endotoxin exposure confirm that inhalation induces airway inflammation and bronchial hyperreactivity. Blaski and colleagues (1996) reported that both normal control subjects and atopic individuals developed airway neutrophilia and reduced airflow following inhalation of 0.4 mcg/kg of endotoxin. Jagielo and colleagues (1996) found that the endotoxin content of grain dust was responsible for its ability to induce inflammation and obstructive airway physiology in normal volunteers. Michel and colleagues (1989) found that endotoxin inhalation by asthmatics resulted in significantly more airflow reduction than in normals. Among asthmatics, the reduction in airflow (Michel et al, 1992) and development of symptoms of chest tightness and dyspnea (Kline et al, 2000) are greater than the difference in development of airway inflammation. Even among non-asthmatics, a significant variability in responsiveness to the effects of inhaled endotoxin can be seen (Kline et al, 1999); this appears to be explained, at least in part, by genetic factors (Arbour et al, 2000).

Mycotoxins, beta-glucans, and other components of fungal pathogens appear to have a similar range of toxicity to endotoxins, including both inflammatory and immunostimulatory effects. These compounds, however, have been less well studied in human exposures, and their concentration in CAFOS is unknown (American Thoracic Society, 1998).

6.3.1.5. Volatile Organic Compounds

Of the thousands of gases, vapors, particles, and aerosols present in CAFOs, over 24 odorous chemicals, often referred to as odorants, have been identified (Cole et al, 2000). Volatile acids, mercaptans, and amines are particularly odorous even in miniscule concentrations. Ammonia and hydrogen sulfide, as noted above, are also pungently aromatic.

Although long recognized as a neighborhood nuisance, recent studies have suggested that odiferous exposures emitted from CAFOs may well have adverse health effects (Schiffman et al, 2000). Odor appears to play a significant role in the recognition of and concern over symptoms in neighbors of hazardous waste sites (Shusterman, 1992; Shusterman et al, 1999). Schiffman and colleagues (1995) from Duke University have reported that indicators of altered mood, assessed using validated scales, are significantly worse in subjects who live in the vicinity of intensive swine operations compared with control subjects.

Chen and colleagues (1999) have demonstrated, using odor threshold dilution analysis, that odor intensity in swine buildings is reproducible and measurable. Zahn and colleagues (2001) have analyzed malodorous volatile organic compound components of swine production facility air samples, and have demonstrated, using an artificial swine odor solution, that alterations in the concentrations of these components can be detected by study subjects. No odor studies were found that related the quantitative measurement of odor intensity in the downwind air stream from livestock facilities with adverse health effects among community residents. However, there is an extensive literature relating non-CAFO odors and adverse health effects that are relevant to community exposures to CAFO exposures.

Of the hundreds of gases, vapors, particles, and aerosols present in CAFOs, 331 volatile organic compounds (VOCs) and fixed gases were recently characterized by Schiffman and colleagues (2001). These compounds, assessed at the point of emission, included many acids, alcohols, aldehydes, amides, amines, aromatics, esters, ethers, fixed gases, halogenated hydrocarbons, hydrocarbons, ketones, nitriles, other nitrogen-containing compounds, phenols, sulfur-containing compounds, steroids, and other compounds. The authors (Schiffman et al, 2001) further observed that the vast majority of these compounds were found at concentrations below their published irritant or odor thresholds, yet human assessments of the combined odors and their irritant effects were described as "strong" at a distance of 1000 feet.

While CAFO odors have long been recognized as a neighborhood nuisance, recent studies have suggested that odiferous exposures emitted from CAFOs may well have adverse health effects (Schiffman, 1997; Schiffman et al, 1995; Thu et al, 1997; Wing and Wolf, 2000). Direct measurement of odorous or other noxious substances were not made in these studies, therefore, a direct linkage to level of exposure could not be reported. A Duke University workshop summarized by experts in assessing the potential health effects of odor from animal operations (Schiffman, Walker, Dalton, Lorig, Raymer, Shusterman and Williams) addressed this issue (Schiffman et al, 2001). They observed that health symptoms have been reported with increasing frequency from low level exposures from manures and biosolids; "the most frequently reported health complaints include eye, nose, and throat irritation, headache, nausea, diarrhea, hoarseness, sore throat, cough, chest tightness, nasal congestion, palpitations, shortness of breath, stress, drowsiness, and alteration in mood". They further observed that these symptoms usually occurred briefly at the time of exposure, but that hypersensitive individuals, such as asthmatics, could have their condition exacerbated with persisting symptoms.

Exactly how odors from CAFOs may result in these symptoms is not well understood. The Duke workshop discussed freeways, or paradigms, by which ambient odors may produce health symptoms (Schiffman et al, 2000). In the first paradigm, the symptoms may occur at levels of exposure that would also be expected to cause irritant effects from combinations of irritants that may be additive or synergistic in their effect. In this paradigm, the adverse health effect typically occurs at a higher level than the concentration at which the odor would first be detected.

In the second paradigm, symptoms may occur at odor concentrations below that expected from irritants. The mechanism by which these odorants may cause their adverse effects is not known (Schiffman et al, 2000). Schiffman and colleagues (1995) reported that CAFO odors perceived as unpleasant can impair mood. Shusterman and colleagues (1991) observed increased symptom prevalence and an "odor worry" interaction associated with odor from hazardous waste sites. Schiffman and colleagues (2000) summarized evidence that negative mood, stress, and environmental worry may lead to biochemical and physiological effects with subsequent health outcomes. Other studies suggest that bias concerning odors can alter the response relating to health effects (Dalton et al, 1997). These results provide evidence that both the perceived odor and cognitive expectations about a chemical can significantly affect individual response. Other studies have also demonstrated that ones current cognitive state can bias ancillary characteristics of an odor such as preference or acceptability (Knasko, 1993). Some studies have shown that persons can report experiencing strong odors as an outcome by showing that cognitive factors can lead to reports of odors when none are present (Knasko, 1992; O'Mahoney, 1978). Knasko and colleagues (1990) have also observed that an odorant stimulus is greatly influenced by the environment surrounding the exposure, which can include the social context or the perceiver's mental state. It is also recognized that those working in an odorous environment may adapt to the odor following long term exposure. Dalton and Wysocki (1996) have advocated for the development of laboratory procedures that combine long-term odor exposure in a naturalistic setting with psychological tests.

A third way for paradigm, is when the odorant is a part of a mixture that contains bioactive pollutants such as bioaerosols containing organic dust, endotoxin, glucans, allergens, microorganisms, or other toxins (Schiffman et al, 2000). In this paradigm, the individual is exposed to odors, but the adverse health effect is likely to arise from a non-odorant toxin. Relevant to this paradigm is the study of Reynolds and colleagues (1997) who sampled at 60 meters for hydrogen sulfide, ammonia, endotoxin, and total dust. A reason to sample for dust and ammonia together is that it is now recognized that some ammonia absorbs to respirable dust particles thereby providing a vehicle to transport ammonia and dust-latent toxins, like endotoxin, deep into the lung.

To date there has been relatively little research quantifying odorants. Zahn and colleagues (2001) completed a multi-component analysis of malodorous DOCs found in air samples from 29 swine production facilities using a 19-component artificial swine odor solution. The results of this study concluded that this approach can be applied toward estimating perceived odor intensity. Schiffman and colleagues (2001) studied six swine operations in North Carolina. In addition to quantifying the DOCs and fixed gases from these facilities, they used six methods for trained human panel members to assess the intensity of odor at varying distances from swine facilities. Scentometer measurements were made at 12 feet, 750 feet, and 1250 feet from the swine facilities and range from a high of 170 D/T (dilutions to threshold) to a low of 2 D/T.

It is recognized that there is great variability between odors arising from CAFOs, and that odorous gases may be transformed through interactions with other gases and particulates between the source and the receptor (Peters and Blackwood, 1977). It is also recognized that there is variability in odor persistence, "persistence factor" defined as the relative time that odorous gases will remain perceptible (Summer, 1971). There is a need to combine quantitative assessments of odors with environmental measurements in well-designed, controlled studies of symptoms and other health outcomes at the community level.

6.3.1.6. Experimental Occupational Exposures among Naïve Subjects

Workers in CAFOS are exposed, on a daily basis, to a wide array of gases, vapors, dusts, and other compounds. Thus, it is challenging to identify, in this occupational setting, which specific components of their exposure is responsible for health outcomes. Experimental occupational exposures among normal volunteers have addressed this issue.

Two clinical epidemiological studies of normal volunteers in swine CAFOs have been reported, both from Canada. Cormier and colleagues (1997) exposed 7 previously non-exposed, normal subjects to a swine building and found significant respiratory symptoms, declines in lung function, and clear evidence of a marked inflammatory response via analysis of bronchoalveolar lavage (BAL) fluid post exposure. Total dust, endotoxins, and ammonia were measured but no individual exposures, rather a mixed exposure, appeared to be responsible for these adverse health effects. Senthilselvan and colleagues (1997) made similar observations among 20 naive subjects, while also showing that treatment of the swine facility with canola oil significantly reduced symptoms, declines in lung function, airway hyperresponsiveness, and mean dust and endotoxin concentrations.

6.3.2. Occupational Health Effects

The first description of health hazards to people working in these CAFO's was in 1977 (Donham et al, 1977). This early study revealed that over 60 percent of veterinarians working in these facilities experienced one or more respiratory health symptoms. This report led to many subsequent studies in the US, Canada, and Europe (Donham, 1993). In addition to respiratory illnesses, other occupational health problems associated with CAFOs have been documented, including traumatic injuries, noise-induced hearing loss, needle sticks, hydrogen sulfide and carbon monoxide poisonings, and infectious diseases (Donham et al, 1982a; Donham et al, 1982b; Donham, 1985).

Workers in confined poultry and dairy operations are also at risk, but most beef operations are in open lots, thus reducing worker respiratory exposures. The increasing industrialization of livestock production will continue to result in more independent producers leaving the industry, or becoming quasi-employees of large-scale producers as contract growers. Furthermore, many minority workers are becoming employees of larger producers, raising potential legal issues of undocumented workers and further need of OSHA regulation of these large operations. In the past, OSHA has been restricted in agriculture because of a federal law that restricts enforcement on farms with ten or fewer employees. Many of the large industrial CAFOs now employ hundreds of workers and these workers will work full shifts in animal confinement buildings in contrast to smaller, independently owned CAFOs where periods of exposure are typically much shorter. This increase in large, industrial CAFOs will, therefore, likely lead to increased cumulative exposure and thus greater risk to adverse health effects. To date, OSHA has not addressed the CAFO issue, in spite of strong evidence of worker health risks.

The worker health component of this review is assembled to characterize the range of occupational health hazards associated with large-scale livestock production, but concentrates on health effects from air toxics and a brief discussion on measures needed to decrease health risks among workers.

Table 2 lists major categories of hazards and then further classifies diseases or health outcomes within those categories. The order does not necessarily relate to incidence, prevalence, or severity—these are common health risks among all intensive livestock production operations. The vast majority of the research in this area has been with swine production. Therefore, this report will deal largely with swine operations. However, similar exposures and adverse health effect observations have been made among those working in concentrated poultry production (Bar-Sela et al, 1984; Lenhart et al, 1990; Morris et al, 1991).

The principal health risks for CAFO workers result from respiratory exposures to a wide range of toxic, irritant, and inflammatory substances emitted into the air. Ammonia, hydrogen sulfide, carbon monoxide, particulate matter, endotoxin, and other bioaerosols have received the majority of research attention. However, infectious diseases, noise, trauma, fires, explosions, electrocutions, thermal stress, poisonings, and drowning are all also important causes of morbidity and mortality (Randolph and Rhodes, 1993). Often overlooked are emotional stress and chronic musculoskeletal pain that can lead to significant impairment and to disability in this workforce. This report will be limited to air toxics and resultant respiratory diseases.

6.3.2.1. Respiratory Diseases

Respiratory exposures lead to the most common health hazard among swine farmers and CAFO workers. There are both acute illnesses and chronic respiratory diseases among CAFO workers. The most serious acute hazard is hydrogen sulfide poisoning, which results from sudden exposure to high levels (> 500 ppm) of this gas. This is a confined space entry hazard (areas that are not vented and may trap toxic gases) in CAFOs, with hydrogen sulfide the principle hazard (Donham et al, 1982a; Osbern and Crapo, 1981). Acute respiratory distress syndrome (ARDS), or pulmonary edema, can result in CAFO workers from acute or chronic exposure to hydrogen sulfide (H_2S). There have been at least 19 acute deaths in workers resulting from sudden H_2S exposure of above 500 ppm secondary to liquid manure agitation. These people may collapse and stop breathing following only a few breaths at this high exposure (hydrogen sulfide is an asphyxiant). Severe pulmonary edema from the irritant properties of hydrogen sulfide and death may result. Longer-term lower exposure may also lead to ARDS during or following an accumulative or multiple period exposure (Donham et al, 1982a).

Other respiratory illnesses result from less acutely toxic exposures and lead to non-fatal acute lung insults as well as chronic declines in lung function (Bongers et al, 1987; Choudat et al, 1994; Cormier et al, 1997; Crook et al, 1991; Donham et al, 1984). Respiratory problems associated with this environment are listed in Table 3 by upper respiratory tract, airway, interstitial, and mixed airway and interstitial lung diseases. The pathogenesis of these respiratory diseases is primarily acute and chronic airway inflammation. Classical immunologically mediated asthma and hypersensitivity pneumonitis appear to be uncommon among CAFOs workers (Matson et al, 1983).

Acute bronchitis is the most common complaint among CAFOs workers, affecting as many as 70 percent of those exposed. This is an irritant-induced inflammatory condition of the airways. The symptoms of bronchitis are cough and sputum production. Chronic bronchitis is noted by chronic phlegm for two or more years. This condition affects about 25 percent of CAFO workers. Acute and chronic bronchitis may be accompanied by an asthma-like condition, with symptoms of chest tightness, wheezing, difficulty breathing, and shortness of breath (the symptoms most typically reported).

Frequent upper respiratory tract conditions include sinusitis and rhinitis. Some studies have referred to these collectively as mucus membrane irritation (MMI) (Rylander, 1994; Rylander et al, 1989). MMI may be attributable to the combination of bioaerosol, endotoxin and ammonia and other irritant exposures (Donham, 1986; Donham et al, 1986a).

Sinusitis is often chronic among CAFO workers who may complain of a continual or frequent cold "they just cannot shake," of a stuffy head, difficulty in breathing through the nose, headache, and/or "popping ears." These symptoms are a result of a noninfectious, toxic inflammation and swelling of the mucus membranes of the sinus cavities and the Eustachian tubes leading to the middle ear. This is often accompanied by a chronic irritant rhinitis and pharyngitis.

Allergic rhinitis (also called hay fever) has rarely been attributed to confinement exposures. Such persons may have a specific allergy to some component of the swine environment. These symptoms are similar to irritant rhinitis, except it usually develops after only brief exposure to the environment and may be accompanied by itchy, watery eyes and possibly acute chest tightness (allergic asthma). Workers with pre-existing allergic rhinitis often self-select themselves out of CAFO work which contributes to a selected, or survivor, population of CAFO workers.

An asthma-like syndrome, similar to byssinosis (a condition of workers exposed to cotton and other vegetable textile dusts), has been described among CAFO workers. This condition is characterized by chest tightness, wheezing, and/or cough on return to work after two or more days of work absence, and mild acquired airway hyperresponsiveness. It may occur early in exposure to the CAFO environment and is not an immunologically mediated condition. It was documented in 11 percent of a population-based study of Iowa swine confinement workers (Donham et al, 1990).

Occupational asthma includes periodic airway obstruction, chest tightness, wheezing, and dyspnea, does not occur on first exposure, but may develop after weeks to months of CAFO exposure. CAFO workers with pre-existent asthma typically experience severe asthma upon first exposure to animal confinement facilities and select themselves out of these jobs. Occupational asthma may result from repeated exposure to the work environment. It has two basic mechanisms: 1) immunologically mediated or allergic, or 2) chronic irritation. Rarely have there been documented allergic (IgE) mediated causes for CAFO workers' illnesses. These "susceptible" workers almost always leave the work force early because of severe asthma, and the condition is very difficult to manage among workers who continue to work in the CAFO environment. Non-allergic occupational asthma, asthma-like syndrome, and/or reactive airways disease, has been found to be common (up to 20 percent) of current CAFO workers. This condition may lead to progressive declines in lung function and chronic obstructive pulmonary disease, which is a chronic irreversible condition (Schwartz et al, 1992; Schwartz et al, 1995b). CAFO exposures, dust concentration, endotoxin concentration, and cross-shift decline in lung function (FEV1) have been found to be significant determinants of progressive decline in lung function over time (Reynolds et al, 1996; Schwartz et al, 1995a; Schwartz et al, 1995b; Vogelzang et al, 1998; Vogelzang et al, 2000).

Occupational asthma is distinct from organic dust toxic syndrome (ODTS). ODTS results in a flu-like spectrum of symptoms including headache, joint and muscle pain, fever, fatigue and weakness, cough, shortness of breath, and irritation of the airways and the cells lining the small sacs of the lung. ODTS may be clinically mistaken for farmer's lung, as they have similar acute symptoms, e.g., the delayed onset of severe influenza-like symptoms, following exposure. However, farmer's lung (hypersensitivity pneumonitis) is seen (now rarely) in mainly dairy farming operations, but has not been documented in swine workers (Rylander, 1994). However, 33 percent (Donham et al, 1990) of swine producers have reported episodes of ODTS, which is an influenza-like illness followed by exposure to a higher than usual dust load, e.g., moving and sorting hogs. A chronic or sub acute condition (a possible variant of ODTS) has been described among swine workers and is characterized by chronic fatigue and possibly persistent mild pulmonary infiltrates (Auger, 1992). However, there are only anecdotal cases observed and no human studies that have been conducted (Donham, 1993); there is some evidence for a persistent pulmonary infiltrate condition from one animal study (Donham and Leininger, 1984).

It is recognized that several of these respiratory conditions may occur in an individual CAFO worker, and they may occur at the same time. It is possible, for instance, for an individual CAFO worker to have signs and symptoms of an asthma-like condition, bronchitis, and episodes of ODTS. This produces an interrelated group of conditions (a syndrome) of illness caused by exposure to the swine building environment (Table 1).

6.3.2.2. Control of the Occupational Environment

CAFO worker health risks can be significantly reduced through a comprehensive program of environmental monitoring and control through the use of management practices, engineering controls, judicial use of personal protective equipment, and health surveillance. However, such programs are exceedingly rare in today's CAFO industry. There is little to no exposure monitoring except for research purposes, and routine health surveillance in this worker population is rare. Engineering controls are generally implemented if they will benefit hog production, but rarely with worker health as the principal motivation. There is some evidence to suggest that healthy swine confinement workers can usually tolerate exposures to total dust (2.5 mg/m^3), respirable dust (0.23 mg/m^3), ammonia (7 ppm), endotoxin (100 EU/m^3), and micro-organisms/m^3 (10^5) without experiencing significant acute respiratory symptoms (Donham et al, 1986a; Donham et al, 1986b; Donham et al, 1990; Reynolds et al, 1996). However, further studies are needed to confirm these findings and to assess the combined effects of common CAFO exposures, including ammonia, endotoxin, and the use of disinfectants, which together appear to influence respiratory disease outcomes (Preller et al, 1995).

It is important to recognize that CAFO workers are a survivor population, meaning that the most severely affected workers have already left the workplace. In addition, there is evidence that workers exposed to inhaled endotoxin develop a tolerance (at least to acute symptoms) to this toxicant.

However, long-term exposure may lead to chronic airway obstruction, even in the absence of acute symptoms. Some previously unexposed individuals in the general community population would be expected to react acutely to lower concentrations of CAFO exposures.

Management practices and engineering controls can significantly reduce exposures to inhaled toxicants (Senthilselvan et al, 1997). These include frequent facility cleaning (frequent power washing from floor to ceiling, at least every three weeks); addition of extra fat and a urease inhibitor, e.g., microaid, to the feed; self-cleaning flooring; and improved lagoon operation (Mutel et al, 1992). The ventilation system, by itself, cannot necessarily assure a healthful environment. Health surveillance and the management procedures, mentioned above, must also be implemented. Also, the ventilation system must be properly engineered and maintained; very often, higher cool weather exchange ventilation rates are needed; and lower animal density (swine mass per unit of barn volume) may be required.

Personal protective equipment should not be considered an effective alternative to good management practices and engineering controls. Without a properly supervised respirator program, it is very difficult to assure that exposed personnel will wear the right respirator and that it fits properly, functions properly, and is worn at the appropriate time. Respirators are not well tolerated, especially for strenuous work in a hot, humid environment. The Occupational Safety and Health Administration (OSHA) requires that if respirators are worn to protect workers, they must be worn at all times, and be fit, maintained, and stored properly through an appropriately supervised respirator program. Respirators are an adjunct to management practices, engineering controls, and health surveillance, especially for specific tasks that result in higher-than-normal exposures or for workers in need of increased protection.

Special attention should be given to pregnant women who work in swine confinement facilities. The unborn fetus is susceptible to carbon monoxide and hormonal drugs used in swine production (e.g., oxytocin and prostaglandins). Pregnant women may be at increased risk for spontaneous abortion if they work in swine barns (Donham and Gustafson, 1982).

6.3.2.3. Relationships Between Indoor and External Air Environments

One cannot directly extrapolate occupational health risks observed inside CAFOs to community health risks outside swine production. Although there is discharge of airborne particulates and gases/vapors from the swine barns to the exterior environment, the aerosols differ considerably in composition and in the concentration of specific agents. As aerosols and gases/vapors emanate from a point source travel downwind, the aerosols disperse, become less concentrated and adsorbed gases/vapors may be stripped from particles. There may also be photochemical reactions and ground deposition. Volatile organics present in the outdoor air in the vicinity of a swine production facility may arise from outdoor manure storage facilities and manure application, in addition to particulate and gases in air discharged from the confinement facilities.

Although there is theoretically a definable dose-response relationship for respiratory diseases by individual compounds, the exposures inside CAFOs are always a complex, mixed exposures and differ in many ways from those outside. Perhaps equally important is the fact that the CAFO and community populations are quite different in terms of susceptibility factors. Some members of the general population, including susceptible children, the elderly, asthmatics, and other susceptible individuals, would be expected to develop responses at much lower doses than healthy workers.

Furthermore, individuals living in the vicinity of CAFOs and who may have their quality of life and social and economic conditions affected and feel stress because they have no control over their living conditions.

6.3.2.4. Conclusion

The scientific literature is quite clear that workers in swine or poultry CAFOs are at risk to acute and chronic respiratory diseases from concentrated emissions inside CAFOs. There is, however, adequate information to protect workers, if the industry and regulators take steps to do so--including monitoring engineering, administrative, and personal protective equipment. The swine and poultry industry needs to develop and manage exposures to their workers, and OSHA should take action to protect the health and safety of workers under their jurisdiction.

6.3.3. Community-Based Studies

Community exposures to environmental contamination, most of which has arisen from industrial and agricultural technology over the last 100 years, are now well-recognized public health problems. Exposures include a vast array of chemicals, noise, and ionizing radiation. Other sources of environmental contamination have arisen from the products of armed conflicts, including the some 250,000 American veterans and their families who were exposed to ionizing radiation during the above ground atomic bomb testing program from 1945 to 1962 (Ellis et al, 1992), those exposed to a variety of environmental agents, in addition to a hostile environment, in the Persian Gulf War (Schwartz et al, 1997) and community residents living in proximity to industrial sites in California (Shusterman et al, 1991). These examples, like community exposures to CAFOs, involve environmental exposures under circumstances in which there is little or no environmental control by the affected community.

Ellis has defined community environmental contamination "as a stress that is unique in terms of: 1) its physical characteristics and resultant adaptational dilemmas, 2) the agent or cause of the injury, and 3) the institutional responses to the contamination" (Ellis et al, 1992). Asked by the Centers of Disease Control to assess any adverse health effects of Iowans who served in the Persian Gulf War, The University of Iowa Persian Gulf War Study Group assessed a number of specific and non-specific health outcomes and a number of environmental exposures as well as global exposure to the Persian Gulf War theater among a sample (n=3695) of active and reserve military personnel who served in the war theater and elsewhere during the study period (Schwartz et al, 1997). Significantly higher prevalence of symptoms of depression, posttraumatic stress disorder, chronic fatigue, cognitive dysfunction, bronchitis, asthma, fibromyalgia, alcohol abuse, anxiety, and sexual discomfort were observed. Assessment of health-related quality of life demonstrated diminished mental and physical differences among the PGW as compared with non-PGW military personnel. While significant associations were observed with a number of self-reported environmental exposures during this time period, the exposures and constellation of symptoms did not fit well into an established category of disease or syndrome, but were similar to previous reports of veterans from previous wars thought to arise from the stresses of war. The specific environmental causes of the increased adverse health effects could not ascertained (nor could they be ruled out) from this study and recall bias, to which any such survey is subject, could also not be ruled out as a contributing factor to these associations. Shusterman and colleagues (1991) studied both "environmental worry" and self-perceived environmental odors (especially petrochemical) among 2000 Californians living in proximity to three industrial sites, as well as control sites. Observations found that both "environmental worry" and perceptions regarding odor were associated both independently and interactively with symptom reporting. Recall bias was recognized as a potential confounder for some of these findings. These methodological approaches are relevant to studies of other community environmental exposures, such as those that arise from CAFOs that include both specific environmental agent exposures and more global (odors/mixed exposures) community exposures, arising from a given source(s) of environmental exposures.

6.3.3.1. Community Studies of Concentrated Livestock Exposures

Schiffman and colleagues (1995) studied North Carolina residents who lived in the vicinity of intensive swine operations (n=44), and compared with matched control subjects who did not live near such operations (n=44). Using a validated Profile of Mood States (Schiffman et al, 1995) they found more negative mood states among those living in proximity to swine operations. The factors affected included tension, depression, anger, reduced vigor, fatigue, and confusion. Greater total mood disturbance was also reported by those living near swine operations. These authors suggested that a variety of factors may have affected the mood of those exposed to odors and living in proximity to swine facilities.

Thu and colleagues (1997) found no difference in the clinical levels of depression or anxiety between Iowans (n=18) living within two miles of a 4,000 sow CAFO and a random sample of demographically similar rural residents (n=18) living near minimal livestock production. However, higher rates of four clusters of symptoms common among CAFO workers and associated with toxic air exposures were observed: (Cluster 1: sputum, cough, shortness of breath, chest tightness, wheezing, p=.02; Cluster 2: nausea, dizziness, weakness, fainting, p=.04; Cluster 3: headaches, plugged ears, p=.06; Cluster 4: runny nose, scratchy throat, burning eyes, p=.12), whereas other symptoms including muscle aches, hearing problems, skin rash, and fever did not differ between the two groups. The authors drew attention to the similarities between the pattern of symptoms among these community residents and CAFO workers and suggested that a larger population-based study was needed.

Wing and Wolf (2000) conducted a population-based study of three rural North Carolina communities, one of which was in the vicinity of a 6,000-head hog operation, one in the vicinity of two intensive cattle operations, and a third area without "liquid waste" livestock operations. A standardized questionnaire was administered by trained interviewers to ascertain health symptoms and indicators of quality of life during the previous 6 months. 155 interviews were completed with a participation rate of 86%. Those living in proximity to the swine operation reported increased rates of headaches, runny nose, sore throat, excessive coughing, diarrhea, and burning eyes compared to rural residents with no livestock operation. Quality of life measures among those living in the vicinity of the swine operation were greatly reduced. The authors were aware of potential recall bias and, therefore, presented the study as a "rural health" study which did not include any questions about hogs, livestock, or odors. They also pointed out that eight symptoms in the miscellaneous category did not differ between the hog and control communities, thereby minimizing the likelihood of significant recall bias.

Hodne and her University of Iowa colleagues are currently testing the relative power of aspects of medical models and bio-psychosocial models to assess the mental health consequences of CAFO community exposures. For example, they report greater traumatic cognitions associated with post-traumatic stress disorder among residents of rural areas with many CAFOs and areas with traditional livestock production than among rural residents in areas with very little livestock (Hodne, 2001).

They are also exploring the types of stress responses in CAFO neighbors that may mediate the relationship between air emissions and odors and physical and mental health outcomes.

The three published, peer reviewed studies of community residents exposed to CAFO emissions are limited and should be interpreted with caution because of the relatively small numbers of participants, because they did not report environmental exposure data and likely contain some recall bias. However, they are notable because they were all well designed, controlled studies and because the two of the three that examined respiratory and other symptoms common among CAFO workers found similar symptom patterns (while not as prevalent or severe) as those observed among CAFO workers. Two of the three studies also reported indicators associated with diminished a quality of life among those living in proximity to livestock facilities as compare to community controls.

6.3.4. Conclusion

Numerous occupational studies have documented significant increases in respiratory disease and other respiratory adverse health effects, including CAFO-related deaths, acute and chronic respiratory diseases and associated symptoms and acute losses in exposure-related lung function and progressive respiratory impairment, among those who work in CAFOs. However, it is recognized that the CAFO workforce is generally healthy, while those in the general community, including children, the elderly, those with chronic impairments such as pre-existing asthma or chronic obstructive pulmonary disease, are expected to be much more susceptible to CAFO exposures. There is experimental and epidemiological evidence that very low levels of exposures to ammonia, hydrogen sulfide, known to be ambient air toxic gases arising from CAFOs, may result in adverse health effects among healthy volunteers and community residents. While limited in number and scope, the currently published, peer reviewed, community-based studies of adverse health affects associated with CAFO exposures find an increased prevalence of similar symptom patterns, especially respiratory symptoms, and similar indicators of reduced quality of life. Taken together with other experimental and epidemiological observations of adverse health effects observed with low levels of exposures to chemical components (ammonia, hydrogen sulfide) of CAFO emissions, these findings support a conclusion that CAFO air emissions constitute a public health hazard, deserving of public health precautions as well as larger, well controlled, population-based studies to more fully ascertain adverse health outcomes and their impact on community health services.

TABLE 2
Major Hazard Categories in Swine Production.

Hazards	Subcategories	Examples
Chemical Hazards	Asphyxiation	Carbon monoxide
	lung injury	Nitrogen oxides, ammonia
	contact dermatitis	Allergic, irritant
	Poisonings	Pesticides, fuels, cleaning agents
	Intoxication	Solvents, silo gas, substance abuse
	Immunomodulation	Adjuvants: biocides, phytotoxins
		Immunosuppressants: pesticides
Biological Hazards	Microorganisms	Pathogenic
		Non-pathogenic
	organic dust	Bacterial toxins: endotoxins, exotoxins, enterotoxins
		Fungal toxins: mycotoxins, glucans
		Phytotoxins
		Inflammatory agents
	Aeroallergens	Arachnid detritus
		Animal proteins
		Allergenic fungi
Infectious Hazards	Zoonotic	Systemic
	non-zoonotic	Lung
	antibiotic resistance	Skin
	emerging pathogens	Ocular conjunctivitis
Biomechanical Stress	Trauma	Animal bites
		Falls
		Needle sticks
		Punctures, lacerations, abrasions, burns
		Crushing injuries
		Repetitive trauma
	Noise	Noise-induced hearing loss
		Reduced safety from impaired hearing
Thermal Stress	heat stress	
	cold stress	
Emotional Stress	Occupational	Suicide
	Marital	Depression
	Financial	Anxiety
Drowning		Lagoons
		Pits
		Farm ponds
Fires/explosions	Chemical	Methane in pits
	Electrical	Ignited building materials or feed
	Welding	Ignited building materials or feed
	organic material	Grain, grain dust, compost, hay
Electrocution		Faulty wiring
		Water associated
Chronic pain	Biomechanical stress	Arthralgia
	Arthritis	Myalgia
Fatigue	sleep deprivation	Planting, harvesting
	chronic fatigue syndrome	Chronic endotoxin exposure

Introduction
The impacts of Concentrated Animal Feeding Operations (CAFOs) should be judged in terms of their socioeconomic impacts on rural Iowa and its communities as well as their impacts on human and animal health. Regulations and management practices should support socially and economically desirable community outcomes, as well as protect human and animal health. It is the role of government to select from among the regulatory options that contribute to economically viable, socially equitable, and environmentally sound communities (President's Council on Sustainable Development, 1996).

7.1 Quality of Life and Community Social Capital
Quality of life factors are emphasized in recent literature addressing the community impacts of CAFOs. The state of Minnesota recently brought together the scientific and public policy communities to advise state government on how to address several CAFO issues, resulting in a Generic Environmental Impact Statement (GEIS) for animal agriculture. It suggests, "Quality of life is related to perceptions of 1) having alternatives in what one does on a daily or life cycle basis, and 2) being respected by family and communities of interest and place." (Flora et al., 1999:A24).

An important aspect of community quality of life is social capital, which includes mutual trust, reciprocity, and shared norms and identity. In general, communities with greater social capital provide greater quality of life (Flora, 1998; Flora, Sharp, Flora, Newlon, 1997; Sharp, Agnitsch, Ryan, Flora, 2001). Also, social capital emerges as an internal resource in instances of controversies.

7.1.1 Agricultural Structure, Quality of Life, and Economic Vitality
Quality of life issues related to the structure and scale of agriculture were examined as early as the 1940's. More than half a century ago, Goldschmidt (1978; originally published in 1946) compared two rural California communities where the structure and size of farms were different, but where total value of farm production was almost identical. In the town where farms were larger and industrialized (with a higher proportion of absentee ownership and employing a higher proportion of farm workers per unit of output) there was greater separation of social classes, i.e. greater social inequality. More decisions about local affairs were made outside the community. This contrasted with the other community where farms were smaller, more likely to be owner operated, and utilized the labor of the operating family with some hired labor. This community had a richer civic and social fabric: residents of all social classes were more involved in community affairs, more community organizations served people of both middle and working class background, and there were more local businesses and more retail activity because more agricultural and consumer purchases were made locally and more income was in the hands of the classes with a greater propensity to spend. MacCannell, in a macro study that included family-farm and industrial-agricultural communities in 98 industrial-farm counties in California, Arizona, Texas, and Florida, found that mean farm size (in acres), gross farm sales, as well as high levels of mechanization "significantly predict declining community conditions not merely at the local agricultural community level, but in the entire county." (1988, p. 63.)

Recent studies, including those in the Midwest, reveal tendencies of economic decline in communities with greater concentration of CAFOs, similar to Goldschmidt's thesis of greater rural community decline with greater industrialization of agriculture. The econometric analysis conducted by Gomez and Zhang (2000) over a decade revealed the negative impact of swine CAFOs on economic growth in rural Illinois counties, as indicated by sales tax receipts. They found that purchases from small businesses declined as concentration of CAFOs intensified. In a Michigan study, Abeles-Allison and Connor (1990) found that local purchases of supplies for swine production decrease as CAFO concentration increases. Local expenditures per hog were calculated at $67 for the small farms and $46 for the large farms. The difference is largely due to bulk feed purchases from outside the community by the larger farms, but is also related to somewhat greater total expenditures per hog on the smaller farms. Durrenberger and Thu's (1996) finding that increased food stamp utilization is associated with industrialized hog production in Iowa suggests either that industrial agriculture generates inequalities or that industrial agriculture thrives in counties with greater inequalities

Foltz, Jackson-Smith and Chen (2000) examined local purchasing patterns of large and small dairy farms in Wisconsin. They found that the percent of dairy feed purchased locally declined as herd size increased. Stronger indicators of local feed purchasing were the physical nearness to and social attachment to the community. In Minnesota, Chism and Levins (1994) found that local spending was not related to gross sales volume on *crop* farms. However, local farm-related expenditures fell sharply when the scale of livestock operations increased.

Otto, Swenson, and Lawrence (cited in Kliebenstein, 1998) found that local property tax revenues and state revenues in Iowa, calculated on a per sow basis, were as follows:

Table 7.1. Net Benefits And Net Revenues To Local And State Governments From Farrow To Finish Operations, Iowa

Size of operation	150 sows	300 sows	1,200 sows	3,400 sows
Net Local Government Benefit per sow	$8.84	$9.35	$10.43	$8.23
Net revenues to State Government per Sow	$16.01	$17.19	$14.59	$12.86
Sum of local and state revenues	$24.85	26.54	$25.02	$21.09

Overall, more moderate-sized farrow-to-finish operations generated more local and state revenues per sow than did small or very large ones.

Quality of life issues that relate to agricultural structures are evident in Eastern North Carolina. This region experienced a tremendous growth in the hog industry beginning in the 1980's that includes both contract and corporate production facilities and meatpacking plants. Many citizens there perceive that this ha s left them with a power structure in which the interests of large pork producers dominate those of local residents at all levels of government (McMillan and Schulman, 2001; Thu and Durrenberger, 1994).

In North Carolina, Wing, Cole, and Grant (2000) have found patterns of disproportionate siting of corporate CAFOs in rural lower-income and African-American communities. This places residents of these communities at disproportionate risk for health and socioeconomic problems.

7.1.2 Quality of Life, Community Social Capital and Community Conflict

Wing and Wolf's (2000) study of 50-55 individuals from each of three North Carolina rural communities showed that quality of life was greatly diminished among who residents near a

6,000-head swine confinement operation, compared to residents near two intensive cattle operations or near an agricultural area without livestock operations that required liquid waste management. Quality of life was indicated by the number of times that neighbors could not open their windows or go outside even during nice weather due to CAFO odors.[1] Thirty percent of respondents from around the hog CAFO as compared to a maximum of three percent from the other two communities indicated that each of these problems had occurred 12 or more times during the past six months. Many rural residents comment that it is difficult to plan social activities in their homes because of the uncertainty of whether the air will be tolerable for guests (see Donham & Thu, 1996; Wright et al., 2001, pp. 28-30, for similar health and social responses near Minnesota CAFOs). Such limitations on social relations with one's neighbors indicate a decline in community social capital (Ryan, Terry, & Besser, 1995).

Lasley's Iowa Farm and Rural Life Poll (1998) shows substantial concern among Iowa farmers about hog odors. In the 1992 and 1998 polls, respondents were asked "how many days per year they would be willing to tolerate odors from a neighbor's livestock operation before they would consider it a major nuisance." Fourteen percent were unwilling to tolerate more than two days; 34% were willing to tolerate only a week or less, and fully 50% would view odors as a major nuisance if they affected them as many as ten days out of the year. The latter figure rose from 44% in 1992 (Lasley, 1995). Three-fourths of Iowa farmers live within half a mile of a neighbor. In addition the proportion of respondents agreeing with the statement, "Increasingly, manure management is a major issue in the livestock industry," rose from 61% to 85% of Iowa farm respondents between 1992 and 1998.

Characteristics of the nearest CAFO and of the affected neighbor influence the latter's level of annoyance with CAFO odors. Van Kleek and Bulley (1985), in a study conducted in the early 1980s in British Columbia, chose 14 swine farms, 14 beef feed lots, 11 laying hen firms, and 10 broiler farms located at least 800 meters (somewhat less than ½ mile) from any other livestock farm. A least 12 residences (non-producers of livestock) were within 800 meters of each livestock farm. Those residents rated their perception of the livestock farm "as it relates to your living here" on a five-point scale from "no nuisance/very compatible" to "severe nuisance/incompatible."

The authors found that nuisance potential decreased with distance, but it decreased the least for hog farms. Larger farms were a greater nuisance than smaller ones, but the difference disappeared for residences that were at very close ranges from the livestock farm. Hog farms were considered the greatest nuisance, followed by cattle feedlots and then by poultry CAFOs. Odor represented 75% of the total nuisance, but the proportion differed according to the type of farm; for hog farms, 95% of the nuisance responses related to odor; for broilers, ¾; for layers, 2/3; and for feedlots, only about half. People with rural backgrounds were less tolerant of livestock farms than were those who had come from urban areas; those with farm backgrounds did not differ from those without farm backgrounds. Lohr (1996) found that among neighbors of a swine farm, tenure of residence, previous contact with the

[1] Miedema and Ham (1988) used an independent dispersion olfactometric testing method in a study designed to determine if specific complaints and symptoms from odors were indeed correlated with independent measurement of the presence of agricultural and industrial odors. Individuals living near a pig sty, a rapeseed oil extraction plant, and an electric wire insulation factory, were surveyed. Level of annoyance with the odor and reported frequency of having to shut windows because of the odor were linearly related to the frequency of detection of odor using the olfactometric test. Interestingly, the pattern of relation was not specific to the type of odor being measured.

farmer, and economic dependence on farming all negatively correlated with the degree of odor annoyance.

Debate continues, in popular and academic circles, on whether CAFO odors are best characterized as primarily nuisances of varying degrees or whether these odors are also linked to negative health outcomes (Thu, 1998). Donham (2000) describes possible non-toxic mechanisms for CAFO odors to generate physical symptoms through complex interactions of the brain and somatic systems. Shusterman (1992) describes some of these mechanisms in his review of the health impacts of environmental odor pollution.
The well-researched linkage of physical symptoms to the uncontrollability of various stressors including environmental stressors (e.g., noise) may be applicable to CAFO odors as noted in Chapter 6.3. In addition, the variety of family, neighborhood, and community stressors sometimes associated with CAFOs may also generate stress-induced symptoms and illness. However, these possible linkages have not yet been reported.

All sides of CAFO controversies tend to frame their issues and identities in terms of rights and entitlements, as described in McMillan and Schulman's (2001) research on the hog industry in North Carolina. For example, producers defend their property rights and a right to earn a living from their land, while neighbors defend their right to enjoy their own property. De Lind (1995) documents that in response to local opposition to a corporate CAFO or "hog hotel" in Parma township in Michigan, the Farm Bureau, the Pork Producers Council, and other agricultural interests defended the right of "hog hotels" to exist without regulation by appealing to the right to farm.

Constance and Bonanno (1999) document actions of anti-CAFO groups in the Texas Panhandle. They focus on episodes of resistance carried out by local residents and environmental groups who were mainly motivated by human health and property value concerns. Corporate responses to community resistance primarily involved reconstruction of their corporate image as environmentally friendly.

A decline in social capital is associated with swine CAFOs, according to rural residents of Iowa, North Carolina, Minnesota, Michigan, and Missouri who describe violations of core rural values of honesty, respect, and reciprocity, as reported in an interdisciplinary workshop held in Iowa on swine CAFOs (Thu et al., 1995, p. 76). For example, CAFO neighbors often consider it a violation of respect when their concerns are labeled as emotional, perceptual, and subjective or are dismissed as invalid or unscientific.

Recent findings are presented by Kleiner, Rikoon and Seipel (2000), who found that in two northern Missouri counties where large-scale corporately owned swine CAFOs are dominant, citizens expressed more negative attitudes regarding trust, neighborliness, community division, networks of acquaintanceship, democratic values, and community involvement. The county that was dominated by independently owned swine operations had the most positive attitudes regarding trust, neighborliness, community division and networks of acquaintanceship.

The siting of a swine confinement facility in Parma, Michigan in the mid-80s (DeLind 1995, 1998) generated conflict when the firm established a five-unit CAFO with manure lagoons. Neighbors believed the three open-air 42 million gallon lagoons compromised their health and quality of life. Local resistance culminated in the emergence of two grassroots organizations and a four-year litigation process. Consequences of this conflict were anger on the part of residents who believed that their environment and their integrity had been violated, resentment towards public officials, polarization within the community, vandalism, alienation, and verbal threats and physical aggression by both sides. Although the opponents of the CAFO won the battle on the local level (the CAFO went bankrupt), when they were interviewed a few years later, they felt the personal acrimony and divisions in the community resulting from conflict over the smell from the lagoons were too high a price to pay.

Wright et al. (2001) reported results from a six-county study in southern Minnesota regarding changes in animal agriculture. Over one hundred producers, community leaders, and others were interviewed, either in roundtable discussions or individually. Three patterns reflect the decline of social capital that resulted from the siting of CAFOs in all six rural communities: 1) widening gaps between farmers who produce livestock within CAFOs and their neighbors, including non-CAFO livestock producers; 2) harassment of vocal opponents of CAFOs; and 3) perceptions by both CAFO supporters and opponents of hostility, neglect or inattention by public institutions that resulted in perpetuation of an adversarial and inequitable community climate.

The North Central Regional Center for Rural Development (1999) examined recent, dramatic increases in corporate hog production and meatpacking in a rural Oklahoma county. Social capital indicators measured mutual trust, reciprocity, and shared norms and identity. Individual security was measured in terms of crime, and community conflict was measured in terms of civil court cases. The overall crime rate increased dramatically between 1990 and 1997. Violent crimes increased 378 percent compared to the average 29 percent decrease in violent crimes over the same period in comparison farming-dependent counties with no dramatic changes in animal agriculture. Theft-related crimes also increased in the case county by 64 percent, compared to a decrease of 11 percent in comparison counties. Civil court cases, indicating community conflict, increased in the county by 7 percent, while they decreased 11 percent in comparison counties. This study dramatically reveals the costs to social capital in counties experiencing rapid and dramatic change in the structure of animal agriculture.

7.2 Agricultural Restructuring and Population Trends

The primary purpose of this section is to provide background for partially answering Director Vonk's question 4: "What do you think should be done to address any other emerging issues with respect to industrial CAFOs in Iowa?" It is useful to begin with a discussion of rural population patterns in Iowa since the beginning of WWII. That is followed by an examination of recent changes in the structure of animal agriculture (and crop agriculture insofar as it interacts with animal agriculture) and how public policy relates to those changes. The general trends in livestock and poultry production are presented in Chapter 2.

7.2.1 Rural Population Dynamics since WWII

Agricultural restructuring since the initiation of WWII transformed the landscape of rural Iowa. As a result, Iowa's rural population generally has decreased across the decades. Using a definition of rural as an incorporated place with fewer than 2,500 residents plus those who live on farms or in the open country, Iowa had about 1,454,000 rural residents in 1940 and 1,094,000 in 1990. Although final figures are not available from the 2000 census, it appears that a slight increase occurred in Iowa's rural population in the 1990s. Major differences have emerged among three sectors—residents of farms, small towns, and the country. The first of these dropped substantially[2], the second remained much the same[3], and the third grew substantially[4] across the decades.

Small towns tend to have the oldest age structure of the three types; that is, that have proportionately greater numbers of older and fewer numbers of younger residents than do the farm or country categories. This is because many older residents do not move in later life (or if they do change residences, they move from the countryside to nearby towns) and many high school graduates seek urban-based educational and occupational opportunities. This loss of youth is later magnified as they form families elsewhere. The farm population approaches a pyramidal shape, in part because many older residents move from the farm in later life; some others stay on the farmstead but no longer operate the farm (which may be absorbed into a neighbor's farm operation). Of the three groups of rural residents, the country population most closely approaches the classical pyramidal age structure. It includes younger residents with children. Country residents often are newcomers to the area; they may have perspectives that differ from those held by long-term residents. It is not easy to categorize country residents because of their more diverse origins and backgrounds.

7.2.2 Restructuring of Livestock Production in the Past Decade

Until the past decade or so, the industrialization of farm production had largely bypassed Iowa, with the exception of the fat cattle industry, which had its heydey in Iowa in the 1950s and 1960s (see Table 2.9 in this report). In the 1990s, Iowa hog and poultry (particularly egg) production were transformed (see Chapter 2, Table 3 of this volume). Furthermore, different types of animal production systems may generate different socioeconomic impacts at the level of the farm and community. Farmers, rural residents, and others express concern that increasing CAFO production is having negative impacts on the traditional family farm structure (e.g., Halverson, 2000). Buttel and Jackson-Smith (1997) surveyed 1,100 randomly selected Wisconsin farmers in 1995 and repeated the survey with 1400 farmers in 1999 (Jackson-Smith, et al., 2000) regarding their views toward large-scale livestock production. Only 17 percent of the respondents perceived expansion in the livestock industry as a good initiative, while 45 percent perceived it to be negative. Only 15 percent indicated that non-farm investors should invest in dairying in the local community (Buttel and Jackson-Smith, 1997). Results were similar in 1999.

Wisconsin farmers' views towards livestock expansion were not shaped primarily by concerns about the environment but instead by concerns about farm structure in their state. Farmers' responses indicated strong support for family-scale operations as opposed to large-scale farms using hired labor-type and to investor-owned dairy operations.[5] The authors

[2] Number of persons resident on farms has declined across many censuses. Since 1940, when 917,000 lived on farms, Iowa lost at least 120,000 farm people each decade to 1990, when 257,000 were counted, the most recent data available (the 2000 farm population will be released later in 2002). The number of farms in Iowa decreased from about 213,000 farms in 1940 to 91,000 in 1997.

[3] Small towns (fewer than 2,500 inhabitants) contained about the same number of residents in 1990 (460,000) as they held in 1940 (471,000). From 1990 to 2000, 464 of the 829 towns with fewer than 2,500 residents in 1990 increased in size. Only among the smallest-sized category—places with fewer than 100 residents in 1990—did a majority of towns decline in population.

[4] About 66,000 country residents were counted in 1940 and 377,000 in 1990. In 1990, for the first time, country residents outnumbered farm residents in Iowa. Strong increases among country residents have occurred in each decade for which data are available. Gains among country residents tended to occur across counties regardless of the trends among farm or small-town residents.

[5] The Iowa Farm and Rural Life Poll (Lasley 1999) has not asked questions that get as directly to views of the structure of agriculture, but they appear to hold similar views. In the 1999 poll, over half of farmers

concluded that the bulk of the farmers who oppose livestock expansion do so because of a strong concern that it would erode the status of family farming in the state.

The increasing production of hogs through contract relationships, following that of poultry (Morrison, 1998), is becoming central to socioeconomic, health, and environmental concerns regarding CAFOs. One reason that agribusiness firms contract with producers, or contract with intermediary firms who subsequently contract with producers is to gain greater control over the production process (Welsh 1997), moving decision-making from the farm level to higher levels in the vertical system. Rarely do poultry growers own the birds they raise, and the pork industry appears to be moving in that direction (Morrison, 1998). Among major livestock production systems, cow-calf operations remain the most staunchly controlled at the farm-level.

In Kentucky the fulcrum of recent agricultural policy debate has been a proposed joint liability provision within state regulations. This provision would make corporations that retain ownership of animals (integrators) and the growers who raise animals jointly liable for resultant environmental damages or production facility closings. Burmeister (2000) suggests this joint liability provision reflects a societal attempt to control the social risk of changes in animal agriculture.

Research on the social/community impacts of different forms of contracting versus spot markets is scarce. For example, there has been no systematic research on animal producers who lose production contracts. Certain contract livestock producers are organizing to gain more regulatory and contractual protection (Hamilton, 1995; Roth, 1995). Whether such protection will generate substantial socioeconomic and environmental benefits to these producers and their communities may be measurable in the future.

Contract farming, while seen by some livestock growers as their best available option for remaining in farming, is problematic for others. In 1999, 70 percent of Iowa farmers favored greater regulation of contracts in farming (Lasley, 1999). Other alternatives should be encouraged—particularly ones that are compatible with changes in consumer demands and with environmental quality. A growing proportion of consumers are concerned about sub-therapeutic use of hormones (as discussed in the Executive Summary), humane treatment of animals[6], and the health and well being of producers. The socioeconomic, health, and ecological benefits of sustainable methods of agricultural production, including pork production as described by Ikerd (1998), are gaining recognition. For example, Lyson and Barham's (1998) found evidence of greater sustainability of middle-size, family farm operations over large-scale, corporate farms. They used measures of profitability, decreased

---

responding strongly agreed with the statement, "There is too much economic power concentrated in a flew large agribusiness firms, and when the "agreed" category, the proportion agreeing rises to nine in ten farmers. The percentage agreeing with the statement, "If things continue as they are now, in a few years farmers will be treated like employees on their own farms," was only modestly lower (46% and 85%, respectively).

[6] In an unpublished survey conducted by the Animal Industry Foundation in 1989 nearly 80 percent of those polled supported current practices of farm animal treatment (cited in Ohlendorf, Jenkins and Tomazic, forthcoming). But in the same survey two-thirds of those polled were in favor of increased regulation of production practices. Following up on this data, Ohlendorf et al. asked more than 2,700 consumers whether they agreed or disagreed with the statement "I would be willing to pay more for meat if it meant more humane treatment of farm animals." While 23 percent of those surveyed were undecided, one-half of all respondents agreed with the statement. There is no significant variation in agreement with this more pro-animal attitude across economic classes. This is at odds with the prevalent notion that consumer concern is much more different socioeconomic groups would be willing to pay.

resource use, and stable or increasing farm numbers in a community (See also Lasley, Hoiberg, & Bultena, 1993).

Thus, it is not necessary that CAFOs be the only, or necessarily even the dominant, way in which livestock will be fattened or milk or eggs will be produced in the future. Perhaps, it would be more correct to say that public policy—the collective will—could lead animal production either toward a continued growth of CAFOs at the expense of all others, or toward more pluralistic production regimes—which would undoubtedly include CAFOs without their necessarily being the dominant form of production.

7.2.3 Market Restructuring

While the structure of livestock production is changing rapidly, so is the marketing structure. The most important shift in livestock marketing is the expansion of vertical integration and the potential of an alternative form, vertical coordination (see Tweeten & Flora, 2001, for a thorough treatment of this topic). Vertical *integration* occurs through a *supply chain,* while vertical *coordination* operates through a *value chain.* Table 7.2 indicates important differences between the two.

Supply chains are oriented by myriad decisions of many producers—usually in an atomized market or perhaps nudged by government supply-limitation (until 1996) or supply-encouraging (after 1996) incentives. Value chains respond to the demands of consumers. Increasingly supply chains have come to be vertically integrated, reducing the freedom of the farmer to make on-farm and marketing decisions. The poultry grower neither owns the birds, nor makes decisions about how they will be produced. S/he is required to market

Table 7.2 Comparison of Features of Supply Chains and Value Chains

SUPPLY CHAIN	VALUE CHAIN
Producer oriented	Consumer oriented
Supply driven	Demand driven
Emphasis on reducing costs	Emphasis on creating value
Focus on volume	Focus on quality
Undifferentiated commodity	Differentiated products
Source (of commodity) is anonymous	Product may be traced to specific producer (identity preservation)
Many independent decisions (particularly at producer level)	Few cascading decisions
Open entry of new producers	Entry of new producers is limited
Susceptible to vertical integration	Requires at least some vertical coordination

Table adapted from C. Flora, et al. (1999), who adapted it from Cook (1997) and Hughes (1998).

to the integrator, and cannot be certain of the price s/he will receive for growing the birds. This lack of market discovery is also becoming more common in hog and cattle marketing, as processors, who increasingly buy directly from the farmer, are not required to publicly disclose the prices they pay. In the poultry business, contracts are from year to year. If they are terminated, there may be little likelihood of finding another integrator to sell to, since generally only one or two poultry integrators is active in a particular locale (Bjerklie, 1995; Griffith 1993; Heffernan & Jenkins, 1983).

The processor has typically controlled vertical integration, but increasingly retailers[7] are gaining the balance of power in the food supply chain. Vertical coordination has the potential to be more collaborative and decentralized. Value chains are more amenable to a team approach, since flexibility in production is essential if production is to respond to changing consumer preferences. Farmers have little power under vertical integration, while they may band together to control or share control through vertical coordination. Vertical coordination does not ensure farmer power, but it is certainly amenable to farmers collectively exercising that power—if they are willing to key their production on diverse consumer desires and to devise ways to shorten the supply chain (Tweeten & Flora, 2001). Of course, state and local governments and institutions of higher learning can be helpful with information and linkages, particularly if they address previous constraints to promoting sustainable agricultural practices (Lacy, 1993).

At present, hog production—though much more concentrated than it was a decade ago--is much less concentrated than is pork processing.[8] Heffernan, Hendrickson, and Gronski, (1999) estimated that in 1998, the fifty largest producers controlled about one half of all marketed hogs, and only one of the top five producers had substantial presence in Iowa. Most states where corporate hog production predominates are states where large numbers of hogs were not produced previously or where farms are smaller and less prosperous. One author argues convincingly that broiler integrators chose to focus on the South precisely because small farmers often were underemployed and desperately needed additional income (Bjerklie, 1995). The degree to which integrated hog contracts in Iowa and other parts of the Midwest are favorable or unfavorable to farmers will depend on the overall vitality of the rural parts of those states. When growers have or perceive they have few other options, they are more likely to sign unfavorable contracts.

7.2.4 Impetus for Alternatives in Production, Processing, and Marketing

One means of preserving identity is through shortening the value chain—bringing producer and consumer closer together. Shortening the value chain is important for the development of alternative production systems. Reducing the steps between producer and consumer contributes to quality control. Trust can be substituted for costly inspection systems, and immediate and direct feedback will occur when quality is inadequate. In addition, quality may be redefined in unconventional ways. For instance, the consumer may be willing to forego cuts of meat in uniform and predictable sizes if s/he has assurance that sub-therapeutic hormones are not used, or that animals are treated humanely.

If this sounds like each farm family would do its own direct marketing (which often falls to the female partner in a producer family), it does not have to be. A critical piece is socializing the transaction costs involved in identity preservation and quality assurance. This can be accomplished through devising novel collaborative means of marketing and identity preservation that are satisfying to the consumer, but which do not require each producer family to make its own marketing links or to individually organize its own system of quality assurance. Different kinds of producer-controlled or -influenced value chains, such as marketing cooperatives, joint ventures between corporate entities and producer associations, producer-consumer coalitions such as Community Supported Agriculture (CSA) groups

[7] Between 1997 and 2000, the market share of the top five food retailers operating in the U.S. rose from 24% to 42%. Hendrickson, et al. (2001) argue that increasingly, market power is shifting from processors to food retail chains.

[8] In 1998, the top four pork processors marketed 57% of all hogs in the country. The following year, according to the New York Times, the top six firms processed 75% of all market hogs. In 2001, the largest processor, Smithfield, bought IBP, which had ranked second in 1998 (Heffernan et al., 1999; 16)

(Cone & Myhre, 2000), or local marketing cooperatives (Ziegenhorn, 1998) can lift the marketing burden from the shoulders of individual producers.

Only with involvement of market (private for-profit firms, including family firms and farms), state (governments at different levels), and civil society (not-for-profit organizations, such as producer organizations, certification entities, etc.) can vertically coordinated value chains compete with vertical integration and supply chains. We often forget just how large a role various levels of government play in subsidizing commodity supply chains and vertically integrated firms within our food system (see North Central Regional Center for Rural Development, 1999: 6-20, for a detailed discussion of the "incentives" used to encourage Seaboard Corporation to build a pork packing plant in Guyman, OK).

Which of these factors may influence the future of the livestock industry in Iowa and how might they relate to odor regulation? Clearly, Iowa's competitive advantage in grain and livestock production is an important element. Some argue that Iowa may regain market share in cattle and hog feeding that has recently been lost to the Great Plains (cattle) and to North Carolina (hogs), given Iowa's competitive advantage in cheap grains. The 1996 Freedom to Farm Act, by dismantling price supports and the supply management system, encouraged production of corn and soybeans (Harl, 2001). Currently, low grain prices do not encourage farmers to shift to higher value crops, since loan deficiency payments increase as market prices decline. This has encouraged CAFO production in the Midwest where grain is cheap. It has also favored CAFO production over diversified family farming. CAFOs can purchase feed grains at market prices lower than costs to family farmers of feeding their own grain, since market prices have recently been below cost of production for family farmers.

Another important factor is the differential contribution of environmental protection to the cost of production by region. All other things equal, the more dense the human population, the greater the cost of environmental protection to the producer—if there are mechanisms for internalizing those costs, rather than their being paid by the society at large. The initial moratorium on building new hog CAFOs in North Carolina and its recent extension suggest that hog odors and water contamination can provide the political impetus for internalizing these costs in heavily populated areas. Should the Environmental Protection Agency increase the amount of land that is required for disposal of manure because of concern about excess phosphorus application, production in Iowa would be favored over North Carolina, although Iowa might be disadvantaged vis-a-vis the Great Plains.

Policy makers' consideration of alternative means of regulating odors must take into account which farmers are disadvantaged by the regulations and what those regulations may mean in terms of encouraging certain desired futures for rural Iowa—and Iowa in general.

In this section we have provided evidence that industrialized commodity production and corporate controlled supply chains are not the only alternative. Regulation of odors and other airborne products should take into account various options, and encourage those that are more socially desirable.

7.3 Changes in Property Values

In the next section we consider changes in animal agriculture as they relate to the final form of community capital - financial capital. Several studies examine effects of nearness to a CAFO on real estate values. Abeles-Allison and Conner (1990) chose eight Michigan hog CAFOs and then examined residential sales within a five-mile square block centered on each CAFO. They analyzed data on 288 sales between 1986 and 1989. For every thousand hogs added in the five-mile area, they found an average drop in sale price of $430 per property. The depression of sale price was much greater when the residential property was less than 1.6 miles away from the respective hog farm. Using state-wide data, they found, for the first half of 1989, that odor complaints were 50 times more likely to be lodged against any particular hog CAFO of over 500 head than against smaller hog operations.

Palmquist, Roka, and Vukina (1997) studied residential property values close to hog CAFOs in North Carolina. Controlling for other characteristics of the property, they examined patterns of non-farm home sales prices (n=237) over an 18-month period in 1992 and 1993. They found that nearness to large hog CAFOs and the amount of nearby manure jointly acted as a significant depressor of sales prices of up to nine percent, depending on the number of hogs and their distance from the house. Phillips et al. (1999), suggest that odors cannot be separated from other local effects from CAFOs that could also depress sales prices. These could be noise, dust from trucks, or a general decline in the natural beauty of the area.

Hamed, Johnson, and Miller (1999) found that an average vacant parcel within three miles of a CAFO in Missouri lost about 6.6% in value, but if a parcel with a house on it was within 1/10 mile of the CAFO, it lost 88% of its value!

Finally, Taff, et al., (1996) examined housing sale prices in two counties of southwestern Minnesota. The measures used to indicate feedlot proximity included distance, total animal units within a defined distance, and whether the home was downwind from any feedlots. Feedlot proximity was associated with *higher* sales prices. The authors suggest that perhaps workers desired to live close to their work.

7.4 Impact on Social and Health Services

While not examined here, studies of broader changes taking place in agriculture link housing, public services, natural resources and land use, and historical and cultural resources to the changing structure of animal agriculture. These changes are also reflected in the examples related specifically to animal agriculture.

NCRCRD research in Oklahoma (1999) found that housing rental rates increased nearly 85 percent over seven years in the county where production and meatpacking expansion occurred, compared to a 61 percent increase in comparison counties. At the same time, the influx of new workers resulted in a 47 percent decrease in housing availability. The combined result is overcrowding and shared housing situations, or a commute to neighboring counties with available and more affordable housing. These commuting costs add to the household costs of workers. Of course, the housing industry, among others, benefits from such growth.

The same research notes important implications for local educational systems. While total school enrollment increased 12 percent, resulting in construction of a new elementary school, there was a 125 percent increase in the number of bilingual or limited English speaking students. Despite an 81 percent increase in the county school budget between 1990 and 1997, both dropout rates and student/teacher ratios increased. Community costs due to increased demand on services, such as court costs from increased criminal and civil cases; law enforcement costs, and applications for public assistance and food stamps were also noted.

Other research points to additional costs of large-scale animal production to community resources: impacts on tourism and recreation due to livestock odors (McMillan & Schulman 2001); deterioration of bridges and hard surface roads (Constance 2000); and significant changes in rural landscapes and the number and condition of farm sites (Bowen 2000).

In 1990, the minority population accounted for about 4 of every 100 Iowans (4.1%); by 2000, that figure had increased to more than 7 of every 100 (7.4%). The minority population grew by 103,000 while the (white non-Hispanic) majority increased by 47,000 during the 1990s. For the first time, a significant portion of that growth in minority population occurred outside Iowa's metropolitan areas. These new Iowans were mainly attracted by jobs in meatpacking, and secondarily, in plant nurseries, construction, and certain low-wage service jobs.

While we were unable to find data on the extent of employment of immigrants and other minority groups in CAFOs in Iowa, it is clearer that industrial agriculture (packing plants in particular) employs a growing number of new residents who are culturally different from the long-term residents of rural Iowa (see Grey, 1997, 1998). Turnover in packing plant employment and hence in population (rather than presence of minority groups, per se) contributes to a number of social problems and a need for more local services, but it also brings in young, hard working, entrepreneurial (especially immigrant) families, shoring up the base of population pyramids and offering a larger working age population for years to come in certain communities that before the 1990s were aging steadily. Whether long-term residents and leadership in these communities will see these new residents as a gift or as a threat is still to be seen.

7.5 Concluding Remarks

Generally, Iowa's rural areas have had more difficulty holding their populations than have urban sections of the state. With more deaths than births[9] and greater out- than in-migration, some of these counties have had problems sustaining their populations. The encouraging news is that the only decade in the 20th century during which Iowa had more people enter than leave was the 1990s; net in-migration totaled about 50,000. Even in that case, however, 43 of Iowa's 99 counties had more residents leaving than entering in the 1990s. Although there were some major exceptions, rural counties were more frequently listed among those 43 with net out-migration than were urban counties.

If this migration turnaround is to be sustained, additional attention needs to be given to issues of quality of life. That means that the physical environment, the quality and diversity of services (particularly health and educational services), and employment opportunities will need attention. If jobs are not available, it is unlikely that others will move to the area unless

[9] In 2000, 48 counties had more deaths than births (called net natural decrease) and most were rural; only a few had an incorporated place with at least 10,000 residents. Due to the out-migration of younger people from many rural counties and the tendency of older residents to age in place, a declining proportion of the population is in the reproductive age groups. Hence, in recent decades, the number of counties experiencing net natural decrease has gradually grown. In Iowa as a whole, however, about 100,000 more births than deaths occurred throughout the 1990s.

natural and social amenities provide the premium that would attract them. Some Iowa counties have physical environments (e.g., rivers, lakes, open space) that attract residents. At present, many of the people moving to such locales already live in the state. And natural amenities are likely to be magnets only for the somewhat more affluent. On the other hand, urban areas are much more likely to benefit from employment-related moves. But then the characteristics of jobs also are related to the residents that they attract; that is, the types of employment that become available dictate at least in part the characteristics of those who will move to an area. To attract residents to a rural area, then, requires the perception that such a move may raise the quality of life through improved employment opportunities, and increasingly, access to amenities—both natural and social.

Demographic changes have a number of implications for CAFOs and vice versa. While in the 50 years between 1940 and 1990, the farm population dropped at about twice the rate that the (non-farm) country population increased, many residences remain close to livestock operations (Lasley, 1998). Since it appears that for the past decade the gap between farm population decline and the country population may be closing, hog, and perhaps poultry, CAFO odors will be a growing issue among rural dwellers.

A related issue that is suggested by the demographic patterns is the potential conflict that CAFOs and industrial agriculture generate between employment and amenities. Those communities where odors and health problems from CAFOs remain or become an issue may have a more difficult time attracting or holding population that would otherwise come because of rural communities being "a good place to live and raise a family." The amenity scale may go down not simply because of these problems themselves, but because the odor and health issues generates conflict, reducing social capital and the ability of the community to act collectively to enhance local social and natural amenities. Resolving these questions through alternative livestock production methods may make it easier for communities to encourage employment *and* to increase amenities. For example, a 2001 informal survey of 13 Iowa State University Extension livestock specialists (Honeyman et al., 2001) documented the existence of at least 2100 hoop structures in Iowa, which, with appropriate management practices, can be more environmentally friendly than CAFOs. In conjunction with appropriate marketing structures, other ecological production regimes, such as use of A-frames and rotational pasturing may be feasible.

A final set of demographic issues surrounds the health risks and desires for justice expressed by elderly rural residents residing near CAFOs. They often express concern about being at risk for respiratory problems, as well as concern that antibiotic treatments may fail them when needed. The siting of CAFOs near the rural elderly, who are less likely to move in the later years, seems inequitable to some, as does the decline in quality of life for those who have worked productively for many years, including in support of others in their communities.

Abstract
This chapter reviews the literature with regards to health hazard substances emitted from CAFOs. Furthermore, we reviewed the risk assessment process of pertinent federal agencies in regards to hazardous emissions from CAFOs. Occupational health hazards, for those working in CAFOs, have been long recognized. Research documents that current recommended or legal occupational exposure levels are not sufficient to protect workers. Although the research on occupational exposures of CAFO workers documents the hazardous nature of CAFO emissions at concentrations found inside buildings, the concentration of these hazardous substances are much lower in the ambient air of the community surrounding CAFOs. As occupational exposure limit recommendations are not highly relevant to the community, specific exposure standards are needed to help protect community residents as well as workers.

Regarding community standards, the risk assessment processes of the Environmental Protection Agency (EPA), and the Agency for Toxic Substances and Disease Registry (ATSDR) are the most relevant agencies in making recommendations for limits to community exposures. The EPA estimates levels safe for a lifetime exposure and ATSDR list levels for acute, intermediate or chronic levels. For ammonia, the EPA list 144 ppb for lifetime exposures and the ATSDR list 500 ppb for acute and 300 ppb for chronic exposure. For hydrogen sulfide, the EPA lists 0.7 ppb for lifetime exposure, and ATSDR lists 70 ppb for acute and 30 ppb for intermediate exposures. Considering these recommendations made by EPA and ATSDR, concentration recommendations, recommendations made in surrounding states, and consideration of the possible additive or synergistic effect of mixed exposures, hydrogen sulfide, ammonia, and odors should be regulated. The levels that should be considered are as follows: hydrogen sulfide, one hour time-weighted average of no more than 15 ppb at the residence or 70 ppb at the property line; ammonia, one hour time-weighted average of no more than 150 ppb at the residence and no more than 70 ppb at the property line; odors should be no more than a 1:7 dilution at the residence and no more than 1:15 at the property line.

8.1 Introduction

This chapter will review the scientific literature on exposure limits for occupational and ambient conditions, relative to CAFOs. Also, the relevance of existing standards for the health protection of workers and community residents will be discussed. Furthermore, the circumstances of mixed exposures will be reviewed. Finally, a risk assessment and recommendations for appropriate standards will be discussed.

8.2 Existing Occupational Health Exposure Limits or Recommendations

In the US, there are four sources of recommendations in regards to occupational exposure limits. These include the American Conference of Governmental Industrial Hygienists (ACGIH, 2001 TLV's for Chemical Substances and Physical Agents & Biological Exposures Indices), the American Industrial Hygiene Association (AIHA, AIHA Press, Fairfax VA, 2001), The National Institute for Occupational Safety and Health (NIOSH, Pocket Guide to Chemical Hazards, 1997) and the Occupational Safety and Health Administration (OSHA, Code of Federal Regulations, Chapter 29). The first two organizations (AIHC and ACGIH) are private professional organizations. The third, (NIOSH) is a governmental educational and research organization. OSHA is the only regulatory and enforcement agency of these four. AIHC, ACGIH, and NIOSH, only recommend worker-exposure standards, but develop science-based recommendations, and not subject to the stakeholder pressures from the administration, industry, and labor, and other constituents groups, as is OSHA. The terminology for exposure limits is different for each of these organizations. AIHC, ACGIH, and NIOSH issue, respectively, Emergency Response Planning Guidelines/Workplace Environmental Exposure Level Guides (ERPPGs/WEELs), Threshold Limit Values (TLV) and Time Weighted Average Exposure Limits (TWA). OSHA issues Permissible Exposure Limits (PEL's).

The primary exposures of occupational concern in CAFOs include ammonia (NH3), hydrogen sulfide (H2S), carbon monoxide (CO), carbon dioxide (CO2), particulate matter (PM), bioaerosols, and endotoxin. However, none of the bodies mentioned above have specified limits for bioaerosols or endotoxin. Table 1 lists the indoor concentration levels for each of these bodies for the agents specified.

Table 1. Maximum Concentration Levels Listed for Occupational Health

	NH3	H2S	CO	CO2	Total Particulate Matter	Respirable Dust	Bioaerosols	Endotoxin
AIHA	25 ppm	0.1 ppm	200 ppm	Not listed	Not listed	Not Listed	Not listed	Not listed
ACGIH	25 ppm	10 ppm	25 ppm	5000 ppm	4 mg/m^3 (Grain dust) 10 mg/m^3 (Nuisance dust)	3 mg/m^3 (Grain dust)	Not listed	Not listed
NIOSH	25 ppm	10 ppm	35 ppm	5000 ppm	4 mg/m^3 (Grain dust)	Not Listed	Not Listed	Not Listed
OSHA	50 ppm	20 ppm	50 ppm	5000 ppm	10 mg/m^3 (Grain dust) 15 mg/m^3 (Nuisance dust)	5 mg/m^3	Not Listed	Not Listed

8.2.1 Occupational Dose Response Data For Humans

Exposure-response studies in workers have included an assessment of the response to the amount of time exposed, for particulate matter (PM), endotoxin, NH3, and H2S. Endotoxin and PM concentrations have had the strongest and most consistent relationships to respiratory symptoms and decrements in pulmonary function tests (PFT) (Donham et al., 1989; Donham et al., 1995;

Reynolds et al., 1996). A significant relationship was seen between microbial concentration and bronchitic symptoms (cough and phlegm) (Donham et al., 1989). A weaker relationship of bioaerosol concentrations to tightness of chest and febrile syndromes (flu-like illness with fever) was found (Donham et al., 1989). There was no relationship of bioaerosol to pulmonary function changes. Ammonia did show some relationship to decreased baseline pulmonary function in four different studies (Donham et al., 1989; Donham et al., 1995; Reynolds et al., 1996; Cumro et al., 2001, in press). In one of the studies, the levels of microbes showed a significant dose response relationship to symptoms of hyper-reactive airways (Donham et al., 1989).

A study in The Netherlands (Heederik et al., 1991) suggested that both endotoxin and Gram-negative bacteria were related to reductions in pulmonary function, as measured by forced expiratory volume in one second, (FEV_1) and forced vital capacity (FVC). Also, significant relationships were shown between symptoms of bronchitis, or Organic Dust Toxic Syndrome (ODTS) to endotoxin or Gram-negative bacteria exposure.

8.2.2 Occupational Exposure Limit Studies

There is little scientific doubt that disease symptoms and work-shift declines in pulmonary function are related to several components of the mixture of particulate matter, bioaerosols and gases found inside CAFOs. These components include dust, endotoxin, hydrogen sulfide, and ammonia. However, the most important question in this regard is how much exposure creates a health hazard? Knowledge of the appropriate exposure limits is extremely important for controlling the work environment.

Data, which suggest the exposure limits in relation to adverse pulmonary function and symptoms, are found in four dose-response studies (Donham et al., 1989; Donham et al., 1995; Reynolds et al., 1996; and Cumro et al., 2001, in press). The first is a study of workers on 54 pig farms in Sweden (Donham et al., 1989). Several significant correlations were found between respiratory symptoms and PFT and PM, endotoxin, ammonia, and carbon dioxide. Significant relationships were seen between health measures and environmental measures taken at stationary locations in the buildings. More recent data analyses from US studies have corroborated the previous exposure limit study (Donham et al., 1995; Reynolds et al., 1996). A longitudinal study of 208 swine farmers (randomly selected from a stratified sample of all pig producers in Iowa) resulted in consistent evidence of a dose-response relationship of exposure to the dust and gases found in pig buildings and respiratory symptoms, and decreased pulmonary function. Furthermore, multiple regression analyses of the data, provided results consistent with the exposure limits previously mentioned in the Swedish study.

The fourth dose-response study mentioned previously was conducted in the poultry industry with 149 poultry production workers (Donham, Leistikow et al., 1989). This study analyzed respiratory symptoms and PFT associated with exposures to PM, endotoxin, and ammonia. Regression analysis was used to determine maximum exposure levels that predicted more than 5% pulmonary function decline with adverse health responses (Donham et al., 2000).

These four studies reviewed above are in close agreement in regard to concentration levels of contaminants that represent hazardous exposures to workers in either swine or poultry CAFOs. Table 2, lists the recommended maximum levels from the scientific literature of environmental exposures based on the four studies reviewed above. Recommended maximum exposures for swine health are also listed for comparisons sake. The worker health and swine health levels are reasonably close, indicating that protecting the health of workers also can provide benefits for health and production of swine.

Table 2. Human and pig exposure thresholds for various bioaerosol components found in swine buildings. Exposure to concentrations of contaminants in excess of values given are associated with a higher proportion of ill-health in workers, and with disease, or lower production parameters in pigs. Taken from' Donham et al., (1989);[1] Donham et al., (1995);[1] Donham (1991);[2] Reynolds et al., (1996);[2] Donham et al., (2000).[1]

Bioaerosol component	Human health[1]	Swine health[2]
Total dust mg/m^3	2.4	3.7
Respirable dust mg/m^3	0.23	0.23
Endotoxin EU/m^3	100	150
Carbon dioxide (ppm)	1,540	1,540
Ammonia (ppm)	7.0	11.0
Total microbes cfu/m^3	$4.3x10^5$	$4.3x10^5$

8.3 Ambient Exposure Limits

The EPA currently has national ambient standards for particulate matter (PM), sulfur dioxide, oxides of nitrogen, ozone, lead, and carbon monoxide. Generally, speaking, these emissions are not relevant to CAFOs, except PM. However, tracing the source of PM is difficult at this time, (although there are at least two possible methods for use, LIDAR and chemical analysis of signature molecules attached to particulates.) The U.S. EPA has promulgated standards in response to the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA: 40 C.F.R. Part 302). Under this act, regulated hazardous substances (CERCLA 40 CFR Parts 355 and 370) emitted from a point source may not exceed 100 lb/day for ammonia, hydrogen sulfide and a number of other pollutants. Ammonia emissions from four CAFOs studied swine production systems in Iowa (Zahn et al., 2001a; Zahn et al., 2001b) were recently reported to violate release, reporting requirements for NH_3 under the U.S. EPA Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, U.S. EPA, 2002). The range for ammonia emissions from these swine production sites ranged from 224 lbs NH3/day to 813.9 lbs. NH_3 day^{-1} (nder warm weather conditions). The observed aggregate emission rates for swine production facilities evaluated in this latter study were reported to exceed CERCLA reporting requirements for NH_3 by 55% to 88%. There is an additional federal act that may be relevant to CAFOs. The Emergency Planning and Community Right-to-Know Act (EPCRA) section 329(4), defines a facility to include stationary structures on a single site, or on contiguous or adjacent sites owned or operated by the same person. Under this definition, the aggregated emission rate of registered hazardous substances from all swine production facility point sources is subject to release reporting requirements. As part of the release reporting requirements, the polluting facility must develop an EPA-approved emission abatement plan to curb emissions from the emitting point sources.

Generally, there has been little published information available indicating that CAFO emissions exceed present federal Clean Air Act regulations. The EPA's 1998-draft strategy for addressing CAFO issues has not included health or air quality provisions. However, the pending revision of the

Clean Air Act will likely address these issues. There has been a USDA Air Quality Task Force working on the issues. This Task Force issued a report dated July 19, 2000, titled, "Air Quality Research and Technology Transfer White Paper and Recommendations for Concentrated Animal Feeding Operations" (http://www.nhq.nrcs.usda.gov/faca/Archives/2000/Policy/CAFO.htm) Currently, EPA has commissioned the National Academy of Science to conduct a study evaluating the human health impacts of emissions from CAFOs. This 14-month study has just begun. Generally, this issue has been left up to the individual states. The states of Colorado, and Missouri have odor regulations, based on the sentometry at 7:1, and 5.4:1 dilutions respectively at the property boundary (Colorado Department of Public Health and Environment Air Pollution Control Divisions Odor Concentration Measurement, Scentometry Test Policy for Housed Commercial Swine Feeding Operations, Colorado Department of Public Health and Environment, Denver, Colorado, January 25, 2001, www.Cdphe.state.co.us/ap/hog_policies:html, and Missouri. Pollution Control Agency, Feedlot Air Quality Summary: Data Collection, Enforcement, and Program Development, March 1999). Minnesota and California have state H2S regulations, which are 50 ppb, for not more than one-half hour, and not more than two occurrences per year, and 30 ppb for not more than one-half hour for not more than two occurrences in a 5-day period (property line of the emitter). There is also a provisional 60 ppb human risk value (HRV) limit for not more than one hour (at the receptor) (MN Pollution Control Agency). Current regulations and recommendations in regards to federal and state agencies are reviewed in more detail in chapter 9.0.

8.3.1 EPA Risk Assessments

Risk assessment has been defined as "the characterization of the potential adverse health effects of human exposures to environmental hazards" (NRC, 1983). In a risk assessment, the extent to which a group of people has been or may be exposed to a certain chemical is determined, and the extent of exposure is then considered in relation to the kind and degree of hazard posed by the chemical, thereby permitting an estimate to be made of the present or potential health risk to the population exposed. Regarding the primary inhalation exposures in CAFOs, the U.S. EPA has completed risk assessment evaluations for ammonia and hydrogen sulfide. Both are limited to chronic (24 hour/day lifetime exposure) health hazard assessments for noncarcinogenic effects. The completed risk assessments represent a consensus opinion of EPA health scientists representing various Program Offices and the Office of Research and Development.

The consensus process includes interpreting the available scientific literature applicable to health effects of a risk agent, and using established methodologies to develop values for inhalation reference concentration. With regard to multiple exposure routes, the U.S. EPA's position is that the potential for health effects manifested via one route of exposure (i.e. dermal or respiratory) is relevant to considerations of any other route of exposure, unless convincing evidence exists to the contrary. In other words, if there is convincing data of a health hazard to a specific substance from respiratory exposure, then the EPA assumes dermal exposures are also hazardous, unless there is convincing evidence to the contrary. As more epidemiological, animal studies, and new scientific information becomes available for CAFO-related exposures, EPA intends to review it, as appropriate, and develop more complete risk assessments.

Chronic Health Hazard Assessments for Noncarcinogenic Effects
The inhalation reference concentrations (RfC) and chronic health hazard summaries for NH_3 and $H2_S$ are listed in Tables 3 and 4, respectively. The No-Observed-Adverse-Effect Level (NOAEL) is

the highest exposure level at which there are no statistically or biologically significant increases in the frequency or severity of adverse effect between the exposed population and its appropriate control. Although some effects may be produced at this level, they are not considered adverse, nor precursors to adverse effects. The Lowest-Observed-Adverse-Effect Level (LOAEL) is the lowest exposure level at which there are statistically or biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group. The Reference Concentration (RfC) is an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. The RfC is derived from a NOAEL, LOAEL, or benchmark concentration, with uncertainty factors (UF) generally applied to reflect limitations of the data used. The RfC is generally used in EPA's noncancer health risk assessments.

For ammonia, an uncertainty factor of 10 is used to allow for the protection of sensitive individuals. Additionally, a factor of 3 is used to account for several database deficiencies including the lack of chronic data and the lack of reproductive and developmental toxicology studies. Based on these factors, EPA sets the limit for lifetime exposures to ammonia at 144 ppb. For hydrogen sulfide, the uncertainty factor of 1000 reflects a factor of 10 to protect sensitive individuals, a factor of 10 to adjust from sub-chronic studies to a chronic study, and a factor of 10 for both interspecies conversion and data base deficiencies. Based on these factors, EPA sets the limit for lifetime exposures to ammonia hydrogen sulfide at 0.7 ppb.

Table 3. Environmental Protection Agency Reference Concentrations for Chronic Inhalation Exposure to Ammonia

Critical Effect	Exposures*	UF	RfC
Lack of evidence of deceased pulmonary function or changes in subjective syptomatology {Occupational Study}	NOAEL (HEC): 2.3 mg/cu.m	30	0.1 mg/cu.m (144 ppb)

*The NOAEL is based on an 8-hour TWA occupational exposure.
(HEC) is the adjusted human equivalent dose.
[1]USEPA, last revised 1991.

Table 4. Environmental Protection Agency Reference Concentrations for Chronic Inhalation Exposure to Hydrogen Sulfide[1]

Critical Effect	Exposures	UF	RfC
Inflammation of the nasal mucosa {Mouse Sub-chronic Inhalation Study}	NOAEL (HEC)[2]: 1.01 mg/cu.m (0.73 ppm)	1000	0.001 mg/cu.m (0.7 ppb)

[1]USEPA, last revised 1995.
[2] NOEL (HEC) = No Effect Exposure Level, Human equivalent dose.
*See appendix A for references for these hazard assessment recommendations.

8.3.2 ATSDR Recommended Limits

Ambient exposure guidelines are also provided in the reviews produced by the Agency for Toxic Substances and Disease Registry, the federal agency charged with evaluating possible health risks from chemicals released at waste sites where the general public may be exposed. In their Toxicological Profiles, this Agency has reviewed the extensive literature concerning health effects of ammonia (ATSDR, 1990, reviewing more than 350 articles to assess possible human health effects of this compound) and hydrogen sulfide (ATSDR, 1999, reviewing about 470 articles), probably the two major contaminants of concern from animal operations as far as is currently known. While the ATSDR guidelines are not generally applicable and enforceable ambient standards, their focus is on protection of the public, including sensitive individuals, and thus they are relevant to the situation under consideration here.

The product of ATSDR reviews are generally information and guidelines related to public exposures near waste sites. They state:

> During the development of toxicological profiles, Minimal Risk Levels (MRLs) are derived when reliable and sufficient data exist to identify the target organ(s) of effect or the most sensitive health effect(s) for a specific duration for a given route of exposure. An MRL is an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. MRLs are based on noncancer health effects only and are not based on a consideration of cancer effects. These substance-specific estimates, which are intended to serve as screening levels, are used by ATSDR health assessors to identify contaminants and potential health effects that may be of concern at hazardous waste sites. It is important to note that MRLs are not intended to define clean up or action levels. MRLs are derived for hazardous substances using the no-observed-adverse-effect level/uncertainty factor approach. They are below levels that might cause adverse health effects in the people most sensitive to such chemical-induced effects. MRLs are derived for acute (1-14 days), intermediate (15-364 days), and chronic (365 days and longer) duration and for the oral and inhalation routes of exposure (ATSDR, 1999, page A-1).

Thus the MRLs are designed to protect sensitive populations. However, as the MRLs are derived for individual contaminants; mixtures of chemicals such as CAFO emissions are potentially more hazardous, but difficult to assess from a health effect standpoint. The situation of mixed exposures is discussed in section 8.3.2.

The ATSDR report on ammonia (ATSDR, 1990) establishes a short-term (less than or equal to 14 days) MRL of 500 ppb for inhalation. A long-term (defined as greater than 365 days in this earlier Toxicological Profile) MRL of 300 ppb at the receptor is established. It appears that the 300ppb MRL would be the appropriate comparison value for public exposures beyond the property limits of a CAFO (table 6). Using the occupational 8-hour time-weighted-average recommendation for workplace exposure (nearly 100 times this value), while appropriate for the healthy adult working population, would be inappropriate for continuous exposure of the general public which includes sensitive populations, including infants, the elderly, and those with pre-existing conditions. Observed or estimated CAFO concentrations of 250 ppb are at times uncomfortably close to the long-term ammonia MRL (Subramanian, et al., 1996; Reynolds et al., 1997).

Hydrogen sulfide is another major contaminant of concern near confinements. The July 1999 ATSDR "Toxicological Profile for Hydrogen Sulfide" (ATSDR, 1999) derives "an acute inhalation MRL of 70 ppb" and "an intermediate MRL of 30 ppb" (p. 139); these would correspond to the 1-14 day and 15-364 day durations of exposure, respectively, and would be appropriate for those living adjacent to CAFOs (table 6). These MRLs are public health exposure guidelines, much lower than the occupational limit of 10,000 ppb.

Generally, there is limited peer-reviewed published literature on community assessments of hydrogen sulfide in the vicinity of CAFOs. There is a non-peer reviewed article by Jacobsen, (1997), for both ammonia and hydrogen sulfide. There have been several studies by the USEPA of continuous monitoring around CAFOs. One of these is a 1999 study in Northern Missouri is available from the EPA (Secrest, C.D., "Field Measurements of Air Pollutants Near Swine Confinement Animal Feeding Operations Using UV DOAS and FTIR," Office of Regulatory Enforcement, Air Enforcement Division USEPA, MS 2242A, 1200 Pennsylvania Avenue, NW, Washington, DC, 20460). Furthermore, the Minnesota Pollution Control Agency has conducted monitoring of numerous CAFOs. Their report on "Feedlot Air Quality Summary Data Collection, Enforcement, and Program Development (March 1999)," can be seen at http://www.pca.state.mn.us/hot/feedlots.html. These reports indicate that observed off-site concentrations near CAFOs at times may approach or exceed these ATSDR recommended limits.

There is a very important point to note, that there is variation in concentrations that can be measured, depending on atmospheric conditions. Stable atmospheres, particularly in the evening are condusive to build up of contaminants in the vicinity of CAFOs. Therefore, it is important that measurement periods take these predicable variations into account. In other words, just measuring during the evening as well as the day is important to obtaining an accurate assessment of actual exposure at the receptor.

Table 6. Agency for Toxic Substances and Disease Registry Minimum Risk Levels (MRL) for Ammonia and Hydrogen Sulfide[1]

Substance	Acute Exposure (1-14 days)	Intermediate Exposure (15-364 days)	Chronic Exposure (365 days and longer)
Ammonia	500 ppb	(None listed)	300 ppb
Hydrogen Sulfide	70 ppb	30 ppb	(None listed)

8.4 Relevance of legal or other recommended limits to occupational and ambient air quality associated with CAFOs.

Regarding OSHA occupational health exposure regulations, the PEL's listed for the hazardous substances found in CAFOs is not highly relevant. The reasons are as follows:

1. The scientific literature document s that endotoxin is one of the most hazardous substances to CAFO workers (Rylander, Jacobs, Organic Dusts, Exposure, Effects, and Prevention. CRC Press, 1994). However OSHA has no PEL standard for endotoxin
2. The OSHA PEL for PM is based on a non-biologically active (nuisance) dust. However, the PM inside CAFOs is highly biologically active, (high concentrations of microbes, endotoxins, and glucan) and is hazardous at much lower levels than in the 10 mg/m^3 published PEL (Donham and Scallon, 1986, and Donham and Reynolds 1996).
3. The PEL's are written assuming exposures to one toxic substance. CAFOs result in complex mixed exposures, which lowers the allowable exposure to each individual component of the mixture (Donham and Scallon, 1986, and Donham and Reynolds, 1996). Therefore, the OSHA or other recommended limits are not highly relevant. Although NIOSH, ACGIH, and AIHA are more stringent than OSHA, they are still much higher than research findings indicate they should be to offer, adequate worker protection in mixed exposure situations like CAFOs.

8.4.1 Mixed Exposures – Occupational

OSHA has established a Permissible Exposure Limit (PEL) for nuisance dust of 15 mg/m^3. The OSHA TWA's for respirable particles and ammonia are, respectively, 5 mg/m^3 and 50 ppm. Threshold limit values (TLV's) established by the American Conference of Governmental Industrial Hygienists (ACGIH) include 10 mg/m^3 for nuisance dusts, 4 mg/m^3 for grain dusts, 3 mg/m^3 for respirable dusts, and 25 ppm for ammonia (Table 1, NIOSH, 1994; ACGIH, 1994). However, several published research manuscripts (Donham KJ, et al., 1995, Reynolds S, 1996, Donham KJ et al., 2000) document that these limits are too high for CAFOs where a mixture of biologically active agents can combine to produce respiratory and systemic effects at much lower levels (Cumro et al., in press).

Multiple agents, multiple etiologies, and the potential for multiple interactions make thorough evaluation of health effects from CAFO emitants a very difficult task. The assignment of unquestionable causality to a single agent for a single adverse health effect or dysfunction in confinement workers is unlikely at best. The 2001ACGIH publication for threshold limit values for chemical substances and physical agents states that when mixed exposures are present, and unless other data indicate differently, the effects should be considered additive. For example where C1, C2, and Cn are measured concentrations of hazardous substances, and T1, T2, and Tn, are their respective TLV's, then the relationship to determine if the level is under legal TLV's, the relationship is defined mathematically as follows:C1/T1 + C2 /T2 + Cn/Tn = < 1.

There may be instances when the effects of two substances are greater than additive, defined as a synergistic interaction. If synergy is present then mixed exposures are even more hazardous than if the effects were merely additive. Such a relationship between NH3 and PM in CAFOs, has been defined by Cumro and Donham, (in press). Data were analyzed from an exposure- response study of 149 poultry CAFO worker. Analysis of this data-set revealed prominent dose-response relationships between increasing PM, NH3, and endotoxin concentrations with corresponding cross-shift declines in worker lung function. Specific threshold concentrations were defined including total dust, 2.4 mg/m^3; respirable dust, 0.16 mg/m^3; total endotoxin, 100 EU/m^3; respirable endotoxin, 0.35 EU/m^3; and NH3, 12 ppm (Donham and Cumro, et al., 2000). As health effects to poultry workers from exposure to both dust and ammonia were less than half the published ACGIH TLV's, investigations were undertaken to study possible interactions between these substances. The results demonstrated that when workers are exposed to both PM and NH3, the adverse effect on pulmonary function is up to 156% greater than the individual effects of these gases (Cumro, et al., in press). Assuming a typical swine CAFO winter concentration of 10 ppm of NH3 and PM of 3.5 mg/m^3, and the TLV for grain dust of 4 mg/m^3, the correct relationship to determine if exposure limits are exceeded in this situation would be as follows: ([NH3]/TLV of NH3 + [PM]/TLV of PM) x 1.56. An example for a typical swine building would be as follows: (10 ppm / 25 ppm + 3.5 mg/m^3 / 4 mg/m^3) x 1.56 = 2.0. In other words, a typical building might exceed our recommended limit by two times. Synergy of simultaneous dust and ammonia exposures in a working environment raises the question of redefining exposure limits for organic dust and ammonia when workers are exposed simultaneously to these substances.

8.4.2 Mixed Exposures – The Community Setting

The EPA, in fact, treats mixed exposures in the community as additive (as ACGIH treats occupational exposures) unless there is information to indicate otherwise (USEPA 600890066F Methods for Derivation Inhalation Reference Concentrations and Application of Inhalation Dosimetry http://www.epa.gov/cgi-bin/claritgw). Existing data are clear that the community exposure concentrations are much less than in the occupational setting. The logical public health question is do mixed exposures in the community setting also have additive or synergistic health effects? Fundamental toxicologic principles would predict there would be additive or synergistic health effects of mixed exposures in the community, (as there would be in the occupational setting) if the hazardous substances effect the same body tissues or organ(s).

In the case of CAFOs, ammonia and hydrogen sulfide both have direct effects on the respiratory system, although ATSDR also warns that hydrogen sulfide is also a broad-spectrum poison. Whether exposure indices for these two respiratory irritants with similar short or intermediate term MRLs can or should be added is not immediately clear but certainly possible. A potential method to establish limits in mixed exposures would be to ratio the concentrations to the appropriate MRLs, with a sum below 1 suggesting no respiratory threat (similar to ACGIH for occupational exposures

ACGIH TLV's for Chemical Substances and physical agents and biological exposures indices). Note that a sum above 1 would not necessarily imply overexposure unless known toxic limits were reached, but would be an "indeterminate human health hazard" under the ATSDR classification scheme.

ATSDR notes hydrogen sulfide is considered a broad-spectrum poison. This means that it can poison several different systems in the body. Thus, in addition to possibly additive or synergistic effects on the respiratory system in the presence of ammonia, there may also be additive effects with other components of CAFO emissions. These materials occur together, not only with each other, but also potentially with a variety of other contaminants in hog manure. For example, there are endotoxins and other bioaerosols along with various other substances that contribute to the observed effect. Unfortunately, available research does not allow quantitive assessment of the health effects of all the mixtures of all substances in CAFO emissions.

8.5 Summary of Occupational Exposure Limits as Recommended from the Scientific Literature
There can be no questions that exposure to emissions while working in CAFOs can be a health hazard. There are over 50 publications documenting the risks. There are now 4 dose – response studies that agree quite closely, regarding the lowest observed health effect levels are. As the concentration of the livestock industry continues, and becomes more specialized, we have greater worker exposure because more are working full-time inside the buildings, rather than spending time in other farming activities as in previous diversified farms. OSHA has left the industry alone for the most part, but with many more large operations (with more than 10 employees), this segment of the industry clearly falls under OSHA's mandate. However, as previously discussed, the current OSHA limits are not highly relevant to protection of CAFO workers. The following concentration, listed in table 7, are scientifically supportable guidelines for occupational exposures, and are listed adjacent to current OSHA standards. (Donham et al., 1989; Donham et al., 1995; Reynolds et al., 1996; and Donham et al., 2000.

Table 7. Summary of Scientific Recommendations of Maximum Exposure Concentrations for Occupational Health Considerations of Swine and Poultry CAFO Workers.

	Human Health[1]	Current OSHA
Total dust mg/m^3	2.5	15
Respirable dust mg/m^3	0.23	5
Endotoxin EU/m^3	100	NA
Carbon dioxide (ppm)	1,540	5000
Ammonia (ppm)	7.0	50

8.6 Summary of Ambiant Exposure Limits as Recommended from Federal Agencies and Regional State Regulations

There has been no published literature on dose – response relationships of CAFO emissions and life quality or chronic health effects among community residents. However, several states have adopted emission standards based on the weight of evidence regarding individual chemical exposures (see chapter 9.0) Furthermore, ATSDR and the EPA have made recommendations based on hazard assessment evaluations. Also, consideration for mixed exposures should lower levels set for individual exposures. The following concentrations could be supported for CAFOs, based on the relevant information reviewed above.

H2S:
15 ppb at the residence for a one-hour average measure and 70 ppb at the property line. No more that seven exceedences would be allowed, per calendar year (with notice to the residents and DNR).
NH3:
150 ppb at the residence and 500 ppb at the property line for a one-hour average measure. There should be no more than 7 exceedences (with notice to residence and DNR), per calendar year.
Odor:
Odor would not exceed 1:7 dilutions at the receptor, or public use area, No more than 14 exceedences (with notice), per calendar year. An additional consideration could be given to a 1:15 dilution at the property line. Monitoring would be conducted via scentometry.

8.7 Justification for Recommendations of Exposure Limits

The concentrations listed in section 8.6 above, are based on a combination of data gained from relevant regulations in other states, and recommendations from made by several public health related agencies, including the World Health Organization, the US Environmental Protection Agency (EPA), and the US Agency for Toxic Substances and Disease Registry (ATSDR). The basis for the regulations promulgated in other states are reported in Chapter 9. The justification for levels recommenced by the EPA and ATSDR are described below.

The ATSDR minimal risk levels (MRL's) were developed in response to the mandate for the agency to list hazardous substances commonly found at listed facilities, the toxicologic profiles of these substances and to ascertain significant human exposures. That mandate is specified in The Comprehensive Environmental Response, Compensations and Liability Act (CERCLA) [42 U.S.C. 9604 et seq.], as amended by the Superfund Amendments and Reauthorization Act (SARA) [Pub. L.99-499]. The ATSDR has adopted a method similar to the EPA to determine the MRL's for respiratory exposures, or Reference concentrations RfC's. These levels are estimates of the daily human exposure to a hazardous substance that is not likely to cause adverse (non-cancerous) health effects, over a specified exposure period (acute – 1-14 days, intermediate – 15-364 days, and chronic, greater than 365 days). MRL's are derived when the ATSDR determines there is sufficient data to determine specific and sensitive health effects for a specific duration. Consistent with principles of public health, the MRL's are set to protect sensitive individuals, and that there is a safety factor built in as they are set below levels that might cause adverse health effects. The public health protection principle is also used by utilizing uncertainty factors (UF) when less than complete data are available. The MRL's undergo a rigorous review process, both internal, and external to the agency, are peer reviewed, and are submitted for public comment. As of June 1, 2001, 286 MRLs had been determined, including hydrogen sulfide, and ammonia. The MRL's can be found on the ATSDR website at www.atsdr.cdc.gov/mrls.html. The ATSDR also publishes, "Toxicologic Profiles," which reviews the literature on the toxicology and public health significance, and justifications for MRL's determined for each of the substances for which an MRL is determined (www.atsdr.cdc.gov/toxpro2.html).

As mentioned previously, the more detailed methods ATSDR uses for determination of MRL's are very similar to the EPA methods for setting their risk levels, which are called reference dose concentration guidelines, (RfD's, for oral exposures, or RfC's for respiratory exposures). The EPA method is described in detail here to help explain how EPA and the ATSDR develop their exposure guidelines. The EPA Risk Assessment Method, are described in detail in the 416 page document 600890066F, entitled "Methods for Derivation Inhalation Reference Concentrations and Application Dosimetry" (www.epa.gov/cgi-bin/claritgw). The EPA has a long history of evaluating scientific information and in developing benchmark values for regulatory action to protect the public from adverse health effects. The National Academy of Sciences (NAS) has been charged with the evaluation of risk assessment processes performed by federal agencies to assure that regulations are based on best judgment and analysis of available scientific knowledge (Risk Assessment in the Federal Government: Managing the Process, NAS, 1983, and NAS Report on Sciences and Judgment in Risk Assessment, National Research Council, 1994). The NAS recommends that risk assessment should be separate from policy aspects of risk management to help assure recommendations for protection on the publics' health are not compromised by the political process. Furthermore, NAS defines risk assessment as "characterization of the potential adverse human health effects of exposures to environmental hazards and consists of the following steps:

1. Hazard identification: to determine the cause-health effect linkages of suspected hazardous substances;
2. Dose-response assessment: the estimation of the relation between the magnitude of exposures and the occurrence of the health effects in question;
3. Exposure assessment: determination of the extent of human exposure;
4. Risk characterization: determination of the nature and magnitude of human exposure, along with attendant uncertainty.

The EPA adopted its reference dose concentration guidelines (RfD's) and analogous guidelines for respiratory exposures (RfC's) based on the NAS guidelines, but the method is more rigorously defined and includes guidance for uncertainty factors (UF's) to help guide extrapolation in instances such as applying animal data to human exposures, and incomplete data (Barnes and Dourson, 1988). The process is a quantitative approach to interpretation of toxicology and epidemiologic data to determine a dose-response estimate, followed by a comparison to exposure estimate to analyze risk characterization. The RfC is defined as: An estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without appreciable health risks during a lifetime (24 hours per day for 70 years).

The steps to calculating an RfC are as follows:

1. Determination of a no-observed-adverse-effect-level (NOAEL), which is the highest dose where no health effects are seen, or threshold level (Klaassen, 1986).
2. Determination of a human equivalent concentration (HEC) of the NOAEL, if the latter is based on animal data.
3. Determination of uncertainty factors (UF) that may include necessary extrapolations from:
    a. average healthy to sensitive humans
    b. animal to human data
    c. sub-chronic to chronic data
    d. lowest effect level to NOAEL
    e. incomplete to complete data base
4. Determination of any necessary modifying factors (MF) not addressed by the UF's, such as adjustments for low sample sizes, or poor exposure characterization.

The RfC determination could be defined by the following notation:

$$RfC = NOAEL[HEC] / (UF \times MF)$$

Usually a subjective confidence level is assigned to the RfC, based on the quality and completeness of the data and the extent of UF's used. These are issued not to disregard those with medium or low confidence levels, but to indicate that the values may change as more information becomes available. RfC's with a high confidence level may not expect to change in the future, relative to those with a low confidence level. The EPA's Integrated Risk Information System (IRIS), lists all the RfC's established, and discusses the UF's used in their determination.

9.1 Introduction

Air emissions and odor from Concentrated Animal Feeding Operations (CAFOs) has become the subject of discussion and government action in a number of states. Sometimes the news media, environmental disasters or the large number of constituent contacts, push legislative changes or administrative action on how CAFOs are sited and managed. Occasionally a new scientific study on the topic changes the tone of the debate.

This chapter documents action taken to regulate and manage CAFO air emissions and odor in jurisdictions outside Iowa. It gives examples of the kind of control various levels of government have imposed on the management of these facilities in an attempt to balance economic advantage with public health and welfare.

9.2 Distinguishing the Consequences of Air Emissions: Nuisance or Health Effects

Air emissions from animal waste storage systems, buildings and land application of animal waste contain a number of gasses and particles that include hydrogen sulfide, ammonia, methane, particulate matter and bioaerosols. Hydrogen sulfide is an example of a substance that is both a direct toxic health risk and odorous. Furthermore, this odorous substance, as well as other odorous substances, may also cause adverse health symptoms, from an indirect toxic mechanism via interactions with the central and peripheral nervous system. [See Chapter 6]

Odorous compounds also decrease the quality of life of neighbors. Hydrogen sulfide, for instance, causes corrosion of metals and damage to plants. When a state or local government acts to reduce air emissions, it might describe this as intervening to protect public health or to enhance the quality of life or the government may say nothing about what motivates its action.

The Minnesota Pollution Control Agency (MPCA) places limits on hydrogen sulfide emissions at CAFOs. Minnesota is similar to other states that have recently intervened to reduce air emissions from a type of activity that was formerly thought to be only a local issue.

> In the past, the Minnesota Pollution Control Agency (MPCA) has viewed odors as a natural result of animal production that could best be addressed through good land use planning, with the primary responsibility for land use planning at the local level of government (see Minn.R. 7020.0100).[1]

Just as states have struggled to determine whether state or local regulation is appropriate, they have not found it simple to distinguish the rationale for regulation. It is not simple to say which air emission is a health issue and which a nuisance. Rather there is a continuum from life threatening acute health effects, through acute effects that are not life threatening, to chronic effects that appear after longer exposure, to annoyance smell. Odor or a constituent part of the air emission can have a range of effects. Consider this example. Two Minnesota agencies, the MPCA and the Minnesota Department of Health (MDH) have established values to limit the various adverse effects from hydrogen sulfide emissions from CAFOs. The MDH explains why both agencies have acted.

> The MPCA standard for hydrogen sulfide will protect against symptoms of headache, nausea, and maintain a quality of life for Minnesotans. The MDH acute Health Risk Value (HRV) will protect against respiratory effects by ensuring that hydrogen sulfide is included in

> hazard indexes calculations where hydrogen sulfide is one of many chemicals emitted to air potentially having respiratory impacts.[2]

9.3 Minnesota GEIS on Animal Agriculture

The state of Minnesota has recently brought the scientific and public policy community together to advise state government on how to proceed on several CAFO issues. This extensive process resulted in a Generic Environmental Impact Statement (GEIS) for animal agriculture that was presented at a public hearing on December 10, 2001. Because the technical work papers for the GEIS date from the first half of 2001, this chapter relied heavily on three GEIS Technical Work Papers -- Air Quality and Odor, Role of Government, and Human Health. One finding of the GEIS Technical Work Papers is that air quality has not been the driving force behind government action.

> Existing laws and programs have mostly emerged out of a long-standing concern over surface water impacts, which, while valid, have meant that air, groundwater and other emerging issues are not adequately factored into government decision-making.[3]

Government's slow involvement with air emissions and odor is substantiated by data presented in 1998 survey on Animal Confinement Policy designed by a National Task Force of 15 Extension Specialists representing all regions of the nation. For only 13 of 48 states did those surveyed answer yes to the following question: Are odor standards imposed as a matter of state government policy or court decisions in your state?[4] More than twice as many states regulate discharge to surface water. However, some states like Missouri, which recorded an answer of 'no' to the preceding question, now have odor standards.

9.3.1 Iowa

We will discuss Iowa CAFOs at length below. However it is informative to see the view of our state from our neighbor to the north. The Minnesota GEIS Technical Work Paper on Air Quality and Odor Impacts investigated regulatory programs in a number of states including Iowa. According to the researchers,

> {d}espite having an estimated 3,000 large animal feeding operations that have the capacity for more than 1,000 animal units and receiving many odor complaints from neighbors, the State of Iowa has essentially no program in place for addressing odors or air emissions from animal agriculture facilities.[5]

This strong language points to the inadequacy of present Iowa rules and regulations. However, two members of this research team, one from the University of Iowa and one from Iowa State University were part of a study group which put the following language into Iowa Administrative Rules of the former Air Quality Commission in 1977 when an odorous substance standard was defined as:

> The emission of an odorous substance from an odorous substance source shall constitute a violation of these rules if the emission is of such frequency, duration, quality, and intensity to be harmful or injurious to human health and welfare, or as to unreasonably interfere with the comfortable use and enjoyment of life and property or so as to constitute a nuisance as defined in sections 657.1 and 657.2 of the Code.

The former paragraph was part of the state Administrative Code for only a short time. The rule was rescinded in 1984 when the term "odorous substances" was also deleted from the Administrative Rules.*[6]

While the Minnesota GEIS was our starting point to seek out governmental action on air and odor, we also talked to government officials and staff of non-governmental organizations in pork producing states. We have omitted setback requirements, one type of policy that nearly every state has adopted to reduce the effects of air emissions and odor from CAFOs. We will look at regulations for three constituents of air emissions, hydrogen sulfide, ammonia and odor. We will look at local government activities and we will look at the results of action in the courts. In each category, rather than an exhaustive look we will choose a few jurisdictions to serve as exemplars for the kind of government intervention to control CAFO air emissions.

9.4 Hydrogen Sulfide Standards

The Agency for Toxic Substances and Disease Registry (ATSDR) of the US Department of Health and Human Services, lists 24 states with regulations or guidelines for hydrogen sulfide. In this section we will look at three states with regulations especially relevant to CAFOs.[7]

9.4.1 Minnesota

Minnesota is interesting because it addresses air quality issues from animal agriculture in several ways. First, the MPCA maintains a two-component Ambient Air Quality Standard for hydrogen sulfide. 50 parts per billion (ppb) is not to be exceed for ½ hour twice per year and 30 ppb is the ½ hour average not to be exceed more than 2 times in any 5 consecutive days.[8] These are emitter property line standards for animal feeding operations over 1000 animal units in size.

Second, subsequent to establishing these standards, another Minnesota agency, the MDH, proposed a draft acute Inhalation Health Risk Value (HRV) for hydrogen sulfide of 60 ppb as a 1-hour average and a draft subchronic (3-month average) HRV of 7 ppb.[9] These standards are evaluated at the receptor rather than the emitter's property line. The MDH plans to adopt both HRVs without public hearing in the very near future. In addition, the state addresses air quality issues from CAFOs by requiring each facility with a capacity of 1000 animal units to include an Air Emission Plan in its water quality permit.

The many different air emission limits in a single state for only one constituent makes clear the difficulty in describing laws, regulations and decisions relating to CAFO air emissions and odor. Many authors do not make a distinction between air emissions and odor or between health effects and nuisance. In this chapter we will deal with both odor and air emissions and will try to record accurately which a particular law, regulation or decision is being referred to.

9.4.2 Nebraska

The Nebraska Department of Environmental Quality (NDEQ) implemented an ambient air quality health-based standard of 100 ppb for total reduced sulfur (TRS) in September 1997 (Revised January 1999). The impetus for this action was industrial emissions in Dakota City, Nebraska and not

* Rule 400--4.5 was published as an adopted and filed rule on 6/16/77. On 6/22/83 the rule was transferred to WAWM as rule 900--23.5. An amendment published 9/12/84 changed the catchwords from "Odorous substances" to "Anaerobic lagoons"; rescinded subrules 23.5(1) and 23.5(2) and renumbered subrules 23.5(3) and 23.5(4) as 23.5(1) and 23.5(2), respectively. Rule 23.5 is still in the Iowa Administrative Code.

CAFOs. However, since the revision in 1999, the standard applies to CAFOs. NDEQ prepared an extensive background research paper that focused on low-level exposure to hydrogen sulfide and TRS through inhalation.[10]

> Total Reduced Sulfur (TRS) consists of the total sulfur from the following compounds: hydrogen sulfide (H2S), methyl mercaptan (CH3SH), dimethyl sulfide ((CH3)2S), and dimethyl disulfide (CH3SSCH3) (87). These TRS compounds occur naturally in the environment. H2S makes up the greatest proportion of TRS.[11]

As part of their research paper, NDEQ surveyed the 49 other states and found 27 states that had standards for H2S or TRS. These states based standards on a variety of issues including, odor or nuisance, welfare effects, and health effects. Standards varied considerably to as low as 0.7 ppb for a yearly average (New York) and 5 ppb averaged over 24 hours (Pennsylvania). Many of the standards were based on nuisance including Minnesota's 30 ppb and 50 ppb standards. The lowest standard that was reported to be health based was a 10 ppb 8-hour 10 ppb standard (Illinois).[12]

The authors of the background research paper recommended Nebraska's present health standard of 100 ppb, averaged over 30 minutes. The authors also recommended a much lower 30-day standard of 10 ppb or 5 ppb (depending on average humidity level in the air) to protect against other effects of sulfur compounds. While the state adopted the 100 ppb health-based standard, it has not yet adopted the lower, welfare standard for TRS.

9.4.3 California

The California Ambient Air Quality Standard (CAAQS) for hydrogen sulfide of 30 ppb for one hour was adopted in 1969 and reviewed but not changed in 1980 and 1984. A year 2000 review states the purpose of the standard was to decrease odor annoyance from industry rather than CAFOs. However, the review notes that significant adverse health effects might occur at levels of exposure below the CAAQS.[13] More recently, the California Office of Environmental Health Hazard has adopted a chronic reference inhalation standard of H2S at 8 ppb.

The three states give three motivations for a sulfurous emission standard. Nebraska has a health-based standard of 100 ppb, averaged over 30 minutes at the receptor. Minnesota's health standards vary from an acute 60 ppb 30-minute standard to a sub-chronic 7 ppb, 3-month standard measured at the receptor or nearer the source of the emission. The state also has two nuisance-based property line standards of 50 ppb and 30 ppb averaged over 30-minutes. California's much older 30 ppb for one hour standard is based on nuisance but the state is looking into whether significant adverse health effects might occur at similar levels. The California Office of Environmental Health Hazard has adopted a chronic reference inhalation standard of hydrogen sulfide of 8 ppb.[14] Standards for the three states as well as for federal agencies and the World Health Organization are contained in Table 1.

9.5 Ammonia Measurements

The ATSDR has published a toxicological profile for ammonia, which contains a list of regulations and advisories from various states. The list of acceptable ambient air concentration levels for Ammonia based on 1988 information, contains standards in place in 11 states.[15] (See Appendix and Table 2.) The ammonia standards for the three following jurisdictions are contained in Table 2 at the end of the chapter.

9.5.1 Minnesota

Besides establishing a Health Risk Value (HRV) for hydrogen sulfide, the Minnesota Department of Health has filed a draft HRV for ammonia as well. This HRV, like the other, will receive final approval in the next few months. Both HRVs are scientifically measured standards that protect the public from adverse health effects. The point of measurement would often be at the receptor but it is possible that the agency will take measurements at the property line as well. A brochure prepared for the public explains that being below the HRV does not necessarily take care of odor problems.

> However, keeping emissions at or below the HRV does not necessarily eliminate odors from the agricultural animal operation and may not eliminate health effects from odors.[16]

9.5.2 Netherlands

While The Netherlands is very different from any US state, it is similar in terms of livestock production.[17] [18] The numbers of livestock animals in The Netherlands are 14 million hogs, 108 million chickens, 4.2 million cattle and 1.4 million sheep. On four times as much land mass Iowa has 15 million hogs, 37.8 million chickens, 3.7 million cattle and 270,000 sheep. In The Netherlands, ammonia emissions from agriculture are responsible for 42% of the acidification attributable to domestic sources. Policies set forth in the 1990s aim to reduce by 70% the ammonia emissions compared to the 1980 benchmark. The European Union is working on a directive to reduce ammonia emissions that is being modeled after the Dutch regulation.

Features of the Dutch policy that regulates phosphate, nitrogen and ammonia include a mandated reduction of the pig population by 10%, compulsory minerals accounting and reporting by all intensive livestock farms, a total ban on application of manure in autumn and winter, a ban on application on frozen ground, compulsory use of injection manure application, compulsory covering of manure storage tanks and reservoirs, strict requirements for ammonia emissions from intensive livestock facilities including a requirement that all new livestock housing meet the strict ALARA (as low as reasonably achievable) standards. All facilities will be required to meet ALARA by 2008. Farmers must have adequate manure storage facilities to store their manure from September through February.

Methane and nitrous oxide arising from CAFOs are greenhouse gases that may contribute to global climate change. In The Netherlands, agricultural activities account for an estimated 45% of the total methane emissions and 35 to 40% of the N2O emissions. Measures being taken to reduce ammonia emissions should allow The Netherlands to reduce greenhouse gas emissions to levels mandated by the Kyoto Protocol. Thus far, the U.S. has not taken any steps to control emissions of greenhouse gases from livestock production.

9.5.3 Missouri

The Missouri Department of Natural Resources has been monitoring a Premium Standard Farm (PSF) concentrated animal feeding operation in northern Missouri since the beginning of 2000.[19] Hydrogen sulfide and ammonia concentrations are monitored on a 24-hour basis. The monitor has recorded high concentrations of both ammonia and hydrogen sulfide. Missouri has an ambient air standard for hydrogen sulfide and an ambient acceptable level (AAL) for ammonia of 144 ppb. The Department added a second monitor at another PSF facility late in Fall 2001.[20]

The Missouri Department of Health, the Missouri Department of Natural Resources, the US EPA and the US Agency for Toxic Substances & Disease Registry cooperated in a health evaluation near some of PSF's facilities in the fall of 2001. The health evaluation concentrated on the two pollutants hydrogen sulfide and ammonia. A health evaluation is to determine if a more full-scale health study is needed. The results of the evaluation have not been released.[20] In a recent Consent Decree with the US EPA and a citizen's group, PSF has agreed to continue to monitor for a number of air emissions including ammonia.[21]

9.6 Odor legislation

States can regulate air emissions without referring to a specific chemical constituent. The 1998 national survey of animal confinement policies, referred to above, found thirteen states where odor standards were imposed as a matter of state policy or court decisions.[4] We look at three states that require that odor from CAFOs be held below a threshold. In Missouri and Colorado, the threshold is based on a dilution standard. The Colorado dilution standard of 7:1 means that an air sample collected at the emitter property line is diluted with seven volumes of fresh air. If odor can still be detected by using an olfactometer and panel of smellers, there is a violation. (See description in section 3.4) North Carolina has an idiosyncratic method of deciding on an odor violation, which is covered below. Table 3 summarizes the information in this section.

9.6.1 Missouri

On January 1, 2002, all very large CAFOs in Missouri must have an odor control plan in place describing measures to be used to control odor emissions (10 CSR 10-3.090, Code of State Regulations). All Class 1A CAFOs, those having more than 7000 animal units must comply (twenty-one facilities in total). This air quality specific program approach dates from 1999. A number of farm organizations went to court alleging the state lacked authority to regulate emissions. The state has prevailed at the County Circuit Court and the Missouri Court of Appeals.[22] At this time only 1 of Missouri's 21 Class 1A CAFOs has an approved odor control plan. All the others have not been approved. In general, the disapproved odor control plans lacked specific odor control and reduction strategies. Nearly all of the CAFO owners have appealed the state's disapproval of their plans.[20]

Missouri uses a dilution threshold as a standard. An instrument called a scentometer is used in the field at a dilution threshold of 5.4:1 to determine if a significant odor is present. If odor is detected, an air sample is taken and sent for further evaluation by an olfactometry panel. If the panel detects the odor at a dilution threshold of 7:1 or greater, or at an intensity greater than a reference standard of 225 ppm of n-butanol, then a violation has occurred.

9.6.2 North Carolina

North Carolina CAFOs with liquid waste systems are required to first meet a number of best management practices for things such as dead animal disposal. Besides these management practices requirements, certain swine operations fall under the regulation's complaint response and odor management program. Compliance with the rules depend on facility size and distance from an occupied residence, business, school, hospital, church, outdoor recreation facility, park, historic property, or childcare center. According to materials gathered in the Minnesota GEIS process, the North Carolina complaint response system is quite involved and seems to be a time consuming process. It consists of the following steps.

Complaint response system

When a citizen complains to the state, they are asked to log complaints and weather conditions for 30 days on a form provided by the North Carolina Air Quality Division (NCDAQ). Once the logbook is returned to the state, the following formal investigation takes place.

a. An inspection is scheduled during weather conditions and time of day similar to when typical objectionable odor was reported
b. Evaluation is made at the location of the residence of the complainants
c. An "odor snapshot" is made by regional office investigator (one of 5 rankings)
d. The snapshot evaluation is reported to a regional supervisor
e. The regional office submits a recommendation to Division Director
f. The Division of Air Quality Director makes a final decision whether an objectionable odor exists.

If a determination of Objectionable Odor is made, the NCDAQ will require a Best Management Plan (BMP) of a facility—this is a revision of the original submitted plan. The BMP must be submitted within 90 days. Then ensues a process of plan approval and revision. If the BMP is found to be inadequate, the NCDAQ notifies the operation that it must submit a revised BMP under the same time schedules. Only then can the state order a facility to initiate any specific action.

> If the revised plan fails to adequately control, odors, the facility is required to install add-on control equipment and must submit a permit application for this installation within 90 days of receiving notification that their revised BMP was not adequate.[24]

Thus far only 25 facilities have had an Objectionable Odor determination. Each is currently in the process of providing a BMP to NCDAQ. As of early 2001, none had moved to the final step in the process, the installation of add-on control technology.

9.6.3 Colorado

Missouri and North Carolina demonstrate the significant length of time required to decide what action to take to abate odor. A different approach was followed by the state of Colorado where a referendum on the state ballot led to regulations addressing odorous gases and odor emissions from new and existing housed commercial swine feeding operations. The list of rules is extensive. They include, a cover requirement of anaerobic process wastewater lagoons, aerobic lagoon requirements, land waste application setback requirements, and mortality waste handling requirements. Housed commercial swine feeding operations must use technologies to minimize off-site odor emissions from all aspects of the operation (confinement structures, waste treatment facilities, manure management and land application), develop a comprehensive odor management plan and obtain an operating permit.

The regulation applies to all CAFOs that contain more than 800,000 pounds of live animal weight. Colorado CAFOs of this size must meet two ambient odor concentration standards, a dilution standard of 7:1 at the facility boundary and a dilution standard of 2:1 at any receptor (building, school or a municipal boundary). "The plans must also identify the odor monitoring that the facility intends to conduct in order to ensure compliance with the odor standards identified above."[25] While the requirements apply to more than 110 individual facilities, there are only eight owners of these facilities. The new regulations have reduced odor complaints substantially according to Phyllis Woodford of the Department of Public Health and the Environment.[26]

9.7 County and Local Action

Citizens who are not satisfied with state level governmental action to mitigate the effects of CAFOs have two other venues to protect their rights. They may pursue restrictions at the local government level or they can go to court in a private cause of action.

Rural counties have not generally adopted the zoning protection of more urban areas. However this seems to be changing.[27] In Missouri, reticence to zoning restrictions in a rural county was overcome by the arrival of large confinement operations. A resident of a township next to Premium Standard Farm's facility in Missouri, describes the area's change of view that caused it to adopt zoning.

> You've got to make plans and provide for the control of the situation before it occurs. Otherwise, by the time you realize you need zoning, its too late, and they've set the hook.[28]

While the eminent arrival of a CAFO might cause citizens to demand more protection from local government, local government is often prevented from playing a part in how CAFOs are regulated. State legislation to regulate animal agriculture has often been passed with the provision that local governments are prevented from intervening. Preemption of local action has been widely discussed in the literature.[27] Abdalla and Becker give several examples of the preemption of local government's abilities to deal with CAFOs. The authors explain resort to preemption laws by agricultural interests as simple economics.

> The economics of political influence clearly leads to a general preference for state level regulatory authority by organized interest groups. Monitoring and lobbying at the state level is much less expensive than providing these services at hundreds of local governmental units.[29]

9.7.1 Iowa

In Kuehl v. Cass County (1996) the Iowa Supreme Court held that all agriculture, including an animal feeding operation, is exempt from any county zoning. Before this decision, Humboldt County adopted four ordinances governing "large livestock confinement feeding facilities." While a district court upheld three of the ordinances, as a proper application of "home rule" authority, the Iowa Supreme Court struck down all the ordinances in their decision in Goodell v. Humboldt County, Iowa in 1998.[30] Presently an ordinance from Worth County is proceeding through the courts. This will test whether counties can regulate CAFOs based on public health. Whatever the outcome of the latest case, the Iowa preemption law has made county government reticent to try to regulate the location of CAFOs.

9.7.2 North Carolina

A website at the School of Public Health at the University of North Carolina contains reports on six county in the state that have passed ordinances regulating CAFOs. Ordinances required such things as operating permits, closure plans, graduated setback requirements and well testing. The Moore County ordinance for instances, required that confinement buildings and lagoons be set 2 miles from any golf course.[31] In 2001, two North Carolina court decisions struck down two county ordinances and put the remainder in jeopardy. The courts found that the General Assembly did not want to impose an unnecessary economic burden on hog production caused by each county passing its own set of rules. Chatham County has appealed the Court of Appeal's decision to the NC Supreme Court. A decision is expected in early 2002.[32]

9.7.3 South Carolina

The preemption strategy is not always successful as demonstrated by an attempt in South Carolina to push local government out of the regulatory picture.

> What started out as an attempt to adopt state laws that preempt counties from enacting measures to deal with confined animal feeding operations resulted in a measure that provides for considerable regulation of the activity and significant local involvement in the process.[33]

9.8 State Moratorium on Expansion

We have omitted one form of government action to this point. Moratoria have sometimes been adopted to give state officials time to review and update environmental regulations. In April 2001, Governor Jim Hodges of South Carolina imposed a 15-day moratorium on CAFO expansion to give environmental regulators more time to consider permit regulations.[34] Short-term limitations on any expansion of CAFOs also have taken place in Kentucky, Missouri and Arkansas.[30]

In one state the controversy over CAFO expansion has been so contentious that a continuous moratorium on large CAFO expansion has been put in place. North Carolina placed a two-year moratorium on the expansion of CAFOs with lagoon systems, when House Bill 515 passed in 1997. The moratorium has been extended twice and is now due to expire in September 2003.[35] Such reaction leads one to speculate whether stricter regulation earlier in the process may have better for the industry in North Carolina. The moratorium originally resulted from a number of lagoon breaks but also from the perception that the original regulation was too lax.

It is not even clear that weak legislation, preferred by nearly every industry, is in the best interest of producers in other parts of the nation.

> The Mo and Abdalla study found that overall, the stringency of environmental regulation did not appear to impact hog inventory growth." and "…the amount of staff devoted to animal waste management had an unexpected, but strongly positive relationship to hog inventory growth.[36]

9.9 Individual Legal Action

Local citizens have access to the courts where one can bring a private cause of action under nuisance. However, in many states, state government has attempted to blunt individual legal action through "right to farm" legislation. Hamilton explains the motivation for such statutes.

> Most lawyers and farmers have more than a passing familiarity with the legal concept upon which the laws were originally based—existing farm operations should not become nuisances due to the later development of non-agricultural uses in the surrounding area.[37]

Right to farm legislation has prevented neighbors and environmental groups from using individual nuisance action to require management changes or new locations for CAFOs. DeLind found that successful court action by neighbors against a Michigan swine confinement operation was the impetus for changing the law to give neighbors fewer rights by providing right to farm protection for what she calls hog hotels.[38]

> The official outcome, in other words, undermined both the original set of grassroots concerns and weakened the basis for further local-level action and representation.[39]

However, courts in several states including Iowa have ruled that right to farm laws give only limited protection from nuisance action. Richardson and Feitshans point to the Bormann case decided in

1998 by the Iowa Supreme Court as reducing the effectiveness of this protection for animal agriculture.[40] In that case, removing a citizen's right to nuisance action within a declared agricultural area was found to be a categorical taking of private property for public purposes without just compensation. Thus, the Iowa Legislature had exceeded its authority by authorizing the use of property in such a way as to infringe on the rights of others.[41]

In addition to limiting nuisance suits, another method of reducing the risk of animal agriculture operations from individual legal action has been the "fee shifting" provision. Hamilton gives the example of a 1995 Iowa law that assesses all costs and expenses of the defense side to the losing plaintiff in a nuisance action against a CAFO. Hamilton finds that "From a legal standpoint there are several reasons why this type of "soft" fee shifting is not a significant threat to most people who would file a nuisance challenge."[42]

In the last several months, two Iowa cases have set the stage for an expansion of the Bormann decision to land not in a designated agricultural area. In August 2001, an Iowa district court judge ruled for the first time that an Iowa law that protects CAFOs against nuisance suits is unconstitutional.[43] The decision allowed the Gacke case against Pork Xtra, L.L.C. to proceed in a Sioux County, Iowa court.[44] In January 2002, Pork Xtra was assessed $100,000 in damages.[45]

In December 2001, a court in Calhoun County Iowa made a similar determination that the defendants in Kleemeier v. Beazly Group, Inc and Pork Innovations could go forward. The judge found that the defendant's affirmative defense against nuisance action by neighbors had relied on an unconstitutional statute.[46]

Actual examples of substantial plaintiff victories from CAFOs under nuisance exist in other states. On September 9, 2001 Buckeye Egg Farm in Ohio, was hit with a judgment of $19.7 million for nuisance violations including fly infestations and odor. According to Feedstuffs, Buckeye, which has barn capacity of 11 million hens and 4 million chicks, is considering bankruptcy protection. Buckeye is the fifth largest commercial egg producer in the U.S.[47]

Nuisance need not be only a private court action. The Illinois Attorney General is presently prosecuting at least two swine CAFO operations under two counts of state law--air pollution and public nuisance--as well as under a third count of common law nuisance. There are two noteworthy dimensions of these cases. First, the Illinois AG cites considerable case law indicating that technical measures and depictions of odor and emissions are not required to prosecute air pollution and nuisance violations. Indeed, the nuisance statute itself was created, in part, to allow general citizens equitable access to courses of legal action without recourse to expensive technical measurements or scientific assessments.

In fact, a ruling by a Ninth Circuit Court Judge in one of these cases, affirmed the evidentiary possibility of neighbors proving their case by experiential testimony. Moreover, the state Illinois Environmental Protection Agency (IEPA) that follows-up on odor complaints, does not conduct technical assessments of odor or emissions. Instead, representatives from the IEPA will respond to neighbor odor complaints by making site visits and carefully documenting the presence or absence of odor with their own sensory judgments. Interestingly, the IEPA has issued warnings to prospective CAFO builders and operators (prior to construction of a CAFO) that just because they receive an approved state operating permit does not preclude action against them for violating the state's odor and nuisance standard. In fact, there are cases in Illinois where the Illinois Department of Agriculture will issue an approval for construction and operation while the IEPA will issue a simultaneous warning of potential air quality violations against neighbors.

It should be noted that the air pollution and nuisance statutes of Illinois are similar, if not identical to those found in other states. Hence the issue becomes not one of statutory authority of the Attorney General to prosecute such cases on behalf of neighbors, but more likely a political decision based upon a weighing of competing interests. More importantly, these statutes and associated case law recognize the evidentiary value of experiential assessments of odor by neighbors.

9.10 Non Regulatory Approaches

9.10.1 North Carolina

In July 2000, then North Carolina Attorney General Mike Easley signed an agreement that required Smithfield Foods, by far the state's largest pork producer, to pay $15 million to fund research and testing on better technologies to treat hog waste. Premium Standard Farms has committed $2.5 million for the same research questions under a similar agreement with Easley who is now Governor. In July 2002, a report is due.

> Smithfield-affiliated farmers then have three years to convert their facilities to the recommended technologies. In addition, the agreement requires Smithfield to pay $50 million for environmental improvements such as mapping and closing abandoned waste lagoons in the eastern half of the state.[48]

The technologies being examined must make substantial reduction in a number of emissions including ammonia, odor, disease vectors and airborne pathogens. Since this is early in the agreement, it is well to withhold judgment on whether or not Smithfield facilities will solve their odor and water emission problems.

9.10.2 Oklahoma

Oklahoma is another state in which a livestock producer has signed an agreement with the State Attorney General to change waste treatment systems at facilities.

> Seaboard Farms, the state's largest corporate hog producer, signed an agreement Tuesday (12/04/01) to spend about $3 million to better treat sewage and -–for the first time – control odors scientifically.[49]

Seaboard agreed to several measures including installing a manure treatment system similar to human waste treatment systems and agreed to share monitoring results with the state. The agreement allowed the company to open a second 25,000-sow facility similar to the one where the new treatment devices will be installed.

9.10.3 Missouri

A third case of a settlement of a court case resulted in changes by Premium Standard Farms (PFS) in Missouri. In 1997 Citizens Legal Environmental Action Network (CLEAN) filed suit against PFS for its waste handling procedures. In 1999, the US EPA joined the citizen suit. Settlement of the court case in Missouri has resulted in a civil penalty of $1,000,000. However PSF was allowed to receive credit for payment of $650,000 to the State of Missouri for a previous State Consent Decree. The PSF website describes the settlement as $350,000.[50] The payment of civil penalty was small in comparison to what PSF pledged to invest in upgrades to its facilities in Missouri, which has been reported as high as $50M.[51] [52] Although the PFS agreement is a legal settlement, we treat it in this section because of the requirement that new technologies be introduced and the joining of government entities in citizen suits.

9.11 Role of Research in Public Policy

Government does not always wait for research recommendations before taking action. We have referred often to Minnesota's Animal Agriculture GEIS process for which the state legislature committed $1.4 million beginning in 1998. While the process was underway, in the 2000 legislative session, the ability of the Minnesota Pollution Control Agency (MPCA) to enforce feedlot rules was compromised as follows.

> Lacking evidence of an immediate public health threat, the MPCA may not require operators of feedlots under 300 AU to spend more than $3000 without 75% cost-share, and feedlots under 500 AU cannot be required to spend more than $10,000 without cost-share of 75% of the upgrade, or $50,000, whichever is less.[53]

One reason to expect legislators not to wait for a research process to be complete is the same reason courts side with neighbors who have only their own experience and not exhaustive studies to impart. When legislators heard from their constituents who produced small numbers of livestock, that they did not want to be caught up in regulations for "the big guys" the legislature acted on what they felt was adequate evidence.

Our two colleges have been asked to bring science to regulatory decisions. Similarly in Minnesota and Nebraska, regulatory action was based on a survey of the scientific literature on health and welfare effects of pollutant emissions or on a survey of action in other states. However, both researchers and legislators assert that a scientific recommendation need not necessarily have all the answers before regulations can be promulgated. Regulating air quality from CAFOs can be made on the basis of precaution.

The Precautionary principle provides a guide to environmental policy that places the burden on the proponents of a potentially harmful activity to prove that their actions do not harm human health or the environment. The principle has been stated in many different places and contexts. The1998 Wingspread Statement, which is a consensus document produced by those attending a conference on the issue at the Wingspread Conference Center in Wisconsin, states in part:

> When an activity raises threats of harm to human health or the environment, precautionary measures should be taken even if some cause and effect relationships are not fully established scientifically. In this context the proponent of an activity, rather than the public, should bear the burden of proof.[54]

The precautionary principle already forms the basis of at least a dozen treaties and international laws including the 1987 Montreal Protocol on Substances that Deplete the Ozone Layer, the 1992 UN Framework Convention on Climate Change and the 2000 Cartagena Protocol on Biosafety.[55] [56] [57]

The precautionary principle has often been applied to the introduction of new chemicals into the environment. Kriebel and Tickner assert that science informs policy in many ways. They find that, "A shift from reaction to precaution is entirely consistent with the core values of public health practice."[58]

A public health approach to marshalling evidence may be different from a strictly hard scientific approach according to Krimsky. He describes this difference by referring to Type I and Type II scientific errors. He maintains that minimizing false positives is the priority of the hard sciences while a public health perspective prefers to err on the side of overstating risks (prefer type II errors).[59]

Krimsky demonstrates the wide acceptance of some amount of precaution when he quotes an issue of the journal Chemistry & Industry, which states, "For one thing, it is crucial to avoid even inadvertently suggesting that the 'no evidence of harm' somehow equals 'evidence of no harm.'"[60] However, when considering implementation of precautionary measures, it is imperative that all consequences of such measures be thoroughly evaluated.

9.12 Conclusion

Governments have intervened to mediate between CAFOs and their neighbors in a number of ways. This chapter has sought to demonstrate the range of such intervention. States regulate hydrogen sulfide and TRS. Other states have limited the emissions of odor and ammonia. Local governments have sometimes been allowed to intervene to protect citizens against air emissions, but in most cases the state legislature has reserved this role for itself. Both, where states have acted and where they have not, the courts have intervened to give neighbors of CAFOs protection from air emissions and odor. This chapter is designed to demonstrate to the Iowa DNR and to Iowa government in general that there are examples of Laws, Regulations and Decisions designed to regulate air emissions and odor from CAFOs.

Appendix: Federal and International Air Quality Standards

Federal Standards

CAFO effects on water quality have been addressed by a Unified National Strategy developed by the USDA and USEPA in 1999. Air emission effects of CAFOs have not yet found the same level of federal attention. USDA formed an Agricultural Air Quality Task Force, which has been meeting and in July of 2000 drew up a white paper on research and technology transfer.[61]

Both the USEPA and the Agency for Toxic Substances and Disease Registry (ATSDR) have standards for both H2S and ammonia. These have been cited in Chapter 8.

Specifically for Hydrogen Sulfide, acute exposure guideline levels have been printed in the Federal Register for March 15, 2000.[62] There are several Proposed Acute Exposure Guideline Levels (AEGLs) applicable to the general population. AEGL-1 is set at 30 ppb for both a 10-minute and 30-minute exposure. AEGL-1 is designed to limit exposure to prevent "discomfort, irritation, or certain asymtomatic, non-sensory effects" which are not disabling. According to the web page of the American Petroleum Council. http://www.api.org/ehs/h2s/FalkeAbstract.htm AEGL-1 has not passed all the various reviews and is still considered a draft while two other AEGLs have been adopted.*

* AEGL values were developed for hydrogen sulfide by the National Advisory Committee on Acute Exposure Guideline Levels (NAC/AEGL Committee). These values were published in the Federal Register on March 15, 2000 (U.S. EPA, 2000) for public comment. After reviewing comments, the AEGL values were sent unchanged from the Federal Register Notice to the National Academies for review at their meeting on July 24-25, 2000. Following verbal

International Examples

Jurisdictions often base their standards on peer-reviewed literature and upon choices made by other jurisdictions. The State of Nebraska in adopting their standard of 100 ppb for TRS [see 9.4.2 for the relation between HS and TRS], cited data from the World Health Organization.

> The World Health Organization (WHO) reviewed information on health effects and recommended a daily (24-hour) value of 0.1 ppm H_2S. This value was based on the eye irritation effects at 10 ppm and a safety factor of 100. WHO noted that changes in heme synthesis were found at 1 ppm in pulp mill workers. Since the WHO made its recommendation in 1983, Bhambhani and Jappinen have conducted studies that indicate that eye irritation is not the most sensitive critical health effect.[63]

Table 10-1
Hydrogen Sulfide Standards for Various Jurisdictions

Jurisdiction	Type	Standard
Minnesota MPCA	Nuisance	30 ppb and 50 ppb
Minnesota Dept. of Health	Acute	60 ppb
Minnesota Dept. of Health	Sub-chronic	7 ppb
Nebraska Dept. of Health	Acute	100 ppb
California OEHH	Nuisance	30 ppb
California OEHH	Chronic	8 ppb
EPA – IRIS Chronic	Chronic	.7 ppb
EPA -- AEGL-1 (proposed)	Acute, non-disabling	30 ppb
ATSDR	Acute	70 ppb
ATSDR	Acute	30 ppb
WHO		100 ppb

comments at the National Academies' review, the AEGL-1 values are currently being re-evaluated by the NAC/AEGL Committee for endpoint and key study selection.

Table 10-2
Ammonia Standards for Various Jurisdictions

Jurisdiction	Type	Standard
Minnesota Dept. of Health-draft	Acute	3200 ug/m3
Minnesota Dept. of Health-draft	Chronic	115 ppb
Netherlands Dept. of Agriculture	Not a number std.	
Missouri Dept. of Natural Resources	One producer	141 ppb
EPA	Chronic	141 ppb
ATSDR	Acute	500 ppb
ATSDR	Intermediate	300 ppb

Table 10-3
Odor Standards for Various Jurisdictions

Jurisdiction	Standard
Colorado Dept. of Public Health and Environment	7 to 1 dilutions at the property line
Colorado Dept. of Public Health and Environment	2 to 1 dilutions at the property line
Missouri Dept. of Natural Resources	5.4 to 1 dilutions at the property line
North Carolina Division of Air Quality	Objectionable odor at the source

Chapter 10 Emission Control Systems

Abstract

Emissions odors, gases, and dust from livestock production facilities arise primarily from three sources; buildings, manure storages, and land application (1). Emissions from buildings and storages form a baseline emission level. Eliminating emissions from one of the sources will likely not eliminate emissions entirely. Control technologies often address only one of the three sources. *Many of the technologies reduce emissions; none eliminate them.*

Emissions from buildings can be reduced by inhibiting contaminant generation, or by treating the air as it leaves the building. Frequent manure removal is one of the best ways of reducing contaminant generation within the building. Frequent removal requires outdoor storage. Other methods include the use of bedding, oil sprinkling, chemical additives, and diet manipulation. Treating the air leaving a building can be done with washing walls or biofilters. Natural or manmade windbreak walls may be beneficial.

There are four types of storages; deep pits, outdoor slurry storage, anaerobic lagoons, and solid stacks. Outdoor storages are the most apparent source of odors. Controls include permeable and impermeable, natural and synthetic covers. They have been shown to be effective when managed properly. Solids separation has not been proven effective to reduce odors. Proper aeration will eliminate odors from outdoor storages, but is expensive in a liquid system. Composting works well for solid manure. Anaerobic digesters reduce odors, but are also not economically feasible. Manure additives are generally not reliable.

Emission control during land application is best done by direct injection.

General Introduction

Buildings, whether they are naturally ventilated (depend on natural breezes for ventilation), or mechanically ventilated (depend on fans for ventilation), buildings must have continuous air movement through them for the health of the animals and workers. Building emissions, along with emissions from the manure storage, form a baseline emission level for a production site (2).

Different types of storages are used for confinement systems. Outdoor pits and lagoons have the advantage of removing manure from the buildings more frequently than the "deep pit", which stores the manure under the building. Because they're exposed to the wind, outdoor storages may have a greater potential for odor and gas release.

Odor and gas releases are reduced during cold weather. Outdoor storages freeze, and building ventilation is reduced.

A high percentage of complaints each year occur due to land application of manure (3). Unlike buildings and storages, land application only occurs once or twice a year, and the impact is for short period of time. Air quality impacts involve a combination of intensity and duration. Buildings and storages represent the "baseline" emission levels. Land application can cause short term, more intense emissions.

10.1 Emission Control Strategies from Building Sources

Introduction

There are two basic approaches to minimizing odor emissions from buildings. The ideal odor control method is to minimize the odor generated in the building. The second option is to capture and treat odor as it is emitted from the building. The first method benefits the people and animals in the building as well as the neighbors. Either method helps minimize effects on neighbors.

Minimizing Odors within a Building

There are a number of recognized methods of minimizing odors generated within buildings. One of the more popular and effective is simply frequent manure removal. By using anaerobic lagoons so that "dilute" liquid is available to flush the areas where the manure collects frequently. The concept is very similar to human waste management where we flush the stool after each use. Animal facilities that flush once a week have better air quality than those that flush less frequently.

Bedded solid manure is thought to release fewer odors than liquid systems (4). Although firm scientific data has not proved it, most people feel that odors from bedded systems are less bothersome than from liquid systems, although dust may be worse from bedded systems than liquid.

Sprinkling vegetable oil in very small amounts inside swine buildings has been shown to control dust as well as odor and some gases (5,6,7). Once a day sprinkling at 0.5 ml/ft^2 has reduced dust 40-50%, odor up to 60%, and H_2S up to 60% (8). No reduction in NH_3 was found. A disadvantage is that building surfaces become oily and requires the use of degreasers in cleanup.

Chemical additives to reduce manure odors and gases have been popular with producers and vendors for many years. Unfortunately researchers have found it very difficult to prove the effectiveness of the many additives that are available. Of the products tested, relatively few have been shown to significantly reduce odor or gases. The most recent study was done by the National Pork Board (9). It investigated 35 products. Of the 35, none reduced odors at the 95% confidence level. Hydrogen sulfide was reduced at that level by 7 of the products, and 8 products reduced ammonia. Only one product was effective for both gases. These results are typical of studies over the years where given products may work for one gas, but not for anything else. Another reason additives are not recommended is their cost, which can be significant.

One application where an additive has been shown to be effective is in the poultry industry. Alum has been shown to reduce ammonia volatilization very significantly during a 42-day incubation of poultry litter (10), and also found to be cost effective due to increased production when it is used.

Ozone is a powerful oxidizing agent and germicide that has been investigated for its odor control characteristics. It's a natural component of air, and has been used to disinfect water supplies for years (11,12). It is being tested in a swine barn where it's distributed with ventilation air (13,14). Ozone's disadvantages are that it is very unstable, so it doesn't last long, and it can be very toxic and corrosive at high levels. OSHA's exposure limit is 0.1 part per million for an 8-hour exposure (15).

Diet manipulation has significant potential for ammonia reduction by reducing nitrogen (protein) in the feed (16,17). This concept is becoming more popular, but must be used with care since production can be significantly effected if protein levels are reduced too far.

Capturing and/or Treating Odor Emitted from Buildings

There are several ways of treating air before it's released from a building to lessen its odor and gas emission potential. The following are some methods that have been researched to some degree.

Washing walls is a concept that has been tested to reduce dust and odors (18). Water is used to "scrub" air as it leaves buildings similar to systems used in industry. Water recirculates through evaporative pad scrubber as exhaust fans blow air from the building. Such a system requires power ventilation systems (not natural ventilation). Washing Walls used in a swine finisher reduced total dust 20-60%, NH_3 33-50%, and reduced odors only slightly. As might be expected, better cleanup was achieved with low airflow rates compared to high rates.

Biofilters similar to those used in Europe have been adapted in the US. They use biomass and microorganisms to treat ventilation air as it leaves the building. Design parameters have been tested on a full-scale 750-head sow facility in Minnesota (19,20,21,22). At that facility the biofilter achieved odor and H_2S reduction of 80-90%, and NH_3 reduction of 50-60%. Weed control and rodent control were the primary problems experienced. A critical element in the use of biofilters is their dependence on power ventilated buildings where fans push the air through the filter. They don't work on naturally ventilated buildings.

A similar system is the biomass filter (23). Although not quite as effective as a biofilter, biomass filters do not depend on microbes to the extent of a biofilter, and they don't restrict airflow as much. Like a biofilter, power ventilation is required to use a biomass filter.

Windbreak walls are a type of wall that has been tested in the Southeast US to deflect exhaust air upward from tunnel ventilated building so it mixes with clean air, which dilutes odors and gases (24).

Windbreak walls can be constructed of various materials such as metal, straw, or wood. Without a wall, exhaust air moves along the ground and is not diluted. A Windbreak wall helps to direct barn exhaust air upward for better dispersion/dilution.

Natural windbreaks accomplish some of the same things (25). They, however, take some time to establish. Odor reduction not well researched, but thought to be beneficial through mixing, and dispersion. Natural windbreaks are naturally esthetically pleasing.

10.2 Emission Control Strategies from Manure Storages

Introduction

There are four basic types of storages that require different treatment for air quality preservation. They are deep pits outdoor slurry storage basins or tanks, anaerobic lagoons, and solid manure storage systems. The following briefly defines each type:

Deep Pits and Slurry Storage

A deep pit is a manure storage area underneath, or in the "basement," of a livestock production building. The manure storage is not visible from outside the building, and wind does not blow across the storage unit and pick up odors and gases. Manure is typically removed from deep pits only once or twice a year. No extra dilution water is added to the manure. Outdoor slurry storages may be used in place of deep pits. They may be made of earth, concrete, or steel. The earthen storages were popular due to their low cost (less than ½ the cost of the others) until regulations made them unfeasible to construct. Outdoor storages have the advantage of more frequent removal of manure from the building to provide better air quality within the building.

Anaerobic Lagoons

Anaerobic lagoons are considerably larger than earthen storage since they are designed as treatment method (26). Originally designed as an odor control method, they use microbes to digest manure solids and stabilize the manure (27). To avoid accumulating concentrations of some constituents (particularly ammonia) that are toxic t the microbes, dilution water is added. Earthen construction is used due to the large storage volume needed to accommodate the manure and dilution water.

Solid Stacks

Solid stacks can result either from using bedding to create solid manure, or from solids separated from liquid streams. Either type should be solid enough to pile up in a stack. Stacks may or may not be composted. They typically compost naturally somewhat, but may become anaerobic if piled too deep, or if the particles are too fine to admit enough oxygen for composting (28). If a stack becomes anaerobic it can be a source of odors and gases like a liquid system. Properly composted solids emit few odors (29).

Air Quality Control Technologies

Storages are the most "apparent" odor source on many farms. Since many people know that the odors coming from animal farms originate with the manure, it is natural for them to focus on the manure storage facility. The visibility of manure sources can make a difference in both the odor frequency and magnitude of what people smell. Landscaping improves the appearance of production and manure storage facilities and helps hide storages.

Covers

Synthetic impermeable covers hold gases and odors inside tank. Covers may be either rigid (wooden, concrete, fiberglass), or flexible (plastic). Synthetic plastic covers may either float on the liquid surface, be inflated, or be held above the liquid level by cables. Inflated covers are difficult to protect from high winds, so floating covers are the most common. Gas and odor reductions have been reported from 40 – 90% (2, 30).

Biocovers such as straw or cornstalks protect liquid manure from air passing over storage. Even though they are permeable, they still reduce diffusion from liquid surface to gas above (31). Some researchers feel that aerobic action occurs within the cover. In some situations a natural crust will develop which accomplishes the same result as an artificial biocover.

Other synthetic permeable covers have been developed such as a geotextile cover for earthen storages, and clay ball covers (Leka rock) on concrete slurry pit

The benefits of some of the above covers have been shown to be significant, while others are less successful (31). All covers require additional management, whether it's extra chopping of straw to avoid plugging lines, or peeling back synthetic covers to provide access for pumpout. The capital cost of covers also reduces their acceptance by producers. Approximate costs of the various types of covers follows:

Biocovers (straw)	$0.10/sq ft each year	$0.40 per head
Clay balls (LEKA)	$2-5/sq ft every	$0.33 - .80* " "
Geotextile	$0.20-$0.40/sq ft every	$0.03 - .07 " "
Plastic cover	$1-$2/sq ft every	$0.16 – 0.33 " "

* Assumes 10 year life, 10% annual interest

Solids Separation

Separating solids from liquid manure reduces the load on anaerobic lagoons, which should help reduce odors from the lagoons. Solids separation is very difficult to accomplish with liquid swine manure. Removal rates may range from 5% 5o 50% (32,33). Although the theory is sound, odor/gas reductions have not been documented due to solids reductions resulting from separating solids (34). Solids separation also creates a second waste stream to manage which may be detrimental to overall air quality if the system is not managed correctly. The cost of solids separation ranges from $10-$20 per1000 lb bodyweight per year making it very expensive. Overall solids separation is not a good alternative for air quality protection in most instances.

Aeration

Complete aerobic treatment nearly eliminates odors and undesirable gases. Many municipalities and industries use aeration for waste treatment. Continuous aeration can be achieved via floating aerators, fixed aerators, or submerged air lines. Air can be bubbled up through the liquid, whipped into the liquid, or the liquid sprayed up into the air. The disadvantage of aeration (and the reason producers don't use it) is that it requires very large amounts of energy (electricity) to accomplish the air entrainment necessary (35). The energy cost for aerating liquid manure is estimated to be $20-$40/1,000-lb bodywgt. -year

Partial Aeration can reduce odors and gases, although if under designed may actually increase odors. Floating aerators may be used for partial aeration, with the number of units determining the completeness of the aeration.

Composting is a method of aerating solid manure. Like liquid aeration, it significantly reduces odors (28). In addition, it is less energy intensive, since periodic mixing can be done relatively cheaply. Bedding in solid manure tends to make the manure "fluffy" so air naturally mixes with it to help maintain aerobic conditions. The mix of gases released is different than anaerobic treatment. Composting costs can vary significantly, but some estimates are \$0.20-\$0.40/1,000-lb bodywgt per year.

Anaerobic Treatment

Anaerobic treatment takes place in the absence of oxygen. The most common type is the anaerobic lagoon. Although the general public has a poor opinion of anaerobic lagoons, a properly operating one emits low odors. Lagoon design is based on volatile solids or COD loading, with the objective of keeping the bacterial populations in the lagoon in balance. When they are in balance, odors are minimal. In Iowa, cold weather interferes with balanced, steady state operation, and makes odor control more difficult. Oversized lagoons are sometimes used to reduce concentrations within the lagoon, thus reducing odors. The cost of oversizing lagoons can be expected to be about \$200 per 1000 lb bodyweight capital cost for extra earthwork.

Anaerobic digesters are very different from anaerobic lagoons. Digesters provide more "intense" treatment. Digesters are heated and the manure is thicker than lagoons. An overloaded condition can cause intense odors and gases. Digesters reduce odors by containing the gas that is produced so that it can be burned, and by stabilizing the liquid before it goes to the open storage tank or lagoon. Anaerobic digesters are misunderstood by the general public. Digesters are complex living organisms that are expensive to install, and require significant additional management. They do reduce odors, BOD/COD, and provide energy as heat, electricity, or both. But they do <u>not</u> reduce the volume or nutrient concentration of the manure significantly. The cost of constructing an anaerobic digestion system is approximately \$100/pig, or \$500-1,000/dairy cow capital cost. Some of the costs can be offset by the captured energy, but without higher energy prices or large government grants anaerobic digesters are not economically viable (36).

Manure Additives

Many additives are available to add to pits, lagoons, or animal feed. They work in a variety of different ways. Microbiological additives include digestive deodorants. They may be designed to enhance solids degradation, and may be pH or temperature dependant. One of the main factors that is discouraging about microbiological additives is that to work effectively, they must become the predominate bacteria. Since most bacteria are ubiquitous, if the environment favored the selected bacteria, it would already predominate in the manure (37).

Chemical (non microbiological) additives may include several mechanisms for control:
pH control
chemical oxidation
precipitation
odor masks or perfumes
adsorbents

A recently completed study of 35 additives conducted by the National Pork Board found that none of the additives decreased odors at the 95% confidence level, 6 decreased hydrogen sulfide, and 8 reduced ammonia (8).
Cost of biological/chemical additives
$0.20-$1.00/pig mktd

Emission Control from Land Application of Manure

Applying manure to cropland returns nutrients to the soil. The manure provides nutrients to the crops that would otherwise have to be purchased as commercial fertilizer. The other reason manure is land applied is *because federal law forbids discharging agricultural wastes to waters of the state or nation.* Unfortunately, land application can result in very significant odor occurrences. Even though they are not long lasting, odors from land application can be very obnoxious.

The best way to reduce odors from land application of liquid manure is direct injection of the manure below the soil surface (38,39). Research has shown that injection that accomplishes good soil cover of the manure results in odor reductions up to 90% compared to broadcast manure. Lack of complete coverage reduces odor control. Broadcasting followed by rapid incorporation also significantly reduces odors compared to broadcasting only (40), but it is not as effective as direct injection. The additional cost to inject manure is typically 1/10th of a cent per gallon more than broadcast. Some of the additional cost is offset by better nitrogen retention.

Other methods of reducing odors from land application include dilution with clean water, placement below the crop canopy (the canopy reduces air movement across the manured soil), and other potential treatments. Pretreatments have been shown to reduce odors 80%, and certain specific gases such as hydrogen sulfide up to 90% (41), but pretreatment with additives is unreliable and expensive. Research is being conducted with ozone to remove odors and reduce ammonia and hydrogen sulfide, but results aren't yet known. It's known that the technology works, but cost and management requirements haven't been proved.

Solid manure is generally less odorous than liquid, but still deserves some attention. Because it cannot be injected, rapid incorporation of solid manure is the best method to minimize odors.

Some of the best odor control results for observing common sense rules that account for wind direction and speed. Watching weather forecast, and not spreading when the wind is blowing towards neighbors can minimize severe odor "events". Several models have been developed by universities and government agencies, such as EPA's INPUFF and Minnesota's OFFSET model (42, 43), to predict odor movement and estimate their effects on neighbors.

Summary

Table 1 summarizes methods to reduce gas, odor, and dust emissions from animal facilities. Odor and gas emission sources associated with animal production facilities can be broken down into three categories: buildings, storages, and land application. Eliminating emissions from any one of the three will not eliminate emissions entirely. A number of technologies exist that are capable of reducing emissions from all three. Cost, increased management requirements, and lack of economic or regulatory incentives to encourage their use are the primary reasons more producers have not adopted the technologies. Technologies that work well, are easily managed, and are affordable have seen increased use throughout the state. These include biocovers on outside storages, utilization of deep pits (eliminating outside storages), greater use of bedded systems and composting, and manure injection during land application.

Table 1. Summary Table of Emission Reducing Strategies

Emission Source*	Emission Reducing Strategy	Targeted Components**	Documented Reduction
Housing Unit Emissions (25)			
Feeding floor (60)	Frequent, short-term pressure washing	dust, odors	65 - 70 %
Feeding floor (60)	Urine separation, complete scraping to sealed under-floor storage	dust, odors	50 - 65 %
Under-floor storage (40)	Frequent, complete scraping, water follow-up	odors	
Under-floor storage (40)	Air exchange avoidance with room air	odors	80 %
Ventilation air exhausted (100)	Dust suppression using oil sprayed on internal building surfaces	dust, odors	50 - 60 %
Ventilation air exhausted (100)	Dust suppression using biomass filters	dust, odors	50 - 60 %
Ventilation air exhausted (100)	Dust and gas suppression using biofilters	dust, odors	85 - 90 %
Storage Unit Emissions (25)			
	Floating permeable man-made covers	odors	60 - 75 %
	Floating impermeable man-made covers	odors	80 %
	Impermeable man-made covers	odors	95 %
	Chopped-straw covers	odors	75 %
	Natural crusting of manure surface	odors	75 %
	Anaerobic digestion of manure	odors	80 - 85 %
Land Applying Unit Emissions (50)			
	Surface applied, incorporation delayed 24 hours	odors	0 - 5 %
	Surface applied, incorporation delayed 12 hours	odors	0 - 5 %
	Surface applied, incorporation delayed 6 hours	odors	0 - 5 %
	Surface applied, incorporation delayed 3 hours	odors	0 - 10 %
	Surface applied, incorporated immediately by plowing	odors	50%
	Injection with full soil coverage	odors	85 - 90 %

* ( ) implies roughly the percent of total system emissions (Kroodsma et al, 1993)
** odors implies all gases emitted from livestock production systems

Attachment 3. Glossary of Terms

ACGIH - American Conference of Governmental Industrial Hygienists
Acidic equivalent[1] - pollutants differ in their acidic effect per gram. A pollutant's effect on acidification is expressed in acidic equivalents
Acidification[1] - the process by which a soil becomes increasingly acidic. This can be caused by emissions of sulphur dioxide, nitrogen dioxide and ammonia.
Acid precipitation[1] - the mechanisms by which acidity reaches the earth's surface. These include gaseous and particle pollutants in dry, occult or wet deposition.
Acute toxicity - effects of a single dose or multiple doses measured during a twenty-four-hour period
Adverse effect[2a] - change in morphology, physiology, growth, development or life span of an organism exposed to air pollution, which results in impairment of functional capacity or impairment of capacity to compensate for additional stress or increase in susceptibility to the harmful effects of other environmental influences
Aeration[3] - a process forcing intimate contact between air and a liquid by one or more of the following methods: spraying the liquid in the air; bubbling air through the liquid; agitating the liquid to promote absorption of oxygen through the air liquid interface
Aerobic bacteria[3] - bacteria that require free elemental oxygen for their growth. Oxygen in chemical combination will not support aerobic organisms
Aerobic decomposition[3] - reduction of the net energy level of organic matter by aerobic microorganisms
Aerosols[4] - an assembly of liquid or solid particles suspended in a gaseous medium long enough to enable observation or measurement.
Agitation[3] - the turbulent mixing of liquids and slurries
ALARA principle[1] - the "As Low as Reasonably Achievable Principle" according to which rules and regulations are based on a balanced assessment of available technology, economic costs and environmental interests
Ambient[5] - surrounding, as in the surrounding environment. The medium surrounding or contacting an organism (e.g., a person), such as outdoor air, indoor air, water, or soil, through which chemicals or pollutants can be carried and can reach the organism
Anerobic bacteria[3] - bacteria not requiring the presence of free or dissolved oxygen. Facultative anaerobes can be active in the presence of dissolved oxygen, but do not require it.
Animal health[6] - a state of physical and psychological well-being and of productivity including reproduction
Animal unit - many emission quantities published are based on a per animal unit (AU) basis. Unless otherwise noted, one AU is equivalent to 500 kg body weight (1,100 lbs.)
Application regulations[1] - regulations governing when and how livestock manure, sewage sludge, compost, black soil and combinations of the above may be applied on land
Appraisal[7] - cognitive process of assessing the extent to which a threat, challenge, or loss exists and the availability of needed coping resources
Asphyxia[8] - impaired or absent exchange of oxygen and carbon dioxide on a ventilatory basis.
Asthma[9] - a lung disease with the following characteristics: 1) airway obstruction (or airway narrowing) that is reversible (but not completely so in some patients) either spontaneously or with treatment; 2) airway inflammation; and 3) airway hyper-responsiveness to a variety of stimuli.
Bacteria[1] - A group of universally distributed, rigid, essentially unicellular procaryotic microorganisms. Bacteria usually appear as spheroid, rod-like or curved entities, but occasionally appear as sheets, chains, or branched filaments.
Bioaerosol - includes the sub-class of viable particulates that has an associated biological component
Biogas[3] - gaseous product of anaerobic digestion that consists primarily of methane and carbon dioxide
Bioterrorism[10] - the overt or covert dispensing of disease pathogens by individuals, groups, or governments for the explicit purpose of causing death or disease in humans, animals, or plants. Biological terrorism agents include both living microorganisms (bacteria, protozoa, viruses, and fungi), and toxins (chemicals) produced by microorganisms, plants, or animals.
Blue baby syndrome[11] - see Methemoglobinemia
Bronchiolitis obliterans - a disease of the airways of the lung that is characterized by fibrosis (scarring) of the small airways (bronchioles). Known causes include some viral infections, rejection of a transplanted lung, and inhalation of some mineral dusts and irritant fumes.

CAFO - Concentrated Animal Feeding Operation; also known as Confined Animal Feeding Operation; generally, a facility where large numbers of farm animals are confined, fed, and raised, such as dairy and beef cattle feedlots, hog production facilities, and closed poultry houses. EPA has developed a specific regulatory definition of CAFO for the purpose of enforcing the Clean Water Act.[2]

Chronicity index[12] - ratio of the acute to chronic LD50 dosage

Chronic effects - effects produced by prolonged exposures of three months to a lifetime

Clean Water Act[11] - federal legislation administered by the U.S. EPA that serves as the primary means of protecting and regulating the surface water quality of the United State. The goal of this legislation is to eliminate the discharge of contaminants into Untied States waters and to achieve a level of water quality capable of supporting propagation of fish and wildlife and water-based recreation

Cognitive[7] - relating to thinking processes and related brain functioning

Coliform-group bacteria[1] - a group of long-living bacteria predominantly inhabiting the intestines of warm blooded animals, but also found in soil. It includes all aerobic and facultative anaerobic, gram-negative, nonspore-forming bacilli that ferment lactose with production of gas. This group of "total" coliforms include escherichia coli which is considered the typical form of fecal origin. The fecal coliforms are often used as an indicator of the potential presence of pathogenic organisms.

Concentrate feed[1] - animal feed containing mineral supplements

Concentration[7] - the strong trend of monopolization and vertical integration in agricultural production, processing, and marketing, as well as in the manufacturing of farm inputs

Contract feeding[7] - a method of livestock production in which companies provide farmers with young animals, feed, medications, etc. and the farmers provide the building, equipment, and labor, while receiving a set amount per pound or head and absorbing many of the risks of production

Control condition[7] - condition in which no treatment occurs, thus allowing comparison of the effects of the experimental treatment

Coping[7] - efforts to decrease, tolerate, or master the demands created by stressors; may be adaptive or maladaptive

Depression[7] - disorder related to brain chemistry and biologic factors that is characterized by sadness, despair, low self-esteem, low positive affect, sleep disorders, or change in appetite

Designated areas[1] - areas protected by law, in this case areas vulnerable to leaching

Disease[13] - any deviation from or interruption of the normal structure or function of the body that has a characteristic set of symptoms and signs for which there are objective findings (e.g., medical tests, x-rays) and which fits the definition of a specific disease as seen in the International Code of Diseases (ICD-9).

Disposal[11] - the discharge, deposit, injection, dumping, spilling, leaking, or placing of any solid waste or hazardous waste into the environment (land, surface water, ground water, and air)

Diversified operations[7] - farms that produce a variety of grains and livestock in ways (e.g., crop rotation) that promote environmental sustainability

Dosage - toxicity expressed as amount of toxicant per unity of body weight

Emissions - the rate at which gases or particulates leave a surface or ventilated structure. An emission rate is calculated by multiplying the concentration of a gas (mass or volume basis) by the airflow rate (volume of air per unit time) associated with this concentration

Empowerment[7] - enhancement of sense of capability, on individual and social levels, as distinct from power over others

Epidemiology - study of the distribution and determinants of health-related states or events in particular populations; application of this study to the prevention and control of health problems

Escherichia coli, E. coli[3] - one of the species of coliform bacteria in the intestinal tract of warm-blooded animals. Its presence is considered indicative of fresh fecal contamination.

Eutrophication[1] - excessive concentrations of phosphate and nitrogen enter the environment and upset the balance of water and soil ecosystems and diminish the quality of drinking water

Externalization of costs[7] - political and economic processes by which publicly unacceptable (e.g., polluting) aspects of manufacturing or production are directly or indirectly paid by the public, rather than by the manufacturer, such as through hiding or ignoring costs, passing costs along to consumers, or receiving public subsidies

Facultative bacteria[11] - bacteria that can grow in the presence, as well as the absence, of oxygen

Farm commodities[7] - the grain, livestock, fiber, and other materials produced by farmers

FEV1 - forced expiratory volume in one second

FVC - forced vital capacity

Groundwater[14] - that portion of the water below the surface of the ground at a pressure equal to or greater than atmospheric

Hazard[15] - potential for radiation, a chemical or other pollutant to cause human illness or injury
Health[2b] - health is a state of complete physical, social and mental, and social well-being and not merely the absence of disease or infirmity
Housing unit - any facility used to house livestock or poultry incorporating either a mechanical or natural ventilation system for providing fresh-air exchange
H_2S - hydrogen sulfide
Impermeable - not permitting fluids to pass through
Inhalable - the class of particulates or bioaerosols having a mean aerodynamic diameter at or below 100 um
Input standard[1] - the maximum amount of minerals per acre that may be deposited on land. The standard encompasses both the manure produced on the farm and manure or fertilizer inputted at the farmgate.
Inputs[7] - materials needed for farm production, e.g., seed, fertilizer, pesticides
Industrialized agriculture[9] - large-scale, highly capitalized farm production that favors corporate production over family farm production
Irritant[16] - toxicant that exerts its deleterious effects by causing inflammation of mucous membranes with which they came into contact. Irritants principally act on the respiratory system and can cause death from asphyxiation due to lung edema. Other mucous membranes that may be affected by irritants are those of the eyes.
Lagoon[3] - an earthen facility for the biological treatment of wastewater. It can be aerobic, artificially aerated, anaerobic or facultative depending on the loading rate, design, and type of organisms present.
Land application[3] - application of manure, sewage sludge, municipal wastewater, and industrial wastes to land either for disposal or for utilization of the fertilizer nutrients, organic matter, and improvement of soil tilth.
Land application unit - the process of applying animal manure to the soil
Laughing gas[1] - NO_2, forms naturally during nitrification. It is a greenhouse gas.
Loss standard[1] - the amounts of phosphate and nitrogen that may be released into the environment. When losses exceed the loss standard, a levy is raised on the difference.
Low emission manure application techniques[1] - techniques where manure is not spread on the surface but is injected into the sod or ploughed in to prevent ammonia emission.
Low-emission housing[1] - livestock housing with a lower ammonia emission than conventional housing
Manure[3] - the fecal and urinary excretion of livestock and poultry. Often referred to as livestock waste. This material may also contain bedding, spilled feed, water or soil. It may also include wastes not associated with livestock excreta, such as milking center wastewater, contaminated milk, hair, feathers, or other debris. Manure may be described in different categories as related to solids and moisture content. These categories are related to handling equipment and storage types.
Manure disposal contract[1] - contract between a livestock farmer with a manure surplus on his farm and an arable farmer or other user of agricultural land with a manure shortage, or a manure processing establishment
Manure storage unit - any structure used to store manure, including long-term storage inside the housing unit. Includes above- and below-ground structures.
Meteorological[17] - pertaining to the atmosphere and its phenomena, especially of its variations of heat and moisture, of its winds, etc.
Methemoglobinemia[11] - illness caused by high levels of nitrate in drinking water, above about 45 ppm, which infants are particularly susceptible to.
Methane[1] - a gas that is released during the digestive processes of ruminants. Methane is a greenhouse gas
Microorganism - a microscopic organism as a bacteria or fungi
Minerals accounting system[1] - registration of nitrogen and phosphate inputs and outputs on a farm. Input and output should be balanced although some loss is considered acceptable (loss standard).
Minimum risk level (MRL)[18] - an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse non-cancer health effects over a specified duration of exposure.
Multiplier effect[7] - the multiplying of economic activities, including at the community level, including that achieved through raw material production
NH_3 - ammonia
Nitrification[3] - the biological oxidation of ammoniacal nitrogen to nitrite and then to nitrate
NO_2 - nitrogen dioxide

Nonpoint source pollution[19] - Nonpoint source pollution, unlike pollution from industrial and sewage treatment plants, comes from many diffuse sources. Nonpoint source pollution is caused by rainfall or snowmelt moving over and through the ground. As the runoff moves, it picks up and carries away natural and human-made pollutants, finally depositing them into lakes, rivers, wetlands, coastal waters, and even our underground sources of drinking water. In rural areas these pollutants include bacteria and nutrients from livestock, soil sediments, fertilizers, herbicides, and insecticides.

Nutrient pollution[11] - contamination by excessive inputs of nutrient: a primary cause of eutrophication of surface waters, in which excess nutrients, usually nitrogen or phosphorus, stimulate algal growth. Sources of nutrient pollution include runoff from fields and pastures, discharges from septic tanks and feedlots, and emissions from combustion.

Odor threshold[3] - the lowest concentration of an odor in air that can be detected by the human olfactory sense

Operating costs[7] - the costs of farm inputs, labor, credit, energy, etc.

OSHA - Occupational Safety and Health Administration

Particulate - includes the class of both inert and viable aerosols. Includes total, inhalable, and respirable fractions

Parity prices[7] - equality in prices for farm commodities in which farmers get a fair return in relation to their costs of production; historically maintained by government support of farm commodity prices at a level fixed by law and indexed for inflation

PEL - Permissible Exposure Limit

Point source pollution - pollution from a particular source

Poison - see Toxicant

Pollutant[11] - a contaminant that adversely alters the physical, chemical, or biological properties of the environment. The term includes toxic metals, carcinogens, pathogens, oxygen-demanding materials, heat, and all other harmful substances, contaminants, or impurities

Pollution[11] - presence of a contaminant to such a degree that the environment (land, water, or air) is not suitable for a particular use

Price support[7] - a policy mechanism such as the non-recourse loan that sets a floor under farm commodities and thus requires exporters or processors to pay a minimum price. This is in contrast to an "income support" that involves direct payments from the U. S. Treasury to support farm income but does not directly influence market prices.

Pulmonary[8] - relating to the lungs, to the pulmonary artery, or to the aperture leading from the right ventricle into the pulmonary artery

Regulation[11] - a requirement or rule passed by an agency or department of federal, state, or local government that is authorized to create and enforce a requirement or rule through an authorizing statute or constitutional authority

Resistance - the extent to which a disease or disease-causing organism is unaffected by antibiotics or other medications

Respirable - the class of particulates or bioaerosols having a mean aerodynamic diameter at or below 5 um

Restructuring (agricultural restructuring)[20] - changes in the relationships among ownership, management, and labor in the agriculture-food system, with particular emphasis on the production component. Restructuring generally involves technological changes (induding shifts in levels of specialization/diversification) as cause or effect, and may include changes in vertical and horizontal integration or coordination, in ownership of resources (including tenancy and leasing), in farm/firm size, in geographic location of specific agri-food activities, in composition of the work force, and in levels of concentration at various levels in the supply chain.

Risk assessment - the characterization of the potential adverse health effects of human exposures to environmental hazards

Runoff[21] - occurs when input of water exceeds infiltration. Pesticide runoff includes losses from the dissolved and sediment-absorbed pesticide. Though runoff generally results directly in the contamination of surface water, it can also contribute to ground water contamination through recharging ground water by the surface water.

Setback[18] - specific distance that a structure or area must be located away, from other defined areas or structures

Sinusitis[8] - inflammation of the lining membrane of any sinus, especially of one of the sinuses alongside the nose.

Siting[11] - choosing a location for a facility

Social capital - mutual trust, reciprocity, and shared norms and identity that are inherent in relationships between and among groups

Spot market - a market in which buyer and seller come together with no pre-arranged commitment or price with the expectation of exchanging a good or service. The terms of the transaction are public, and, jointly with other similar transactions of the day, define a market price for that day.

Statistically significant difference - a research finding that is unlikely (usually less likely than 5 percent) to be due to chance

STEL - short-term exposure limit
Stress[7] - emotional, physical, behavioral, and social reactions to stressors
Stressor[7] - short-term or ongoing conditions, situations, or relationships that cause stress, often involving change, conflict, or pressure
Subacute toxic effects - toxic effects apparent over a period of several days or weeks
Subchronic toxicity - toxic effects that occur between 30 days and 90 days exposure
Supply chain[22] - the chain of transactions and product transformations that take place between the producer and consumer of a particular commodity. Historically, in agriculture, supply chains have implied openness of entry for new producers, and hence involve mass production of an undifferentiated commodity.
Tolerance - condition in which repeated exposure increases the size of the dose required to produce lethality
Toxicity - the quantitative amount or dosage of a poison that will produce a define effect
Toxicant - any natural or synthetic solid, liquid or gas that when introduced into or applied to the body can interfere with homeostasis of the organism or life processes of cells of he organism by its own inherent qualities, without acting mechanically and irrespective of temperature
Trace element[1] - chemical elements (such as copper, zinc) present in minute quantities in plant or animal tissues and considered essential to these organisms' physiological processes. An overdose, however, is harmful for the organism. Non-essential trace elements such as cadmium are harmful even in very low concentrations.
TWA - Time Weighted Average
USDA - U. S. Department of Agriculture; federal agency that is responsible for select state and local programs regarding agricultural production, conservation, and food
Value-added agriculture[7] - production of farm commodities that are fully or partially processed before being marketed by farmers (as individuals or in groups, e.g., ethanol cooperatives), thus enhancing the income of farmers and rural communities
Value chain[22] - a supply chain characterized at least in part of its links by vertical coordination. Value chains generally involve limited entry at the various levels, or links in the chain, and are focused on providing particular consumer groups with a product that fits their preferences. The emphasis is on quality (or specific qualities), rather than on producing an inexpensive product.
Vertical coordination[23] - synchronization of the vertical stages of a production/marketing system
Vertical integration[24] - coordination of two or more stages in the food chain under ownership via management directive
VOC - volatile organic compound

Mortality and Health Outcomes in North Carolina Communities Located in Close Proximity to Hog Concentrated Animal Feeding Operations

Julia Kravchenko, Sung Han Rhew, Igor Akushevich, Pankaj Agarwal, H. Kim Lyerly

BACKGROUND Life expectancy in southeastern North Carolina communities located in an area with multiple concentrated animal feeding operations (CAFOs) after adjusting for socioeconomic factors remains low. We hypothesized that poor health outcomes in this region may be due to converging demographic, socioeconomic, behavioral, and access-to-care factors and are influenced by the presence of hog CAFOs.

METHODS We studied mortality, hospital admissions, and emergency department (ED) usage for health conditions potentially associated with hog CAFOs—anemia, kidney disease, infectious diseases, and low birth weight (LBW)—in North Carolina communities located in zip codes with hog CAFOs (Study group 1), in zip codes with > 215hogs/km^2 (Study group 2), and without hog CAFOs (Control group). We compared cause-specific age-adjusted rates, the odds ratios (ORs) of events in multivariable analyses (adjusted for 6 co-factors), and the changes of ORs relative to the distance to hog CAFOs.

RESULTS Residents from Study groups 1 and 2 had higher rates of all-cause mortality, infant mortality, mortality of patients with multimorbidity, mortality from anemia, kidney disease, tuberculosis, and septicemia, and higher rates of ED visits and hospital admissions for LBW infants than the residents in the Control group. In zip codes with > 215hogs/km^2, mortality ORs were 1.50 for anemia ($P < 0.0001$), 1.31 for kidney disease ($P < 0.0001$), 2.30 for septicemia ($P < 0.0001$), and 2.22 for tuberculosis ($P = 0.0061$).

LIMITATIONS This study included a lack of individual measurements on environmental contaminants, biomarkers of exposures and co-factors, and differences in residential and occupational locations.

CONCLUSION North Carolina communities located near hog CAFOs had higher all-cause and infant mortality, mortality due to anemia, kidney disease, tuberculosis, septicemia, and higher hospital admissions/ED visits of LBW infants. Although not establishing causality with exposures from hog CAFOs, our findings support the need for future studies to determine factors that influence these outcomes, as well as the need to improve screening and diagnostic strategies for these diseases in North Carolina communities adjacent to hog CAFOs.

Among North Carolina communities, including both high-income and low-income communities, the lowest life expectancy was observed in southeastern North Carolina [1]. Higher risks of chronic kidney disease and low birth weight (LBW) infants have also been reported for this region [2, 3]. These geographic variations in life expectancy and health outcomes have been suggested to correlate with region-specific health behaviors, access to care, and environmental characteristics [1]. One unique environmental characteristic of southeastern North Carolina is the presence of multiple hog concentrated animal feeding operations (CAFOs) [4]. The average number of hogs per farm in North Carolina is much higher than in the areas with hog CAFOs in 2 other US leaders in hog industry—the states of Iowa and Minnesota. Because the population density in southeastern North Carolina is substantially higher than in the areas with hog CAFOs in Iowa and Minnesota, the population of the communities adjacent to hog CAFOs is much greater. Consequently, the proximity of multiple high-density hog CAFOs to a large population makes this region uniquely suited to studying the potential impact of CAFOs on environment and human health.

Previous studies of the potential relationship between health and hog CAFOs were mostly focused on the occupational health risks among CAFO workers [3, 5, 6]. The residents living in close proximity to hog CAFOs may also be at risk as they are chronically exposed to contaminants from land-applied wastes and their overland flows, leaking lagoons, and pit-buried carcasses, as well as airborne emissions, resulting in higher risks of certain diseases [3, 6, 7-20]. In fact, previous survey based studies of residential communities reported significant health risks for residents, including higher risks of bacterial infections, higher frequencies of symptoms of respiratory and neurological disorders, and depression [3, 6, 7, 12, 14, 19, 20-22].

We identified the established health conditions and indicators that were previously used to evaluate community health, including the known medical conditions associated

with occupational or residential exposure to CAFOs. These included an increased risk of anemia and kidney disease (which may serve as an indicator of chronic exposure to toxins) [23-26], miscarriage [27], and LBW infants (which may serve as an indicators of maternal and fetal health) [2]. In addition, a higher prevalence and broader spectrum of antibiotic-resistant microorganisms in areas adjacent to hog CAFOs [28-30] has raised concerns about infections in both occupational and residential settings [31]. Therefore, the outcomes of anemia and kidney disease, acute infection (septicemia) and chronic communicable infection (tuberculosis), and LBW infants were analyzed as indicators of health in communities adjacent to hog CAFOs.

We focused our study on assessing the outcomes of these specific disorders in residential communities in southeastern North Carolina. Our objective was to determine whether, or to what extent, poor health outcomes are associated with the additional impact of hog CAFOs beyond disparities associated with demographics, socioeconomic characteristics, behavioral risks factors, or access to medical care. Furthermore, these health conditions served as potential opportunities for interventions if the determined health outcomes were poor.

Materials and Methods

Data. Data on disease-specific mortality were obtained from a publicly available data source at the State Center for Health Statistics for 2007-2013 [32]. Data on emergency department (ED) visits and hospital admissions were obtained from the Healthcare Cost and Utilization Project's (HCUP) State Emergency Department Database (SEDD) [33] and State Inpatient Database (SID) [34] for 2007-2013. The North Carolina analysis represents part of the larger study on health outcomes in the communities adjacent to hog CAFOs that includes other US states with commercial hog production (eg, Iowa and Minnesota). Therefore, we used the HCUP's state-specific database containing the data in a uniform format facilitating multi-state comparisons and analyses of geographic patterns and time trends in health care utilization, access, and outcomes across multiple US states. The SEDD captures discharge information on all ED visits that do not result in an admission and contains more than 100 clinical and non-clinical variables. Information on patients that are initially seen in the ED and then admitted to the hospital is included in SID, which encompasses almost 97% of all US hospital discharges. The SID and SEDD data for North Carolina for the period analyzed in this study had several issues that were addressed in performed analysis. For example, the 2011–2012 North Carolina SEDD included 2 types of erroneous records, such as duplicated records for ED visits that did not result in an admission to the same hospital and records for ED visits that did result in an admission to the same hospital. The SID dataset for North Carolina for 2007-2008 had problems with the coding of discharge disposition. These issues were identified and resolved according to the guidelines provided by the HCUP Data Center.

The list of swine animal operations registered in North Carolina contained information on geographic locations and the number of swine in each CAFO facility. Information was obtained from the North Carolina Division of Water Resources (NC DWR) for the year 2009. The animal operations are defined by General Statute 143-215.10B as feedlots involving 250 or more swine with a liquid waste management system.

Zip-code-level data on median household income (scaled by $10,000) and education level (defined as a percentage of people aged 25+ who attained an educational level higher than a bachelor's degree) were obtained from the 2010-2014 American Community Survey. County level data on the numbers of primary care providers (per 100,000 residents) and the percent of uninsured individuals was obtained from the Area Health Resources Files (AHRF) for 2008 and 2010-2013. County level data on prevalence of current smokers in age-specific groups were obtained from the Behavioral Risk Factor Surveillance System (BRFSS, CDC) for 2008-2013.

Methods. We studied the health outcomes in two study groups. Study group 1 included the residents of North Carolina communities located in zip codes with hog CAFO(s): 221 zip codes with approximately 2,260,000 residents. Study group 2 represented a subset of Study group 1. This group included North Carolina communities located in zip codes with the highest upper quartile of hog density (with > 215hogs/km^2): 56 zip codes with approximately 400,000 residents. North Carolina communities located in zip codes without hog CAFOs represented the Control group: 601 zip codes with approximately 7,200,000 residents. Geographic locations of zip codes for two Study groups and the Control group are shown in Figure 1.

We compared disease-specific mortality, hospital admissions, and ED visits in these groups for the 2007-2013 period. All-cause, infant mortality, and outcomes of anemia, kidney disease, tuberculosis, septicemia, and LBW infants (see Appendix for respective ICD codes) were studied as the health indicators, with disease-specific mortality as primary outcome. The main predictor was the presence of a hog CAFO in a given zip code. Analyses were performed for underlying cause of death/primary diagnosis and for underlying-plus-secondary causes of death/primary-plus-secondary diagnoses. The illustration of the relations in assessment of potential impact factors/outcome associations used in multivariable analysis is shown in Supplemental Figure S1 in the Appendix.

Age-adjusted rates. We empirically estimated disease-

specific, age-adjusted rates of mortality, hospital admission, and ED visits (per 100,000). 95% confidence intervals (CIs) were estimated based on the approximation suggested by Keyfitz [35]. We compared these rates between Study groups 1 and 2 and the Control group, and additionally to North Carolina and the US average (for mortality rates).

Logistic regression analysis. We used logistic regression analysis (adjusted by age, median household income, education, health insurance coverage, numbers of primary care providers, and smoking prevalence) to evaluate whether a proportion of disease-specific deaths (as well as a proportion of disease-specific hospital admissions and ED visits) among all-cause deaths/all hospital admissions/all ED visits statistically differed between the studied groups. The Control group was a referent group for calculating ORs. This analysis allowed for minimization of potential bias due to uncertainties in population counts in North Carolina zip codes over the study period. SAS Proc Logistic (the SAS 9.4 statistical package; SAS Institute, Cary, NC) was used to evaluate ORs, 95% CIs, and p-values.

The DiSC analysis. We developed and applied an approach we termed the Distance from the Source of potential Contamination (DiSC) analysis to investigate the changes in ORs for all studied health outcomes with closer proximity to the CAFO. The core of this analysis is the new zip-code-specific continuous measure of potential exposures from hog CAFOs constructed using the exact address of each CAFO and the population counts in all census blocks in each zip code. We hypothesized that the risk of mortality (or hospital admission or ED visit) is proportional to the number of hogs in a CAFO, maximal at the location of a CAFO, and decreases with remoteness from a CAFO according to two-dimensional normal distribution (ie, "bell-shaped" distribution) of potential contaminants. Its standard deviation σ is the measure of the distance from the CAFO at which the level of potential contaminants drops 2-fold. The functional form is justified by the theory of diffusion from a point source [36]. The zip-code-specific measures of potential contaminants from CAFOs were modeled by summing the contributions of all census block groups in a given zip code:

$$E_z(\sigma) = \frac{\sum_i p_{iz} \sum_n N_n f(d_{niz}, \sigma)}{\sum_i p_{iz}}$$

where n enumerates all CAFOs; N_n is the number of hogs in the CAFO n; i enumerates all census block groups in a zip code z; p_{iz} is population of census block group i in zip-code z; and

$N_n f(d_{niz}, \sigma)$; where $f(d_{niz}, \sigma) = \dfrac{1}{\sqrt{2\pi}\sigma} \exp\left(-\dfrac{d_{niz}^2}{2\sigma^2}\right)$

is the modeled contaminant level from a specific CAFO in a census block group (where d_{niz} is the distance between them). Since there are no direct measurements that allow for estimating σ, we performed radius-specific analyses corresponding to 4 values of σ: ie, at 2, 5, 10, and 20 kilometers (km). A zip-code-specific value of $E_z(\sigma)$ was then used in the logistic regression analysis to evaluate the associations with disease-specific outcomes in multivariable analysis. The evaluated ORs are per a unit of $E_z(\sigma)$. The OR estimates for different σ are comparable because the measures are normalized equally: sums of contaminant levels over all zip-codes equal the total number of hogs in all CAFOs for any σ.

Sensitivity analyses. Because hog CAFOs are predominantly located in rural North Carolina, and access to medical care likely differs in urban and rural areas, we i) excluded zip codes of the cities of Charlotte and Raleigh, and also ii) excluded 18 urbanized areas defined in the US Census Bureau criteria for urban-rural areas as having ≥ 50,000 residents.

FIGURE S1.
Illustration of the Relations in the Assessment of Potential Impact Factors-Outcome Associations

This figure is available in its entirety in the online edition of the NCMJ.

We also used the generalized estimating equation (GEE) method to account for possible correlations between records in specific zip codes.

We used the greedy matching algorithm [37] to perform propensity score-based matching of zip codes from Control group to zip codes in Study group 2 by demographic and socioeconomic characteristics (see Appendix for detailed description of the matched groups and their characteristics presented in Table S1).

Ethics statement. All data analyses were designed and performed in accordance with the ethical standards of a responsible committee on human studies and with the Helsinki Declaration (of 1975, revised in 1983) and have been approved by the Duke University Health System Institutional Review Board.

Results

Demographic and socioeconomic characteristics. The residents of communities adjacent to hog farms were more diverse than the average North Carolina community. There were more African-American (28.8% vs. 19.3%, $P < 0.001$) and American-Indian (2.4% vs. 0.8%, $P < 0.05$) residents in zip codes with hog CAFOs (Study group 1) compared to the Control group (see Supplemental Tables S2 and S3 in Appendix). Study group 1 also had a lower median household income ($39,005 vs. $46,414, $P < 0.001$), fewer college-educated people with bachelor's or higher degrees (16.5% vs. 24.2%, $P < 0.001$), and a lower number of primary care health providers (54 vs. 76 per 100,000 residents, $P < 0.001$). The differences were even more pronounced for the residents of communities located in zip codes with > 215hogs/km^2 (Study group 2): 31.3% ($P < 0.001$) of the residents were African Americans and 4.1% were American Indians ($P < 0.001$). People from Study group 2 had the lowest (among the studied groups) median household income ($36,520, $P < 0.001$), percent of residents with bachelor's or higher degrees (13.7%, $P < 0.001$), and number of primary care providers (51/100,000, $P < 0.001$) (see Supplemental Tables S2 and S3).

Mortality rates. Cause-specific mortality rates of all studied diseases were higher in North Carolina communities located in zip codes with > 215hogs/km^2 (Study group 2) compared to the North Carolina and US averages (see Table 1). The all-cause mortality rate in Study group 2 was as high as 934/100,000.

The residents from Study group 2 aged ≤ 24 years old had much higher all-cause mortality rates (92.7/100,000) than mortality rates in North Carolina (69.8/100,000) and the US (62.2/100,000) for this age group (see Table 1). Conditions originating in the perinatal period may have substantially contributed to the differences in mortality at younger ages; the mortality rate among infants under 1 year old in Study group 2 was as high as 495/100,000. This is much higher than both the US average (317/100,000) and the North Carolina average (398/100,000). The groups that contributed the most to increased mortality rates due to perinatal conditions were newborns affected by maternal trauma and by disorders related to length of gestation and fetal growth (see Table 1). The rates of infant death related to maternal trauma were much higher in North Carolina communities located in zip codes with > 215hogs/km^2 (149/100,000) than the United States and North Carolina averages. The rates of death related to the length of gestation and fetal growth were higher in both North Carolina (North Carolina average) and Study group 2 compared to the US average.

Patients from Study group 2 with multimorbid conditions such as co-existing septicemia and kidney disease, septicemia and anemia, or septicemia and kidney disease and anemia had mortality rates 1.5-2.2 times greater than North Carolina and 1.8-1.9 times greater than the US average mortality rates for patients with the same respective co-existing diseases (see Supplemental Figure S2 in Appendix). For all studied diseases, the age-adjusted mortality rates were higher in Study group 1 than in the Control group, but lower than in Study group 2 (see Table 2), except for tuberculosis: its mortality did not significantly differ between Study groups 1 and 2.

To highlight the magnitude of higher mortality in the region, we modeled Study group 2 as an independent geo-

TABLE 1.
Age-Adjusted Mortality Rates (Per 100,000) in NC Communities with > 215hogs/km^2 (Study Group 2) Compared to the NC and US Average, 2007-2013. (95% Confidence Intervals are Shown in the Parentheses)

Disease	Age and race group	The US average[1]	The NC average[a]	NC communities with > 215hogs/km^2
All-cause mortality	All ages, all races	750 (749.5-750.2)	**803**[a] (801.3-805.6)	**934**[ab] (922.7-944.8)

Tuberculosis (underlying + secondary cause)	All races, all ages	0.31 (0.30-0.32)	0.30 (0.26-0.35)	**0.63**[ab] (0.32-0.81)
Septicemia (underlying cause)	All ages, all races	10.8 (10.7-10.8)	**13.5**[a] (13.2-13.67)	**16.6**[ab] (15.1-18.1)

[1]Mortality rates are obtained from the Centers for Disease Control and Prevention Multiple Cause of Death data (https://wonder.cdc.gov/mcd.html).
[2]African-American.
[a]Statistically significant difference compared to the US average.
[b]Statistically significant difference compared to NC average.

graphic unit and compared its overall and disease-specific mortality rates to the US states with the highest mortality rates (see Supplemental Table S4 in Appendix). In this model, the geographic area encompassing Study group 2 would be ranked number 4 in the United States for the highest all-cause mortality, number 1 in the United States for mortality from anemia as underlying cause, number 1 for kidney disease, number 2 for septicemia, and number 3 for tuberculosis as underlying-plus-secondary cause.

The rates of hospital admissions and ED visits. For most of the studied diseases, the rates of hospital admissions and ED visits (see Table 2) were higher in Study group 1 than in the Control group, but lower than in Study group 2. Rates did not differ between Study groups 1 and 2 for anemia hospital admissions and ED visits (as primary diagnosis), ED visits for tuberculosis, and LBW hospital admissions (as primary-plus-secondary diagnosis); however, these rates were still higher than in the Control group.

Logistic regression analysis. After adjustment for 6 co-

FIGURE S2.
Mortality Rates among Patients with Co-Existing Anemia, Kidney Disease, and Septicemia: The US Average, NC Average, and NC Communities with > 215hogs/km^2 (Study Group 2), 2007-2013. (95% Confidence Intervals Are Shown in the Parentheses)

This figure is available in its entirety in the online edition of the NCMJ.

TABLE S4.
Age-Adjusted Mortality Rates (Per 100,000) in NC Communities with > 215hogs/km^2 (Study Group 2): Ranks of This Area among the US States and District of Columbia with the Highest Mortality, 2007-2013. (95% Confidence Intervals Are Shown in the Parentheses)

This table is available in its entirety in the online edition of the NCMJ.

[a]Mortality rates were calculated using the Multiple Cause of Death data from the Centers for Disease Control and Prevention (https://wonder.cdc.gov/mcd.html).

factors, the ORs for death, hospital admissions, and ED visits for most of the studied diseases in Study group 1 were > 1.0 (see Table 3). The ORs in Study group 2 were significantly higher than in Study group 1 for kidney disease (all 3 outcomes), tuberculosis (hospital admissions), anemia (all 3 outcomes), tuberculosis (ED visits), septicemia (mortality), and LBW (ED visits) (see Table 3).

DiSC analysis. After adjustment for 6 co-factors, the studied outcomes had similar distance-related patterns: the ORs were higher in close proximity to a hog CAFO than in more distant communities (see Table 4). For example, mortality ORs for kidney disease were the highest in communities located within 2 km of a CAFO (OR = 1.14, $P < 0.0001$), then decreased to 1.02 ($P < 0.0001$) at 20 km. For hospital admissions, the OR for kidney disease was 1.22 ($P < 0.0001$) at 2 km, 1.08 at 5 km ($P < 0.0001$), 1.04 at 10 km ($P < 0.0001$), and 1.03 at 20 km ($P < 0.0001$). The most pronounced changes in ORs were observed between 2 km and 5 km from the CAFO.

Sensitivity analysis. After exclusion of urban areas, no significant changes were observed for mortality risks. Slightly lower ORs than in the main analysis were observed for hospital admissions, and slightly higher ORs were observed for ED visits. The results of GEE analysis also confirmed the main study results; one exclusion was some minor changes in hospital admissions.

Locations of matched zip codes are shown in Supplemental Figure S3 (Appendix): compared to "clustered" locations of zip codes with > 215hogs/km^2, non-CAFOs zip codes are sparsely located in different regions of North Carolina. The mortality rates of all studied diseases and hospital admission/ED visit rates of kidney disease, tuberculosis, and LBW were higher in Study group 2 than in matched zip codes

TABLE 2.
Age-Adjusted Rates (per 100,000) of Mortality, Hospital Admissions, and ED Visits in NC Communities with Hog CAFOs (Study Group 1), NC Communities with > 215hogs/km^2 (Study Group 2), and NC Communities without Hog CAFOs (Control Group), 2007-2013. without CAFOs (the results are presented in the Appendix, Table S5).

Discussion

We found that people living in southeastern North Carolina communities located near hog CAFOs had poorer outcomes for a variety of health conditions in different age groups than the residents of North Carolina communities located in zip codes without hog CAFOs; they had higher mortality due to infections, anemia, kidney disease, and perinatal conditions, and higher rates of hospital admissions and ED visits for LBW infants. The observed higher rate of all-cause mortality is consistent with the lower life expectancy in this area [1].

While the precise causes of higher anemia rates observed in our study are unclear, other studies have suggested that exposure to ammonia, hydrogen sulfide, methane, and particulate matters (PMs) near the CAFOs [23, 24], contamination of water and soil with zinc [25], exposure to the antibiotic chloramphenicol previously widely used to treat infections in hogs [26], and inappropriate human use of veterinary medications (certain NSAIDs or antibiotics) [38] cause anemia. Moreover, anemia is an independent risk factor of death in patients with chronic diseases [39, 40], a complication of renal failure [41] and tuberculosis [42], and a risk factor for preterm birth and LBW infants [43].

Earlier studies reported that workers in the swine

[a]Statistically significant difference from the value of the result at shorter vs. longer distances (eg, 5 km vs. 2 km, or 10 km vs. 5 km) within the same row in the table.

industry have a higher risk for tuberculosis; however, this disease has been recently eradicated from US livestock [44]. Our findings on higher rates of tuberculosis likely result from the impact of a combination of factors in this North Carolina region where co-existing medical and social determinants may exacerbate each other [6, 10]. While no information is currently available on potential risk of occurrence of antibiotic-resistant strains of *Mycobacterium tuberculosis* in the communities adjacent to hog CAFOs, this aspect may require detailed analysis. The increased risk of undiagnosed latent tuberculosis that may be present in these communities, which may have a higher number of foreign-born residents [45], also requires attention. Co-existence of factors that may promote tuberculosis from its latent to active form (eg, diabetes, immunosuppression, and other conditions) needs to be accounted for when developing a strategy for improving identification of latent and active cases (ie, through screening) and treatment adherence in patients who require therapy.

Higher mortality rates for infants living in North Carolina zip codes with > 215hogs/km^2 represent an important health issue for this population that requires the immediate attention of public health and health care specialists. Maternal trauma and the length of gestation and fetal growth contribute the most to infant mortality in these North Carolina communities and can be targeted by special programs on maternal and child health. Higher rates of LBW infants in North Carolina communities adjacent to hog CAFOs are an important parameter of maternal and child health, not only because of the immediate medical care needed for such infants, but also because of their increased lifetime risk of chronic diseases (eg, higher risk of development of diabetes mellitus, arterial hypertension, ischemic heart disease, depression, respiratory diseases, and chronic kidney disease) [46]. Targeted programs in North Carolina communities adjacent to hog CAFOs could provide information about health issues related to women's and children's health to women of childbearing potential, as well as supporting mothers and children from pregnancy through birth and beyond.

The DiSC analysis in our study highlighted a potential opportunity for associating residential and occupational exposures in communities located in close proximity to hog CAFOs; poorer health outcomes among the residents of communities located within 2-5 km from CAFOs could be due to additional exposures because of potential employment at CAFOs. That may provide some guidance as to the most efficient use of resources to screen and diagnose diseases/conditions found to be highly prevalent in these communities.

In this study we do not establish causality between exposures from hog CAFOs and higher risk of mortality, hospital admissions, or ED visits for studied diseases in communities adjacent to CAFOs. One interpretation of our findings could be that people who reside in such communities may simultaneously be affected by multiple risk factors including low income and education, higher smoking prevalence, and lower access to medical care. Nonetheless, after adjusting for such co-factors or comparing zip codes with similar co-factors, persistently poorer health outcomes were observed in the communities located in zip codes with hog CAFOs. Furthermore, the DiSC analysis demonstrated a higher risk of poorer health outcomes in closer proximity to the CAFO. Our sensitivity analysis showed that patterns of use of medical care among the residents of these North Carolina communities may also contribute to the differences in health outcomes. For example, residents of rural North Carolina areas (where most of the hog CAFOs are located) are more likely to use EDs when searching for medical assistance and less likely use hospitals (due to problems with access such as transportation issues, problems with medical insurance coverage, or behavioral patterns of preferring EDs to a staying in a hospital).

The limitations of this study include: i) a lack of individual measurements of exposure, co-factors, and potential biomarkers of exposure; ii) potential misclassification of exposure from spray fields, accounting for weather, season and wind direction, exposure to poultry facilities, and coal power plants; iii) limited list of population characteristics in currently available dataset to match the compared population groups; and iv) potentially different residential and occupational locations for the same person. Further studies must address these limitations. The problems of identifying potential causative agents and evaluation of dose-response relationships in hog CAFOs studies are discussed in the literature; it is difficult to account for all required factors in occupational health studies, but the detection of specific exposures and diseases in residential communities is even more challenging due to additional complexities caused by dispersion of environmental agents, different exposure pathways, and variability of individual susceptibility to contaminants [6].

Community based research has been gaining prominence as a source of information for medical decision-making. It has been recognized that detailed individual-level data on co-factors are rarely available in the US; therefore, opportunities for individual-level analyses that account for multiple risk factors are very limited. To obtain information on health outcomes in certain populations, public health specialists and policymakers have begun to shift their attention from an exclusive focus on individual-level studies toward community level analyses. When contributions of specific risk factors to health outcomes in communities can be evaluated, this information can be used for optimization of resource allocation for medical interventions designed to improve health outcomes [47].

TABLE S5.
Age-Adjusted Cause-Specific Rates (per 100,000) of Mortality, Hospital Admissions, and ED Visits in Communities Located in Zip Codes with > 215hogs/km^2 (Study Group 2) and in Communities Located in Zip Codes Matched by Percent of African Americans, Percent of Children and Adults Aged 65+ in Population, and Median Household Income (Matched Group A) and Additionally Matched by Percent of the Residents Aged 25+ with Bachelor or Higher Degree (Matched Group B), NC, 2007-2013. Conclusion

Southeastern North Carolina communities located in close proximity to hog CAFOs are characterized by poor indicators of health that are not solely due to the impact of converging demographic, socioeconomic, behavioral, and access-to-care factors, but are also due to the additional impact of multiple hog CAFOs located in this area. Although causality with specific exposures from hog CAFOs was not established, our findings suggest research is needed in environmental factors that may influence these outcomes. In addition, these findings suggest an immediate need for improved screening, diagnosis, and intervention for conditions including infant mortality and LBW infants that were found to be overrepresented in these communities. Poor health outcomes in North Carolina communities adjacent to hog CAFOs may also need to be addressed by improving access to medical resources, and future studies to determine the contribution of factors that influence these outcomes are needed. The International Classification of Diseases (ICD) Codes Used in the Analysis

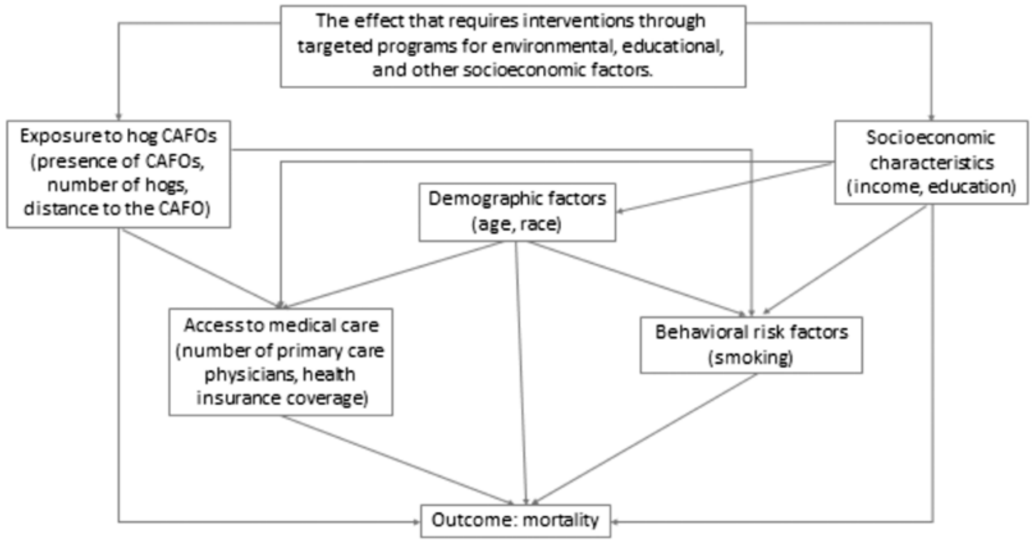
ICD-9 codes (used for analysis of HCUP data)	
280-285	Anemia (includes Iron deficiency anemias, Other deficiency anemias, Hereditary hemolytic anemias, Acquired hemolytic anemias, Aplastic anemia and other bone marrow failure syndromes, Other and unspecified anemias)
580-589	Kidney disease (Nephritis, Nephrotic Syndrome, and Nephrosis)
010-018	Tuberculosis
038	Septicemia, 995.91 – Sepsis
V21.3	Low birth weight
ICD-10 codes (used for analysis of Multiple Cause of Death data)	
D50-D53, D55-D59, D60-D64	Anemia (includes Nutritional anemias, Hemolytic anemias, Aplastic and other anemias and other bone marrow failure syndromes)
N00-N19	Kidney disease (includes Glomerular diseases, Renal tubule-interstitial diseases, Acute kidney failure and chronic kidney disease)
A15-A19	Tuberculosis
A40, A41	Septicemia (includes Streptococcal sepsis, Other sepsis)
P07.1	Low birth weight newborn
P00-P96	Conditions originating in perinatal period
P00-P04	Newborns affected by maternal trauma
P10-P15	Disorders related to length of gestation and fetal growth

79502 APPENDIX 2.

FIGURE S1.
Illustration of the Relations in the Assessment of Potential Impact Factors-Outcome Associations



APPENDIX 3.
Sensitivity Analysis

2a) Proc Genmod was used for GEE analysis

2b). The propensity score for matching zip codes without CAFO to zip codes with > 215hogs/km^2 (Study group 2) was evaluated using the percent of African Americans, percent of children and people aged 65+ among the residents, as well as median household income, and percent of people with a bachelor's or higher degree. The greedy matching algorithm [37] was used to match zip codes with close propensity scores.

The Matched group A included 56 zip codes that were matched by using the percent of African Americans, percent of children (aged 0-19) and people aged 65+ among the residents, and median household income. The Matched group B included 55 zip codes matched by above listed characteristics of Matched group A and additionally by the percent of people with a bachelor's or higher degree. Characteristics of matched zip codes (i.e., the results on balancing the variables in the matched groups) for the Matched group A and Matched group B are presented in Table S1.

79502 APPENDIX 4.

TABLE S1.
Characteristics of Matched Group A, Matched Group B, and Study Group 2, NC, 2007-2013

Variable	Matching design 1 Mean[1]±SE (95%CI)		Matching design 2 Mean[1]±SE (95%CI)	
	Matched group A	**Study group 2**	**Matched group B**	**Study group 2**
% of African-Americans	28.4±2.9% (22.8%-34.1%)	28.92±1.8% (25.5%-32.4%)	27.1%±3.0% (21.2%-33.0%)	28.9%±1.8% (25.4%-32.4%)
% of children (0-19 years old)	26.8±0.6% (25.7%-27.9%)	27.1±0.4% (26.2%-27.9%)	25.5%±0.6% (24.4%-26.6%)	27.3%±0.4% (26.3%-28.0%)
% of adults (65+ years)	14.0±0.6% (12.9%-15.2%)	14.3±0.4% (13.5%-15.2%)	15.0%±0.6% (13.8%-16.2%)	14.3%±0.4% (13.5%-15.2%)
Median household income (US dollars)	\$35,640±\$1,118 (\$33,450-\$37,831)	\$36,521±\$919 (\$34,719-%38,322)	\$34,933±\$1,161 (\$32,658-\$37,208)	\$36,527±\$936 (\$34,693-\$38,362)
% of people with bachelor or higher degree education among those aged 25+ years	n/a	n/a	9.16%±0.8% (7.7%-10.7%)	11.1%±0.5% (10.2%-12.0%)

[1]Means are evaluated without weights representing zip-code populations.
n/a, non-applicable.

Then, age-adjusted total mortality rate and cause-specific rates of mortality, hospital admissions, and ED visits were compared between Matched group A and B and Study group 2 for underlying cause of death or primary diagnosis and for underlying-plus-secondary cause of death or primary-plus-secondary diagnosis. As shown in Table S5, mortality rates for total mortality and anemia and kidney as underlying causes were higher in Study group 2 than in Matched group A and B. Also, mortality rates of anemia, kidney disease, tuberculosis, and septicemia were higher in Study group 2 than in both matched groups for these diseases as underlying-plus-secondary causes of death. Hospital admission and ED visit rates were higher in Study group 2 than in Matched group A and B for kidney disease and tuberculosis (for primary diagnoses and for primary-plus-secondary diagnoses). ED visits rate for children with LBW also was higher in Study group 2 than in both matched groups (for primary-plus-secondary diagnosis).

TABLE S2.
Descriptive Table of the 3 Studied Groups of NC Communities with and without the Hog Concentrated Feeding Animal Operations (CAFOs): Race-Specific Population Groups, Socioeconomic Characteristics, Smoking Prevalence, and Access-To-Care Characteristics, NC, 2007-2013

Characteristics	NC communities with hog CAFOs (Study group 1)	NC communities with > 215hogs/km^2 (Study group 2)	NC communities without hog CAFOs (Control group)
Race (%):			
White	63.9%**	58.3%**	73.7%
African-American (AA)	28.8%*	31.3%**	19.3%
American Indian	2.4%*	4.1%**	0.8%
Asian	0.8%**	0.3%**	2.5%
Other	4.1%	6.0%**	3.7%
Median household income	$39,005**	$36,520**	$46,414
Bachelor or higher degree education	16.5%**	13.7%**	24.2%
Availability of primary care providers (per 100,000 population)	54**	51**	76
Percent of uninsured individuals	18.2%	18.5%	17.8%
Smokers prevalence among those aged 24+ years old	24.4%	25.9%**	24.0%

*P < 0.05.
**P < 0.001.

79502 APPENDIX 6.

TABLE S3.
Person-Years of Observations in Race-Specific Groups of the Residents of NC Communities from the 3 Studied Groups, NC, 2007-2013

Race	NC communities with hog CAFOs (Study group 1)	NC communities with > 215hogs/km^2 (Study group 2)	NC communities without hog CAFOs (Control group)
White	10,054,073	1,588,477	36,675,276
African-American (AA)	4,528,375	851,839	9,593,021
American Indian	370,901	111,226	411,900
Asian	129,901	8,574	1,242,243
Other	642,425	162,896	1,870,849

FIGURE S2.
Mortality Rates among Patients with Co-Existing Anemia, Kidney Disease, and Septicemia: The US Average, NC Average, and NC Communities with > 215hogs/km² (Study Group 2), 2007-2013. (95% Confidence Intervals Are Shown in the Parentheses)

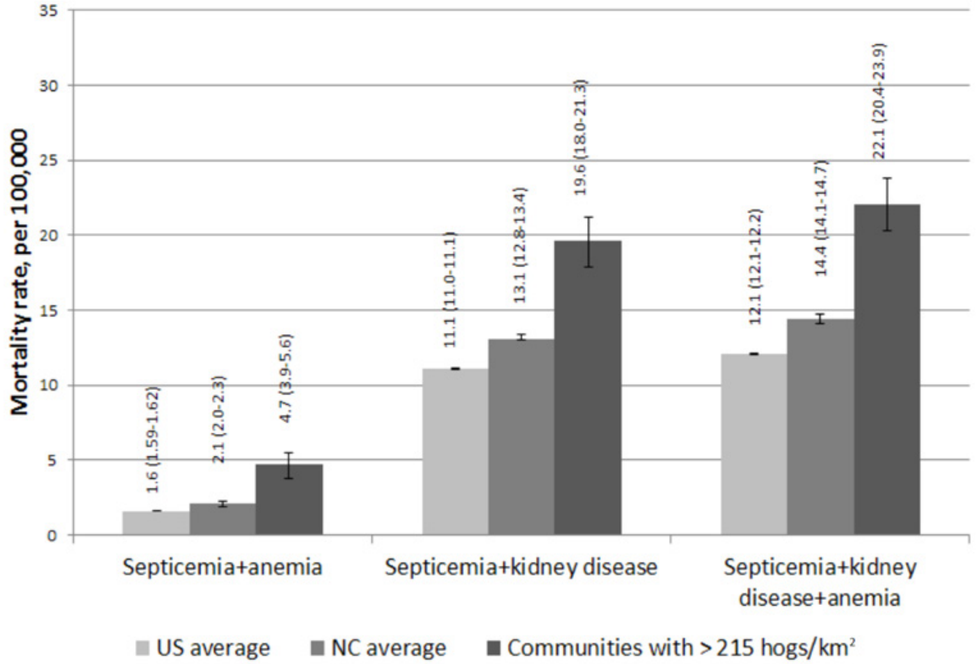


TABLE S4.
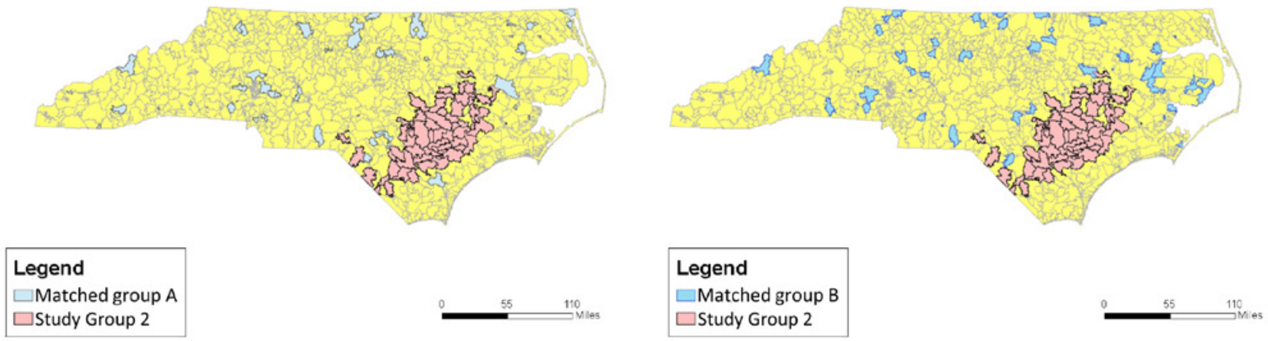
Age-Adjusted Mortality Rates (per 100,000) in NC Communities with > 215hogs/km^2 (Study Group 2): Ranks of This Area among the US States and District of Columbia with the Highest Mortality, 2007-2013. (95% Confidence Intervals Are Shown in the Parentheses)

Disease, cause of mortality	NC communities with > 215hogs/km^2	Rank of the area with > 215hogs/km^2 among the US states with the highest mortality	The US states (with their current respective ranks)[a] with mortality rates closest to the rates of the area with > 215hogs/km^2	
All-cause mortality	934 (922.7-944.8)	#4	#3 Alabama	940 (936.7-943.1)
Anemia:				
• as underlying cause,	2.6 (2.1-3.2)	#1	#1 Mississippi	2.3 (2.1-2.5)
• as underlying+secondary cause	**35.5** (33.4-37.7)	#1	#1 West Virginia	24.4 (23.7-25.2)
Kidney disease:				
• as underlying cause,	24.8 (23.0-26.6)	#2	#1 Louisiana	26.2 (25.7-26.8)
• as underlying+secondary cause	**119** (114.6-122.5)	#1	#1 West Virginia	96.2 (94.7-97.7)
Tuberculosis:				
• as underlying+secondary cause	0.63 (0.32-0.81)	#3	#2 District of Columbia	0.73 (0.49-1.04)
Septicemia:				
• as underlying cause,	16.6 (15.1-18.1)	#7	#6 Alabama	17.0 (16.6-17.4)
• as underlying+secondary cause	75.1 (71.9-78.2)	#2	#1 District of Columbia	83.6 (80.7-86.4)

[a]Mortality rates were calculated using the Multiple Cause of Death data from the Centers for Disease Control and Prevention (https://wonder.cdc.gov/mcd.html).

79502 APPENDIX 9.

FIGURE S3.
Locations of Matched NC Zip Codes without Hog CAFOs (Matched Group A and Matched Group B) and Locations of Zip Codes with > 215hogs/km² (Study Group 2)



79502 APPENDIX 10.

TABLE S5.

Age-Adjusted Cause-Specific Rates (per 100,000) of Mortality, Hospital Admissions, and ED Visits in Communities Located in Zip Codes with > 215hogs/km^2 (Study Group 2) and in Communities Located in Zip Codes Matched by Percent of African Americans, Percent of Children and Adults Aged 65+ in Population, and Median Household Income (Matched Group A) and Additionally Matched by Percent of the Residents Aged 25+ with Bachelor or Higher Degree (Matched Group B), NC, 2007-2013. ATTACHMENT 17

Technical Stakeholder Working Group Meeting Summary – Fall 2021

General permit overview

The Division of Water Resources has been directed by the North Carolina General Assembly to develop general permits by July 1, 2022, for existing Animal Feeding Operations (AFO) that intend to build and operate a digester system. Senate Bill 605, known as the 2021 Farm Act, describes the general permit requirements. Currently, digester systems are processed as modifications to a facility's existing permit.

The new general permits will apply to currently permitted facilities seeking to add digester systems. The Department, under the 2021 NC Farm Act, maintains the authority to require an individual permit for a facility adding a digester when necessary.

Input process

Event	Type of Feedback	Timeframe
Stakeholder Process	Technical Workgroup Sessions	Fall 2021
Stakeholder Process	Public Meeting/Forum - oral, written and electronic comments accepted	Fall/Winter 2021
Public Comment Period	Public Meetings - oral, written and electronic comments accepted	Winter 2021/Spring 2022

Existing permits

As of Sept. 27, 2021, out of 2,083 total permitted swine facilities in North Carolina, there are 15 facilities which have one or more animal waste digester systems.

List of Permits

Stakeholder process

DWR invited a group of approximately 60 stakeholders to gather input on the general permits content over two meetings in November-December 2021. The stakeholders represented community groups and environmental non-governmental organizations, state agencies and universities, and permittee and industry representatives.

Meeting #1: November 19, 2021

28 attendees met via Zoom to learn about the parameters of the general permits and then participated in breakout sessions discussing these sections of the existing general permit:

- Performance Standards
- Operations and Maintenance
- Monitoring and Reporting

- Other Conditions, including Inspections and Entry, General Conditions, Penalties and Definitions

Staff gathered policy and technical questions from attendees to answer in the second session.

Key themes

Participants raised the following issues:

- Monitoring for methane, nitrous oxide and ammonia from constructed biogas operations.
- The potential economic opportunity of the digester systems that could also remove potential pollutants from farm properties.
- More frequent monitoring of groundwater nearby digester operations
- Having the new general permits carry over the same monitoring conditions as the existing general permits.
- Potential expanded alert system for breaches.
- Better explanations of technical components of the general permits and digester systems for the communities near digester facilities.
- Avoiding overly regulating operations that are already regulated under existing permits.
- Further study of cumulative impacts on properties near farming operations.
- Addressing cattle and poultry operations as unique from swine operations.

Meeting #2: December 7, 2021

39 attendees rejoined on Zoom for the second work group session. They heard responses to some questions raised to staff from the first session, and then added feedback on discussion prompts from DWR staff on these items needing further input:

- Notification requirements on construction, completion and startup operations
- Operational parameters
- Priorities for recordkeeping requirements of operations and maintenance
- Parameters, analytical components, frequency and duration of influent and effluent monitoring
- Monitoring and reporting of failures, bypasses and other operational disruptions
- Safety precautions during severe weather or other emergency events
- Requirements for design and equipment in the digester system
- Requirements for infrastructure associated with the transport of biogas
- Conditions for use or re-introduction of tail gas in digester operations
- Requirements for inspection conditions and frequency specific to digester systems

Key themes

Participants raised the following issues:

- Ensuring pipelines carrying gas from digesters are properly sealed and monitored
- General permits capturing the wide range of digester system types that could be used.
- Improving understanding of the reporting process and where public records can be found.
- Potential for expanded notification of neighbors of construction of a digester system.

- Providing more details on responsibility for addressing gas transportation issues beyond the farm property.
- More frequent monitoring of effluent from facilities.
- Not adding additional requirements from existing general permits to new digester system operations.
- Potential need for an expanded emergency alert system for potential spills or leaks.
- Fully defining what elements of the digester and transportation system are covered under the general permits and regulated by DWR.
- Making sure other area of DEQ (particularly the Division of Air Quality) are involved in the general permit development.

Next steps

After draft permits are produced by DWR staff, the Department will hold three public hearings in the spring of 2022. Information on meeting locations and comment procedures for these hearings will be released early next year.

ATTACHMENT 18

DRAFT ENVIRONMENTAL JUSTICE REPORT

Biogas Digester General Permit Development

North Carolina Department of Environmental Quality

2/2/2022

Contents

1 Introduction

In July of 2021, the North Carolina General Assembly passed the Farm Act of 2021, Session Law 2021 - 78. Section 11 of the legislation required the North Carolina Department of Environmental Quality (NCDEQ or Department) to develop a General Permit for facilities that construct and operate a farm digester system. This analysis will evaluate the three types of general permits separately: Swine, Cattle, and Poultry with a Liquid Waste Management System (Wet Poultry.)

Animal operations are defined by General Statute 143-215.10B as feedlots involving more than 250 swine, 100 confined cattle, 75 horses, 1,000 sheep, or 30,000 poultry with a liquid waste management system. The general permits contain the required performance standards, operation and maintenance requirements, monitoring and reporting requirements, policy for inspections and entry to the farms, general conditions and the penalty policy. Each general permit is issued with a Certificate of Coverage that is permittee-specific and designates the permitted number and type of animals.

Based on the goal and scope of this analysis, several methodologies were considered which built upon a previously conducted, smaller scale community analysis which focused exclusively on swine AFOs. All of the methodologies used steady state live weight (SSLW), or the number of animal feeding operations (AFO), combined with proximity either to land or people to determine where (based on permitted facility reporting), the greatest number of animals are likely located near the greatest number of people.

It is important to note that this is an analysis of the facilities with current 2019 general permits and it is not anticipated that every facility covered under the 2019 general permits will apply for the new digester general permits. Additionally, the new digester general permits will replace the existing general permits only if the facility applies for the digester general permit. As it is not possible to predict which facilities will install digesters under the new general permits, this analysis relies on general information and is not a site-specific examination.

2 Methodology

Previously, NCDEQ developed five potential methods from which to select the communities with the highest potential exposure to AFOs (See Table 1). In most methods, SSLW was used as the indicator, assuming that higher SSLW values result in the generation of more waste. Higher amounts of waste may lead to externalities typically reported as complaints associated with facility operations (i.e. odor).

Using the fifth methodology outlined below, NCDEQ was able to effectively identify the areas across the state with the highest amount of SSLW per square mile. SSLW was separated out by the type of certificate of coverage: Cattle, Wet Poultry, and Swine. Due to availability of data, only the types of facilities required to have an NCDEQ-issued certificate of coverage under state law were included in this analysis. The 5 counties with the highest SSLW per square mile for each of the three types of coverage were selected for the analysis. Select demographic data was overlaid with the SSLW per square mile across the state at the county and census tract level. The datasets included in this analysis are poverty (Table S1701, American Community Survey 2019 5-year estimates), race and ethnicity (Table P2, 2020 Census), and limited English proficiency; Spanish (Table C16002, American Community Survey 2019 5-year estimates).

Table 1. Potential Methodologies for Analysis

Method	Description of Methodology
Land Proximity by SSLW: This method calculates the locational proximity of all land parcels (regardless of the parcel's use classification) to SSLW	1) A 2km buffer was placed around each COC 2) All land parcels within 2km of a COC were assigned the SSLW value of that COC. If a land parcel was proximate to more than one COC, the parcel was assigned the total SSLW from all COCs within 2km
Number of Residential Parcels Within 2km of a Swine State COC Per Census Tract: This method calculates the number of parcels in each Census Tract that are within 2km of a COC, without factoring SSLW	1) Residential parcels were selected from county parcel data, and any residential parcels within 2km of a COC were selected 2) The residential parcels were joined to the census tract to calculate the number of residential parcels within each census tract that were located proximate to at least one COC
Average SSLW Near Residential Parcels: This method calculates the average SSLW of residential parcels located within 2km of a COC in each Census Tract	1) Residential parcels were selected from county parcel data 2) Each residential parcel was assigned the SSLW amount of SSLW of each COC located within 2km of the parcel 3) To compare census tracts across the counties, the SSLW values assigned to each residential parcel within each census tract were averaged across the entire tract to produce a single number per census tract.
Overall SSLW: This method calculates the value of SSLW per Census Tract	1) The total SSLW value of every COC would be calculated
Pounds of SSLW/Square Mile: This method calculates pounds of SSLW per square mile per Census Tract	1) The total SSLW value of every State COC located within each census tract in the state was calculated 2) This total number was divided by square miles per census tract 3) The 5 counties with the highest values of SSLW per square mile were included in the analysis, separated by type of animal.

3 Environmental Justice Analysis

Environmental justice (EJ) is the fair treatment and meaningful involvement of all people regardless of race, color, national origin, or income, with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies (US EPA). The primary goal of this Draft EJ Report is to encourage comments and suggestions from the surrounding community, industry, and environmental groups throughout the comment period. Public comments will be considered throughout the remainder of the comment period to inform the Final EJ Report.

The following components are included within this Draft EJ Report:

- Potentially Underserved Communities as defined by NCDEQ
- Existing locations of biogas digester permits
- Existing general permits SSLW distribution
- Comparison of local area demographics to the county and statewide census data (from the US Census; https://data.census.gov/cedsci/advanced)
- Limited English Proficiency
- Tribal Counties
- County Health Rankings

3.1 Potentially Underserved Communities

NCDEQ has selected specific block groups across the state that meet a certain threshold for both race and ethnicity and poverty when compared to the County and State percentages. This is the only portion of the analysis that is on the block group level. Block groups are statistical divisions of census tracts, are generally defined to contain between 600 and 3,000 people and are used to present data and control block numbering. A block group consists of clusters of blocks within the same census tract that have the same first digit of their four-digit census block number (US Census Bureau).

NCDEQ defines potentially Underserved Communities by examining the Race/Ethnicity and Poverty criteria of each block group. The block group is then compared to both the County and the State and selected as a potentially underserved block group if it meets the following criteria for Race/Ethnicity and Poverty:

Racial/Ethnic composition:
Share of nonwhites and Hispanic or Latino (of any race) is over fifty percent **OR**
Share of nonwhites and Hispanic or Latino (of any race) is at least ten percent higher than County or State share.
AND
Poverty rate:
Share of population experiencing poverty is over twenty percent **AND**
Share of households in poverty is at least five percent higher than the County or State share.

Approximately 25% of North Carolina's block groups meet this definition of potentially underserved.

This dataset is a selection of the 2019 ACS data from the data tables B03002—Hispanic or Latino Origin by Race—and S1701—Poverty Status in the Past 12 Months. Learn more about NC DEQ's Potentially Underserved Block Groups 2019 - Overview (arcgis.com).

3.2 Existing biogas permits

The NCDEQ has issued 17 individual permits to date for biogas digesters. These are located across 7 counties in North Carolina:

- Bladen
- Duplin
- Harnett
- Sampson
- Johnston
- Wayne
- Yadkin

Of the existing 17 permits, 4 are located within NCDEQ selected potentially underserved block groups (Figure 1).

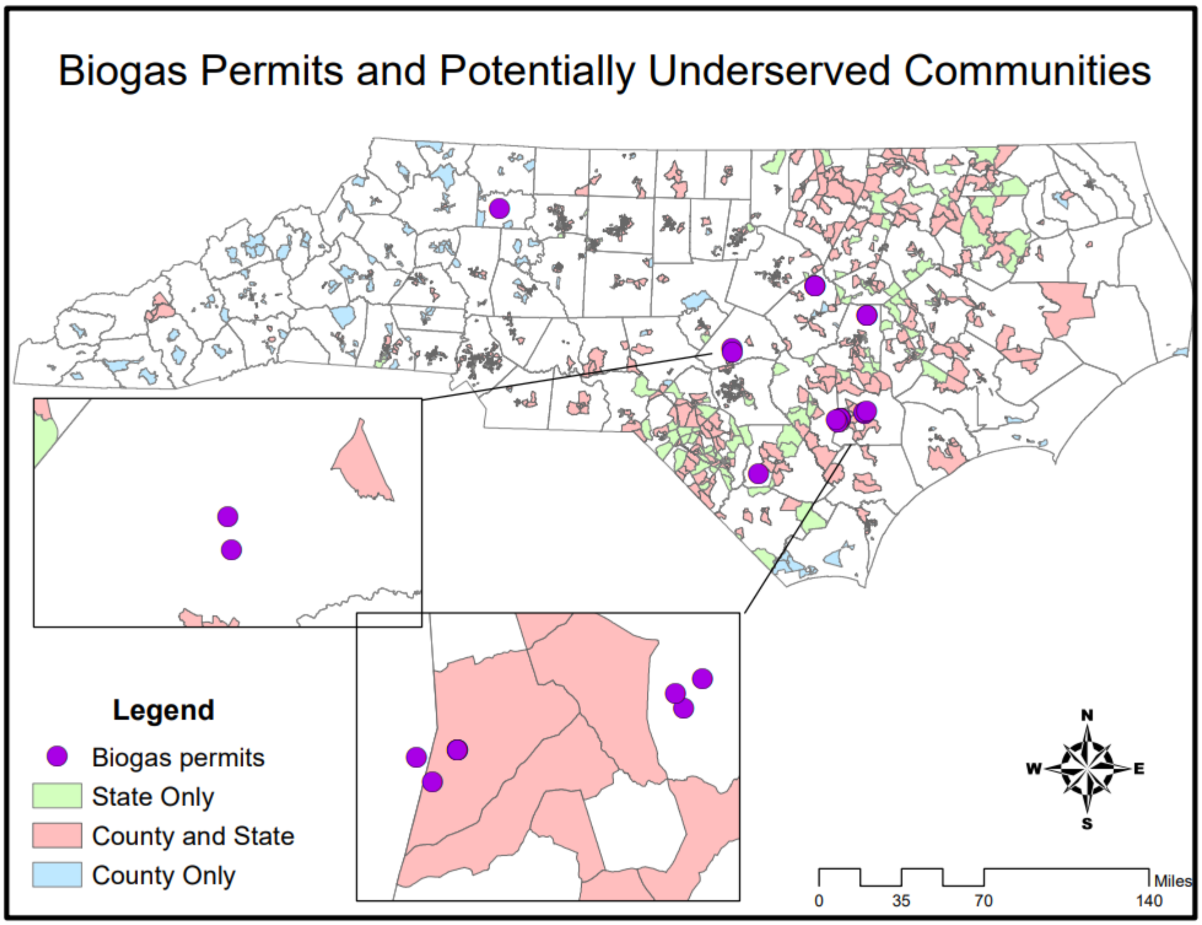

Figure 1. Existing biogas digester permits in North Carolina overlaid with the potentially underserved block group selection.

4 Swine

Across North Carolina, there are 2,161 swine permits covered under the 2019 general permit. The following table (Table 2) outlines the 5 counties in North Carolina that have the highest amount of SSLW per square mile for Swine. Two portions of the analysis are included below. The first portion includes the entire state overlaying the SSLW at the block group level for potentially underserved communities and at the census tract level with Limited English Proficiency for Spanish speakers. The second portion of the analysis is at the census tract level and includes race and ethnicity, and poverty for the top five counties only. For Swine, the certificates of coverage are located across 60 counties.

Table 2. Counties with the highest swine SSLW per square mile

County	SSLW/Sq mile
Sampson County	6,421,962.46
Duplin County	5,876,928.48
Wayne County	4,169,531.19
Bladen County	2,206,113.71
Robeson County	1,734,305.98

4.1 Potentially Underserved Communities

The following figure (Figure 2) shows the potentially underserved block group selection overlaid with the swine certificates of coverage averaged out to show SSLW per square mile.

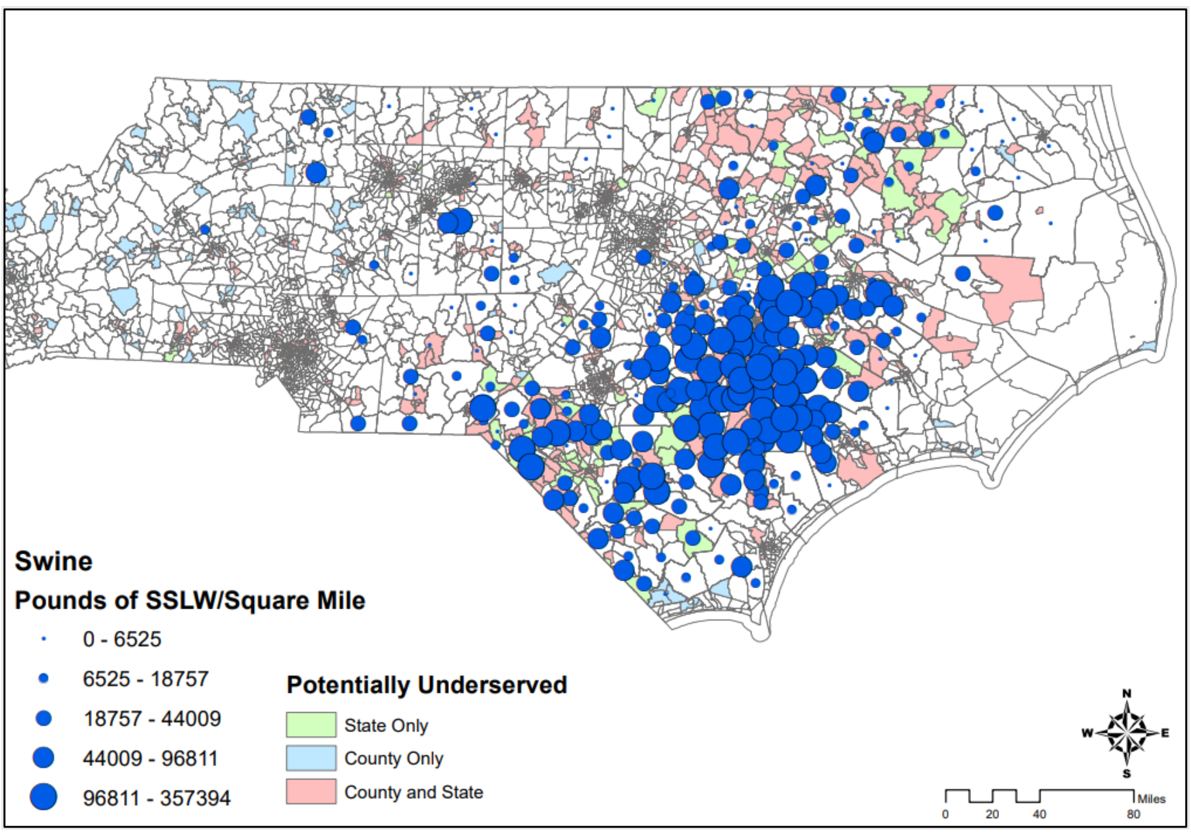

Figure 2. Swine SSLW/Square Mile (census tracts) overlaid with Potentially Underserved Communities (Block Group).

4.2 Limited English Proficiency- Spanish

Per the Safe Harbor Guidelines, should an LEP Group be identified during the permit application process, written translations of vital documents for each eligible LEP language group that constitutes 5% or includes 1,000 members (whichever is less) of the population of persons eligible to be served or likely to be affected or encountered. If there are fewer than 50 persons in a language group that reaches the 5% trigger, then NCDEQ will not translate vital written materials, but instead will provide written notice in the primary language of the LEP language group of the right to receive competent oral interpretation of those written materials, free of cost. The safe harbor provisions apply to the translation of written documents only. Safe harbor guidelines are based on EPA guidance for LEP persons and implemented by NCDEQ when deemed appropriate.

The following figure (Figure 3) shows the census tracts across North Carolina with a population who speaks English less than very well for Spanish greater than 5% and the Swine SSLW per square mile.

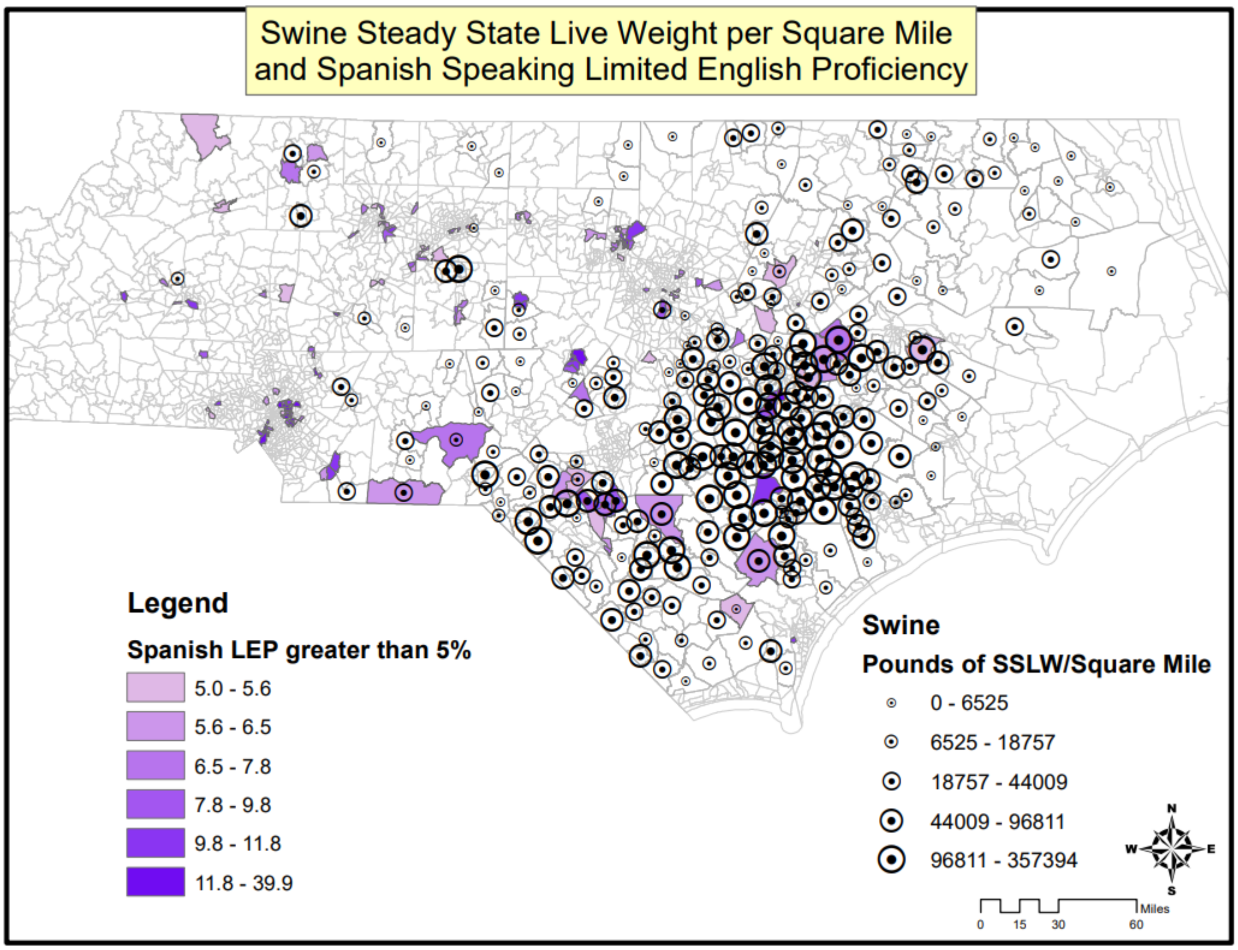

Figure 3. Census tracts with Spanish speaking populations who speak English less than very well and SSLW averages for swine.

4.3 Five County Analysis

Using standard environmental justice guidelines from the EPA and NEPA documentation, the following conditions will be flagged as communities with the potential for having environmental justice concerns:

1. 10% or more in comparison to the county or state average
2. 50% or more minority
3. 5% or more in comparison to the county or state average for poverty

For example, if a census tract has 35% of the population classified as low income but the county consists of 30% low income, the census tract would exceed the county average by 16.7% and thus be flagged as an area with the potential for having EJ concerns. 2020 Census Bureau data is real data gathered every ten years, whereas the estimates from the more recent years are modeled based on the real data.

Race and Ethnicity

The following maps show the top 5 counties as ranked by the SSLW per square mile. This was calculated on the census tract level and summed up to the county level. All census tracts that are flagged in comparison to either the state or county as laid out above are highlighted in yellow in the maps. Table 3 shows the 2020 Census data for the 5 counties and North Carolina.

Table 3. Race and ethnicity for the five counties with the highest SSLW per Square mile for swine and North Carolina

Geography	Total Population	Hispanic or Latino	White	Percent Nonwhite and Hispanic or Latino	Black or African American	American Indian or Alaska Native	Asian	Native Hawaiian or Pacific Islander	Some other Race	Two or more Races
North Carolina	10,439,388	1,118,596	6,312,148	39.5%	2,107,526	100,886	340,059	6,980	46,340	406,853

Poverty

The following maps show the top 5 counties as ranked by the SSLW per square mile. This was calculated on the census tract level and summed up to the county level. All census tracts that are flagged in comparison to either the state or county as laid out above are highlighted in yellow in the maps. Table 4 shows the 2020 Census data for the 5 counties and North Carolina.

Table 4. Poverty levels for the five counties with the highest SSLW per Square mile for Swine and North Carolina

Geography	Total Population	MOE +/-	Percent below Poverty	MOE +/-
North Carolina	9,984,891	1,988	14.7%	0.2%
Bladen County	32,918	214	24.3%	3.2%
Duplin County	58,374	229	21.2%	2.6%
Robeson County	128,917	494	27.7%	1.1%
Sampson County	62,511	272	20.9%	2.5%
Wayne County	120,420	494	20.2%	1.2%

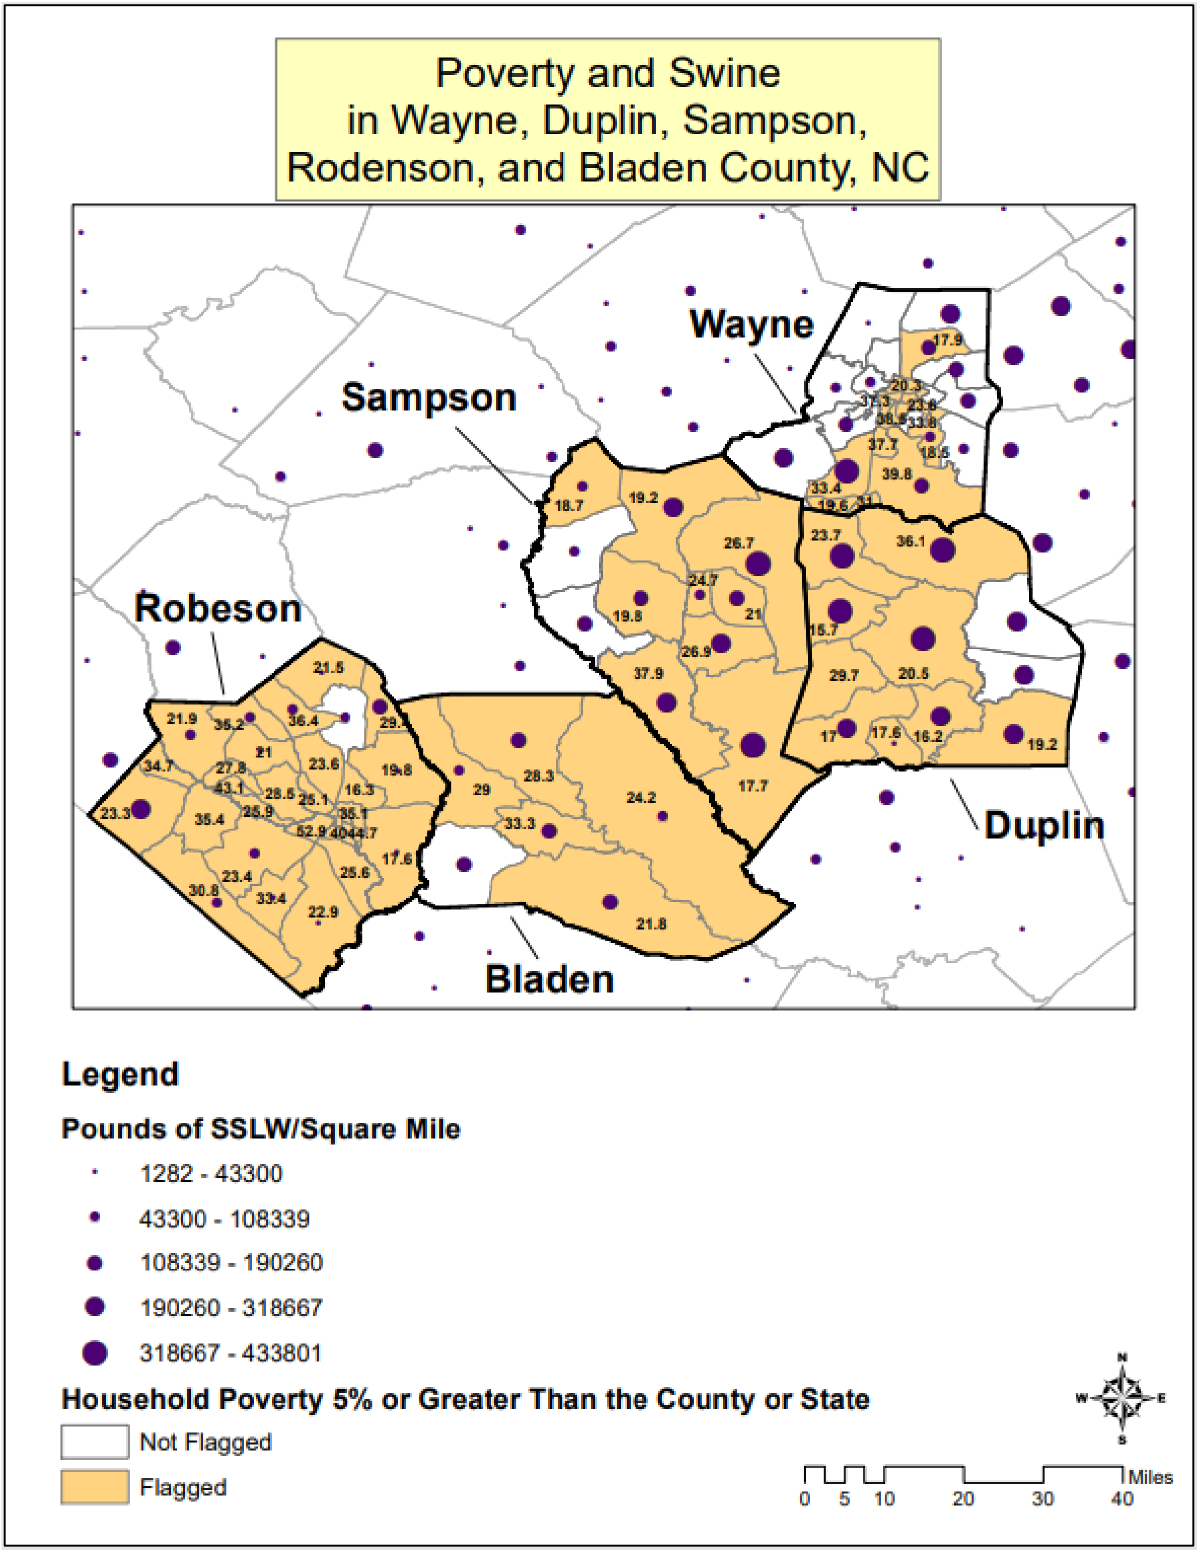

Figure 5. Map for the five counties and flagged census tracts for poverty.

5 Cattle

Across North Carolina, there are 222 cattle permits covered under the 2019 general permit. The following table (Table 5) outlines the 5 counties in North Carolina that have the highest amount of SSLW per square mile for cattle. Two portions of the analysis are included below. The first portion includes the entire state overlaying the SSLW at the block group level for potentially underserved communities and at the census tract level with Limited English Proficiency for Spanish speakers. The second portion of the analysis is at the census tract level and includes race and ethnicity, and poverty for the top five counties only. For cattle, the certificates of coverage are located across 34 counties.

Table 5. Counties with the highest Cattle SSLW per square mile

County	SSLW/Sq mile
Iredell County	1,409,478.90
Randolph County	919,199.30
Lincoln County	431,896.80
Davidson County	408,691.25
Gaston County	351,827.30

5.1 Potentially Underserved Communities

The following figure (Figure 6) shows the potentially underserved block group selection overlaid with the cattle certificates of coverage averaged out to show SSLW per square mile.

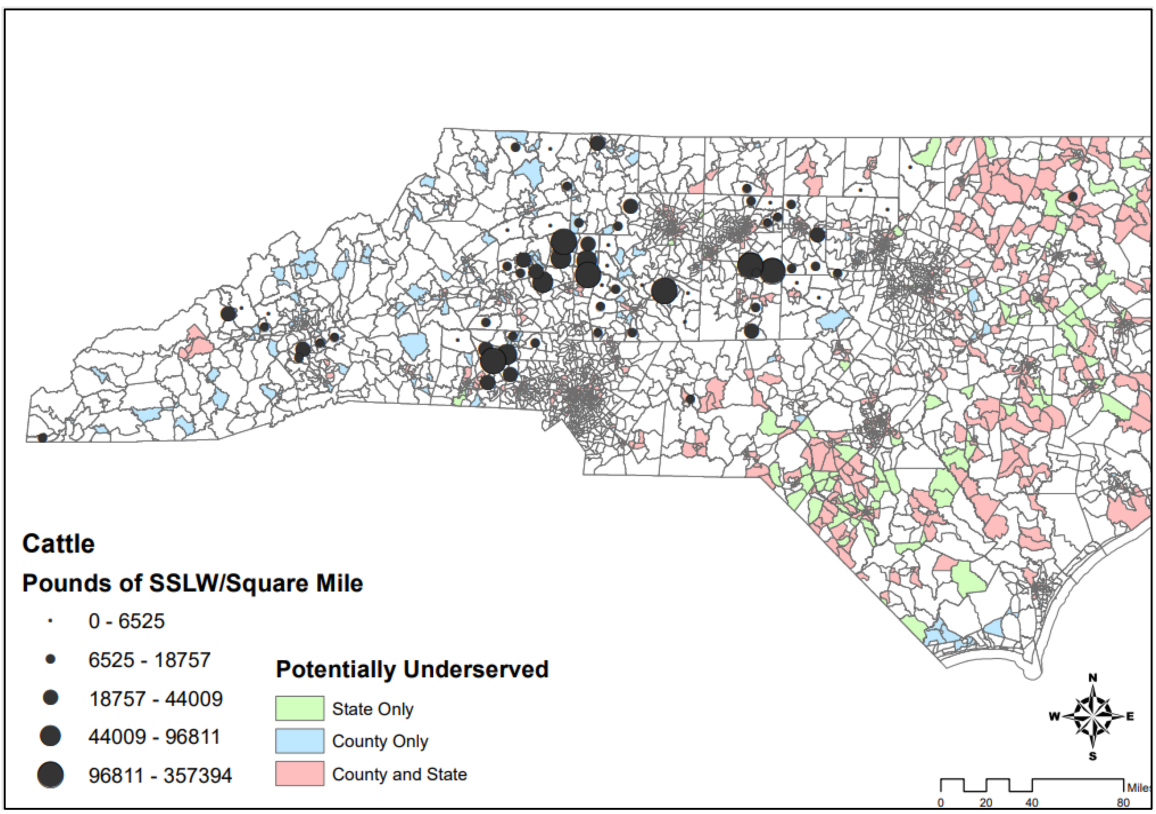

Figure 6. Cattle SSLW/Square Mile (census tracts) overlaid with Potentially Underserved Communities (Block Group).

5.2 Limited English Proficiency- Spanish

Per the Safe Harbor Guidelines, should an LEP Group be identified during the permit application process, written translations of vital documents for each eligible LEP language group that constitutes 5% or includes 1,000 members (whichever is less) of the population of persons eligible to be served or likely to be affected or encountered. If there are fewer than 50 persons in a language group that reaches the 5% trigger, then NCDEQ will not translate vital written materials, but instead will provide written notice in the primary language of the LEP language group of the right to receive competent oral interpretation of those written materials, free of cost. The safe harbor provisions apply to the translation of written documents only. Safe harbor guidelines are based on EPA guidance for LEP persons and implemented by NCDEQ when deemed appropriate.

The following figure (Figure 7) shows the census tracts across North Carolina with a population who speaks English less than very well for Spanish greater than 5% and the cattle SSLW per square mile.

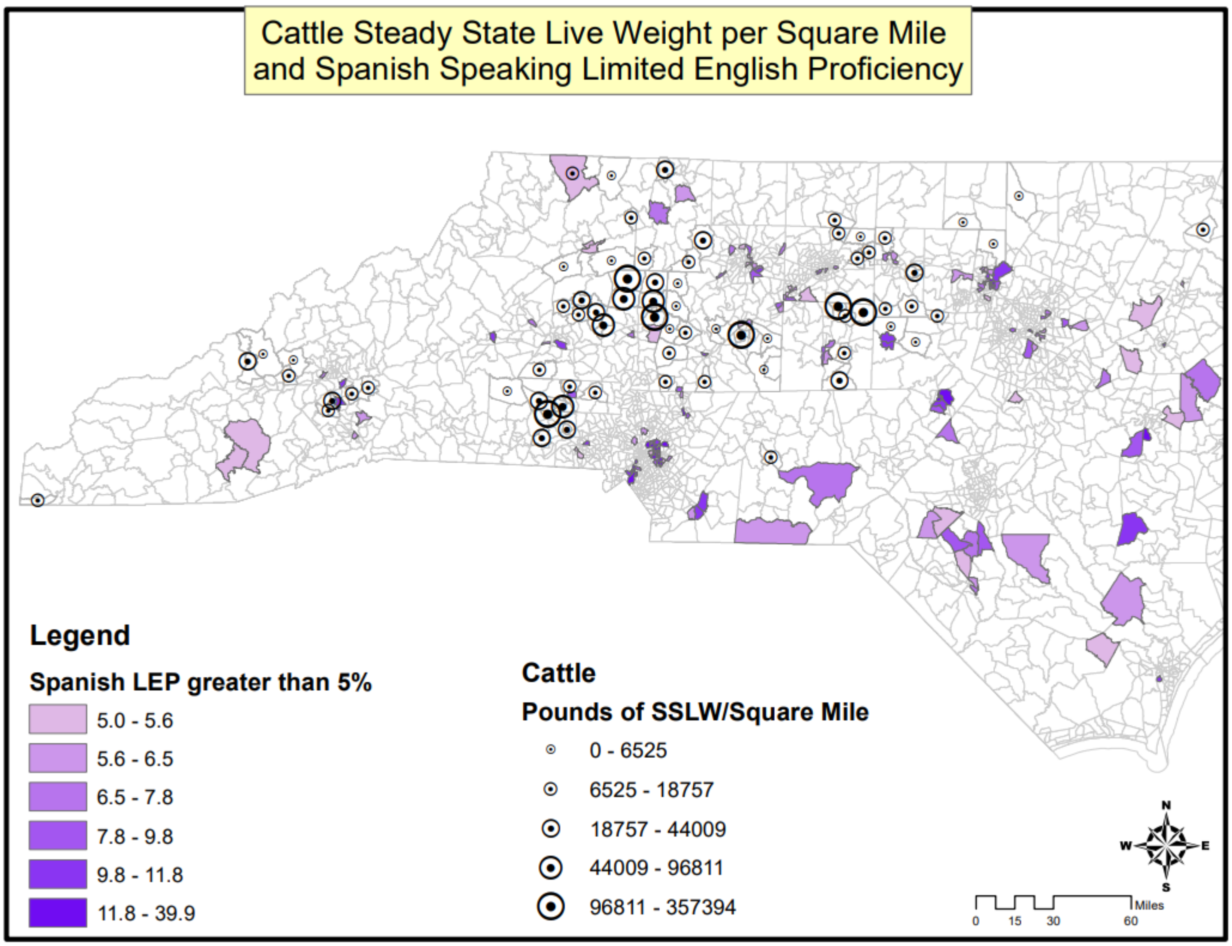

Figure 7. Census Tracts with Spanish speaking populations who speak English less than very well and SSLW averages for cattle.

5.3 Five County Analysis

Using standard environmental justice guidelines from the EPA and NEPA documentation, the following conditions will be flagged as communities with the potential for having environmental justice concerns:

2. 10% or more in comparison to the county or state average
3. 50% or more minority
4. 5% or more in comparison to the county or state average for poverty

For example, if a census tract has 35% of the population classified as low income but the county consists of 30% low income, the census tract would exceed the county average by 16.7% and thus be flagged as an area with the potential for having EJ concerns. 2020 Census Bureau data is real data gathered every ten years, whereas the estimates from the more recent years are modeled based on the real data.

Race and Ethnicity

The following maps show the top 5 counties as ranked by the SSLW per square mile for cattle. This was calculated on the census tract level and summed up to the county level. All census tracts that are flagged in comparison to either the state or county as laid out above are highlighted in yellow in the maps. Table 6 shows the 2020 Census data for the 5 counties and North Carolina.

Table 6. Race and ethnicity for the five counties with the highest SSLW per Square mile for cattle and North Carolina

Geography	Total population	Hispanic or Latino	White	Percent Non-white and Hispanic or Latino	Black or African American	American Indian and Alaska Native	Asian	Native Hawaiian and Pacific Islander	Some other Race	Two or more Races
North Carolina	10,439,388	1,118,596	6,312,148	39.54%	2,107,526	100,886	340,059	6,980	46,340	406,853
Davidson County	168,930	13,902	129,487	23.35%	15,839	665	2,440	43	491	6,063

6 Wet Poultry

Across North Carolina, there are 9 wet poultry permits covered under the 2019 general permit. The following table (Table 8) outlines the 5 counties in North Carolina that have the highest amount of SSLW per square mile for Wet Poultry. Two portions of the analysis are included below. The first portion includes the entire state overlaying the SSLW at the block group level for potentially underserved communities and at the census tract level with Limited English Proficiency for Spanish speakers. The second portion of the analysis is at the census tract level and includes race and ethnicity, and poverty for the top five counties only. For poultry, the certificates of coverage are located across 5 counties.

Table 8. SSLW per Square Mile: top 5 counties for wet poultry

County	SSLW /sq Mile
Union County	119,149.00
Hyde County	34,756.40
Nash County	24,577.80
Orange County	8,571.43
Halifax County	4,528.30

6.1 Potentially Underserved Communities

The following figure (Figure 14) shows the potentially underserved block group selection overlaid with the wet poultry certificates of coverage averaged out to show SSLW per square mile.

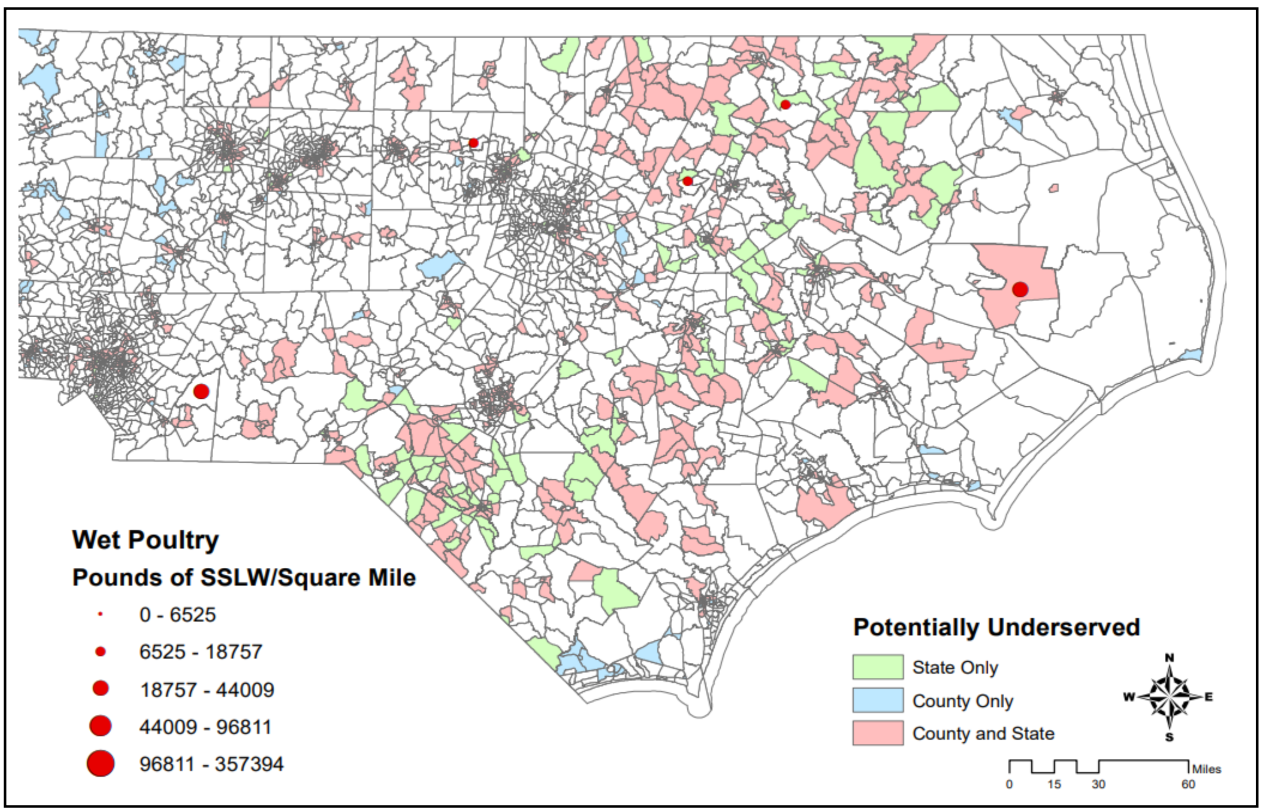

Figure 14. Wet poultry SSLW/Square Mile (census tracts) overlaid with Potentially Underserved Communities (Block Group).

6.2 Limited English Proficiency- Spanish

Per the Safe Harbor Guidelines, should an LEP Group be identified during the permit application process, written translations of vital documents for each eligible LEP language group that constitutes 5% or includes 1,000 members (whichever is less) of the population of persons eligible to be served or likely to be affected or encountered. If there are fewer than 50 persons in a language group that reaches the 5% trigger, then NCDEQ will not translate vital written materials, but instead will provide written notice in the primary language of the LEP language group of the right to receive competent oral interpretation of those written materials, free of cost. The safe harbor provisions apply to the translation of written documents only. Safe harbor guidelines are based on EPA guidance for LEP persons and implemented by NCDEQ when deemed appropriate.

The following figure (Figure 15) shows the census tracts across North Carolina with a population who speaks English less than very well for Spanish greater than 5%.

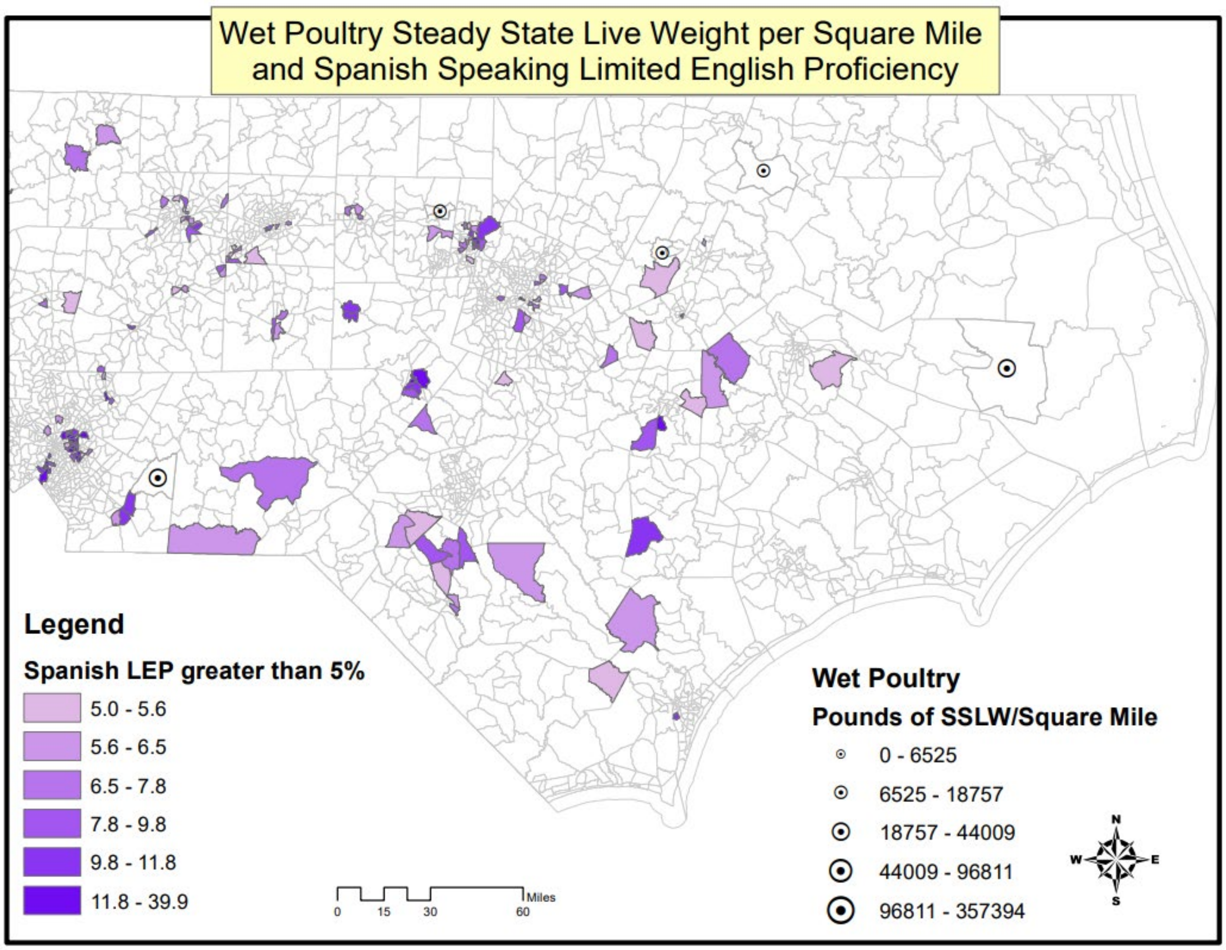

Figure 15. Census tracts with Spanish speaking populations who speak English less than very well and SSLW averages for wet poultry.

6.3 Five County Analysis

Using standard environmental justice guidelines from the EPA and NEPA documentation, the following conditions will be flagged as communities with the potential for having environmental justice concerns:

3. 10% or more in comparison to the county or state average
4. 50% or more minority
5. 5% or more in comparison to the county or state average for poverty

For example, if a census tract has 35% of the population classified as low income but the county consists of 30% low income, the census tract would exceed the county average by 16.7% and thus be flagged as an area with the potential for having EJ concerns. 2020 Census Bureau data is real data gathered every ten years, whereas the estimates from the more recent years are modeled based on the real data.

Race and Ethnicity

The following maps show the top 5 counties as ranked by the SSLW per square mile. This was calculated on the census tract level and summed up to the county level. All census tracts that are flagged in comparison to either the state or county as laid out above are highlighted in yellow in the maps. Table 9 shows the 2020 Census data for the 5 counties and North Carolina.

Table 9. Race and Ethnicity for the five counties with the highest SSLW per Square mile for Poultry and North Carolina.

Geography	Total Population	Hispanic or Latino	White	Percent non-White and Hispanic or Latino	Black or African American	American Indian and Alaska Native	Asian	Native Hawaiian and Pacific Islander	Some other race	Two or more races
North Carolina	10,439,388	1,118,596	6,312,148	39.5%	2,107,526	100,886	340,059	6,980	46,340	406,853
Halifax County	48,622	1454	19,070	60.8%	24737	1593	281	11	142	1334

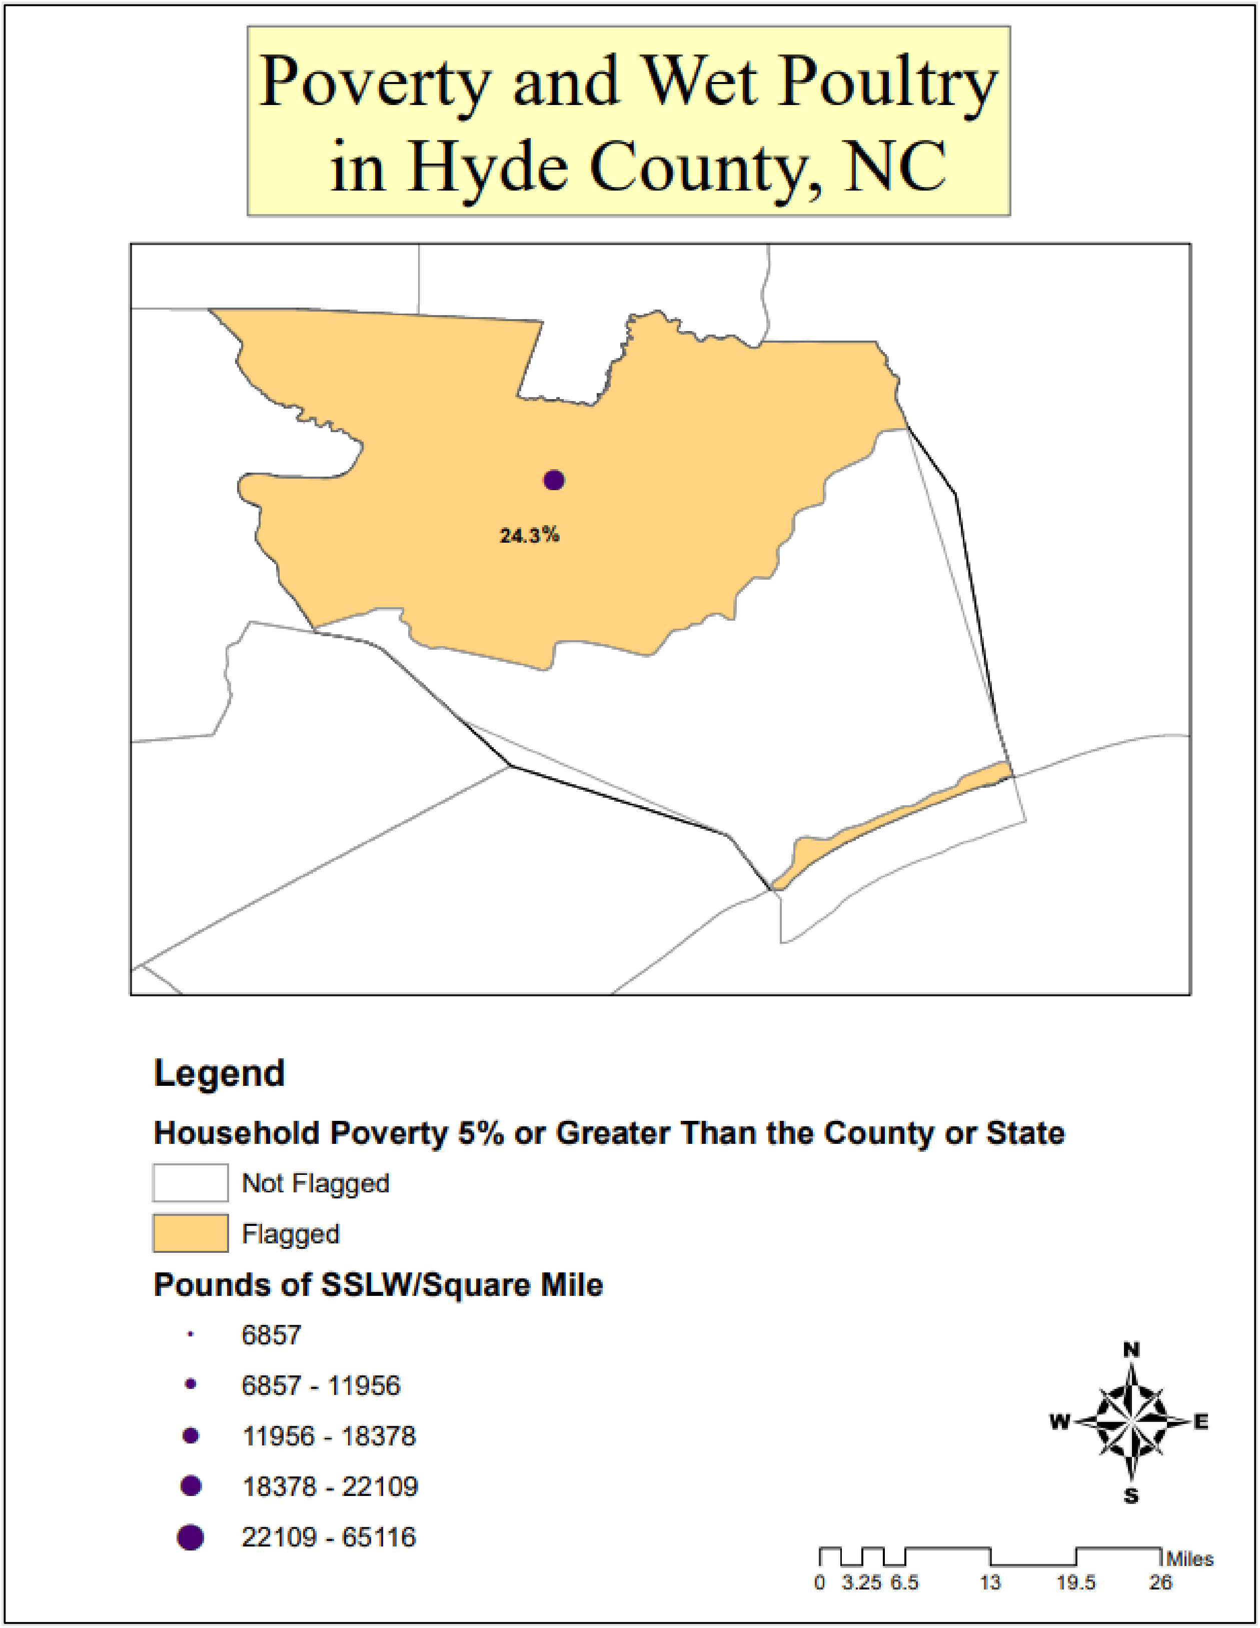

Figure 21. Map of Hyde County flagged census tracts for poverty.

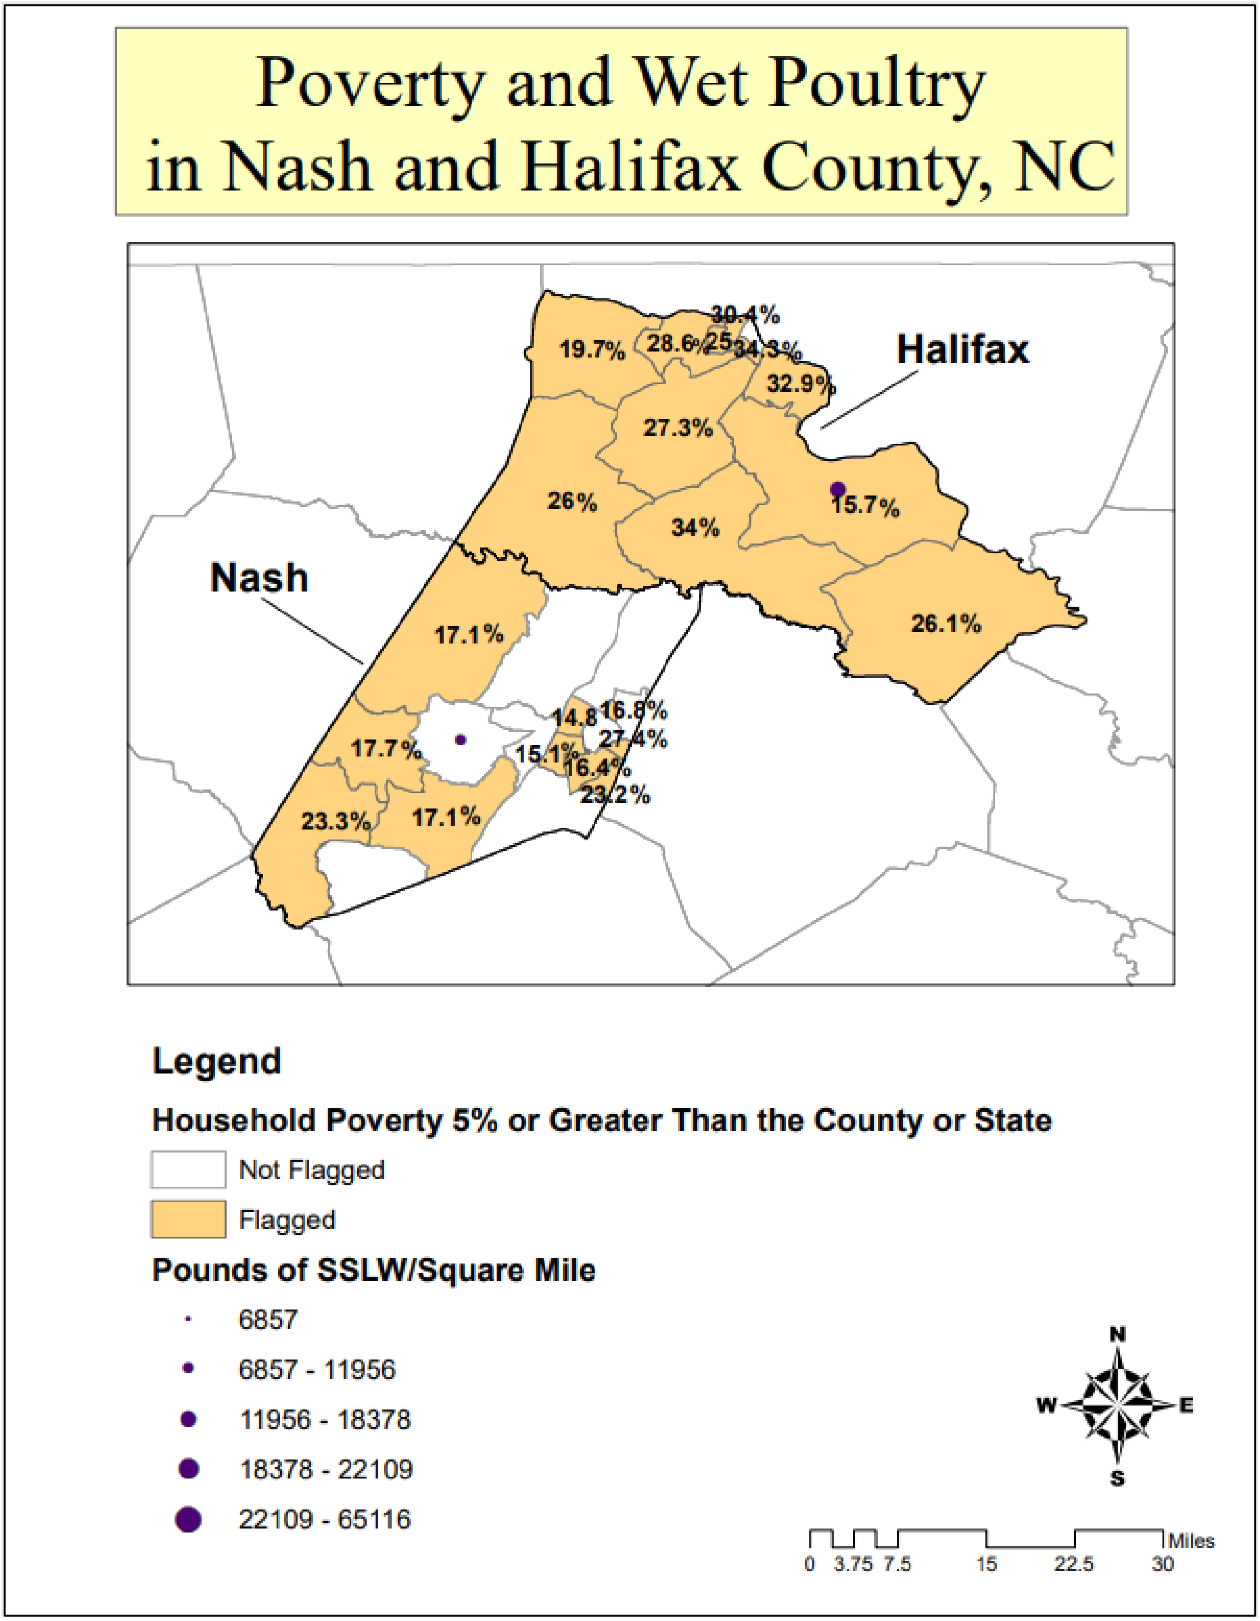

Figure 22. Map of Nash and Halifax Counties flagged census tracts for poverty.

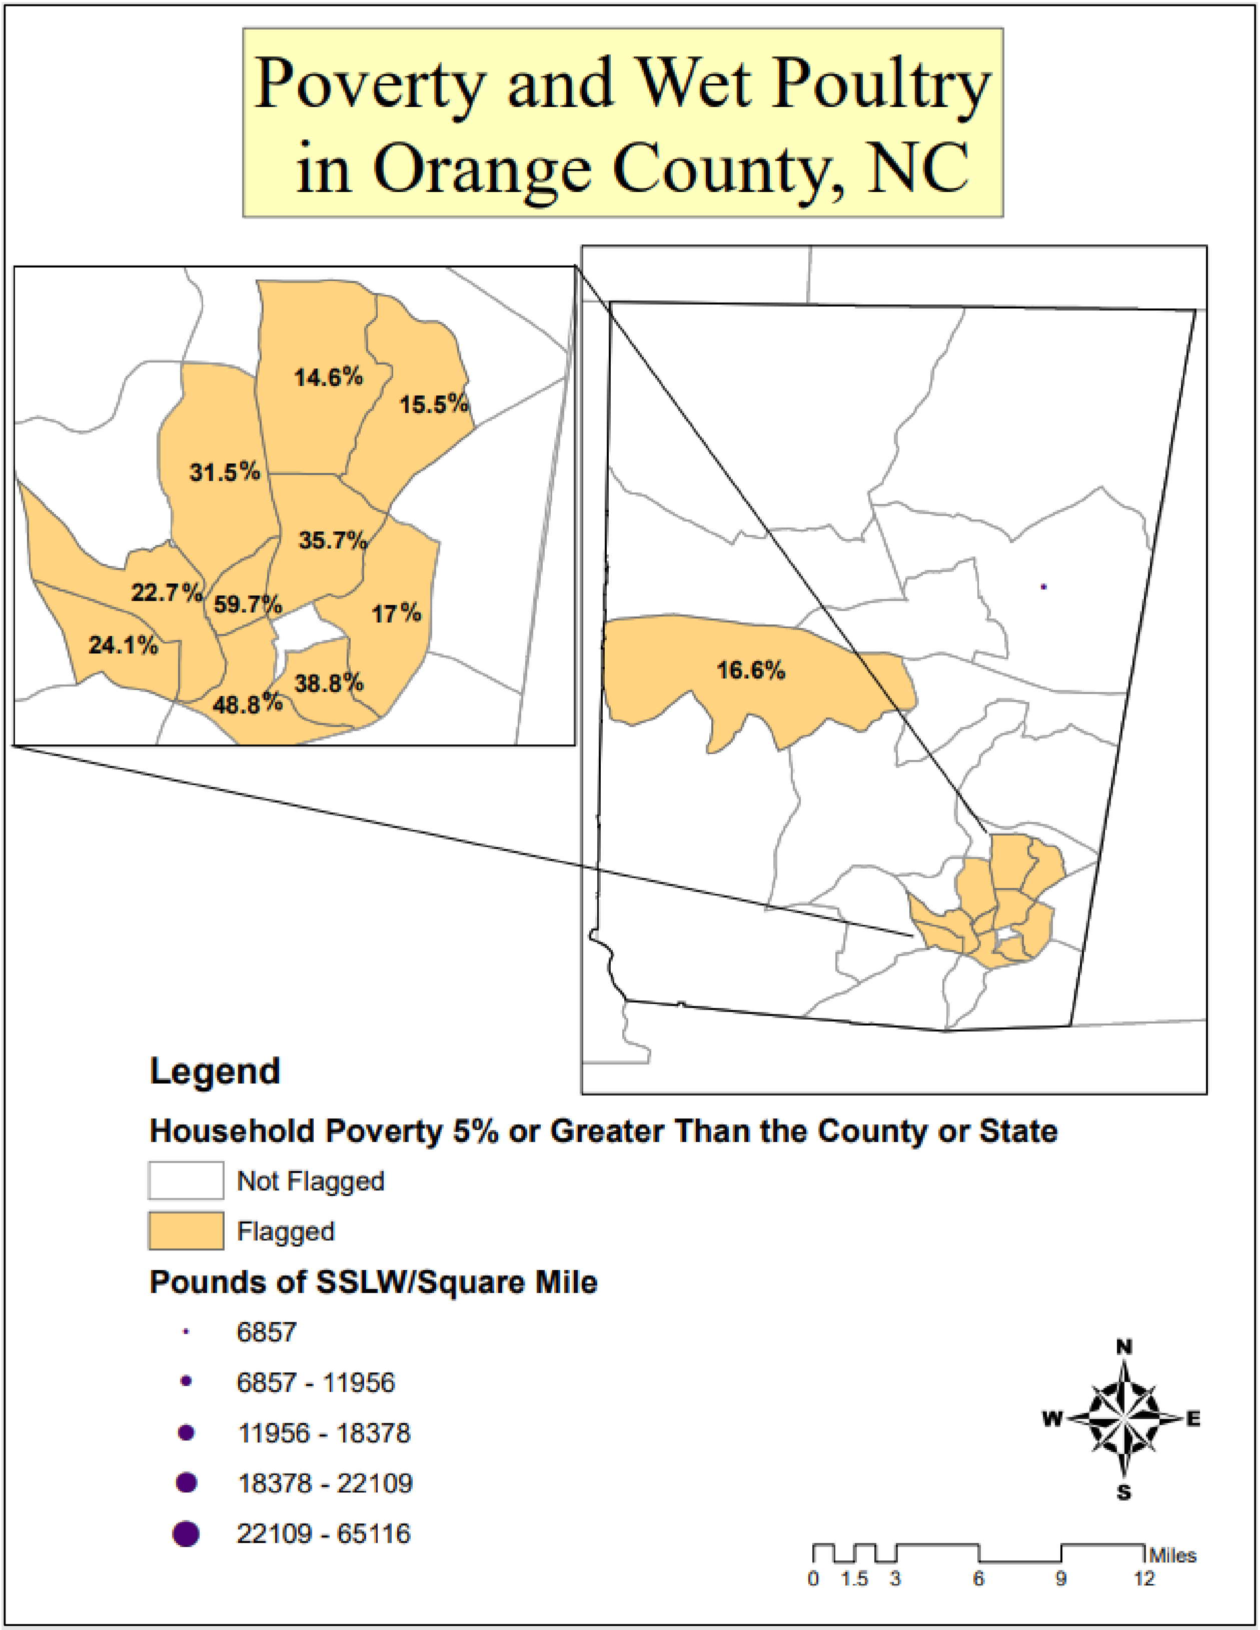

Figure 23. Map of Orange County flagged census tracts for poverty.

7 Tribal Communities

Across North Carolina, there are 7 state recognized tribes and 1 federally recognized tribe. Additionally, there are 4 Urban Indian Organizations. According to the Commission of Indian Affairs, these tribes and tribal organizations reside in 27 counties across North Carolina (Figure 24).

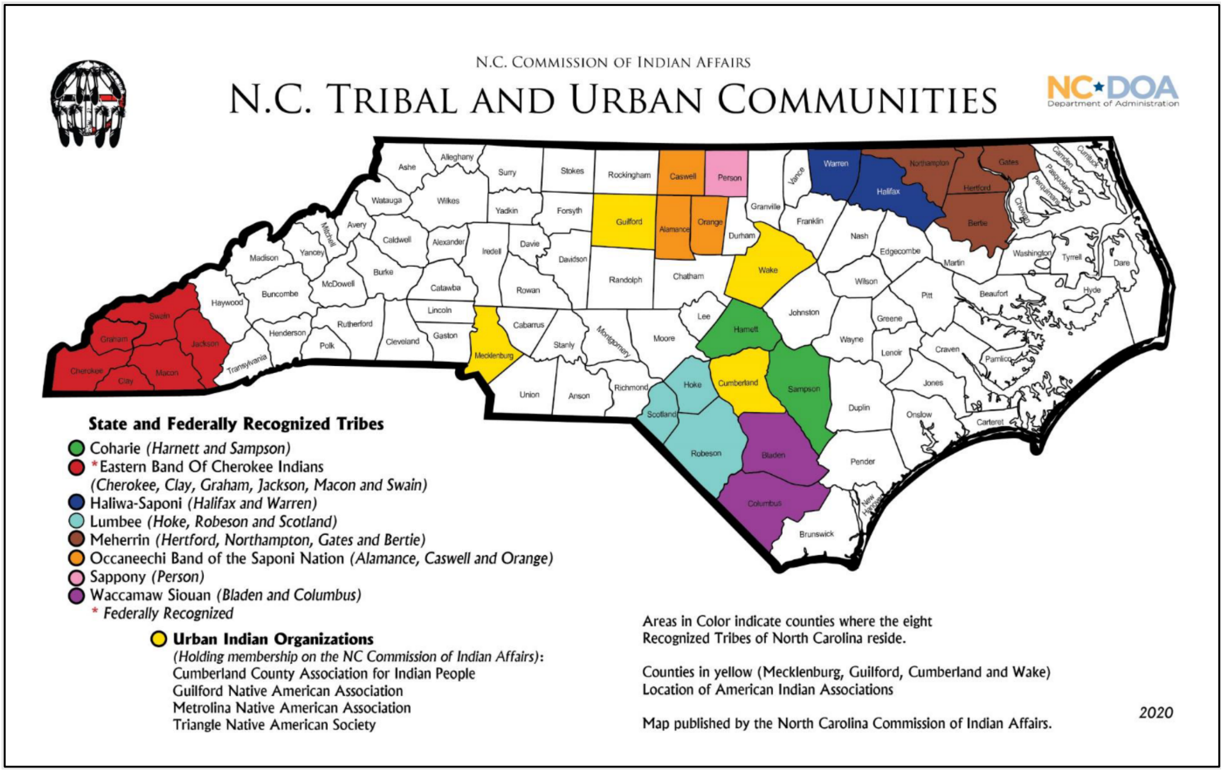

Figure 24. Map of North Carolina Tribal Communities (https://ncadmin.nc.gov/public/american-indians/map-nc-tribal-communities) .

8 County Health Rankings

The University of Wisconsin Population Health Institute, in collaboration with the Robert Wood Johnson Foundation, calculated County Health Rankings for all the States in the United States (www.countyhealthrankings.org). This ranking is based on health outcomes (such as lifespan and self-reported health status) and health factors (such as environmental, social and economic conditions). The following, Figure 25, ranks all 100 counties in North Carolina, with 1 indicating the healthiest. Tables 11-13 outline the health rankings for the 5 counties with the highest SSLW for each permit type included in the above analysis.

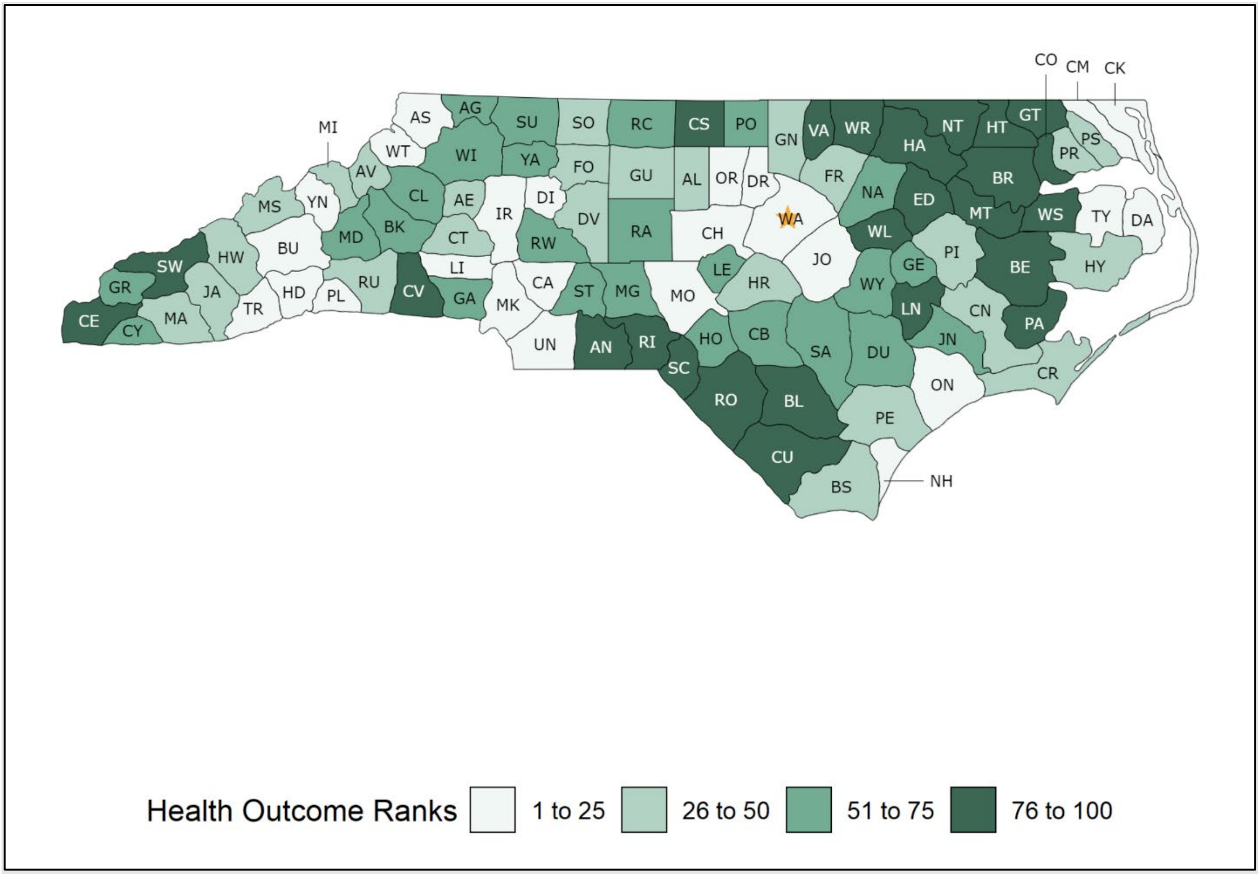

Figure 25. County Health Outcome Rankings for Health Factors in North Carolina provided by University of Wisconsin Public Health Institute

Table 11. Health information for the five counties with highest amount of SSLW per Square Mile for swine

Geography	Health Factors Ranking	Health Outcomes Ranking
Bladen County	93	86
Duplin County	85	58
Robeson County	100	100
Sampson County	80	67
Wayne County	70	64

Table 12. Health information for the five counties with highest amount of SSLW per Square Mile for cattle

Geography	Health Factors Ranking	Health Outcomes Ranking
Davidson County	47	49
Gaston County	40	51
Iredell County	17	15
Lincoln County	26	25
Randolph County	49	52

Table 13. Health information for the five counties with highest amount of SSLW per Square Mile four wet poultry

Geography	Health Factors Ranking	Health Outcomes Ranking
Union County	7	3
Hyde County	86	46
Nash County	63	62
Orange County	1	2
Halifax County	98	95

9 Conclusion

Environmental justice is the fair treatment and meaningful involvement of all people regardless of race, color, national origin, or income, with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies (US EPA). This Draft EJ report examined the SSLW per square mile for the three types of permits in North Carolina; wet poultry, swine, and cattle. Demographic data for poverty, race and ethnicity, and limited English proficiency was also analyzed.

It is important to note that this is an analysis of the facilities with current 2019 general permits and it is not anticipated that every facility covered under the 2019 general permits will apply for the new digester general permits. Additionally, the new digester general permits will replace the existing general permits only if the facility applies for the digester general permit. As it is not possible to predict which facilities will install digesters under the new general permits, this analysis relies on general information and is not a site-specific examination.

Based on the results from this analysis, the following outreach recommendations are recommended:

- Spanish translation for vital documents;
- Include the option for comments via phone lines or mail for the potential for lack of internet access;
- Conduct a mix of virtual and in person meetings, centrally located in the counties included in this report
- Communicate the information and process with the tribes, tribal organizations, and Commission of Indian Affairs across the state;
- Work with known community leaders across the state to distribute information to hard-to-reach communities, with a focus on the counties included in this analysis.

In addition, the NCDEQ Secretary's Environmental Justice and Equity Advisory Board (EJEAB) recommended specific actions in a letter dated August 26, 2021. As a result, NCDEQ has taken several actions, including:

- Scheduling a 90-day comment period on the draft permits;
- Scheduling four public meetings to accept input on the draft permits, including one in Duplin County and Sampson County with 60 days of notice for the public meetings;
- Arranging for Spanish translations of the draft permits and public notices;
- Conducting the fall stakeholder workgroup sessions with an independent moderator;
- Updating the EJEAB members throughout the permit development process.

ATTACHMENT 19

GENERAL ASSEMBLY OF NORTH CAROLINA
SESSION 2021

SESSION LAW 2021-78
SENATE BILL 605

AN ACT TO MAKE VARIOUS CHANGES TO THE LAWS CONCERNING AGRICULTURE AND FORESTRY.

The General Assembly of North Carolina enacts:

VOLUNTARY AGRICULTURAL DISTRICT TECHNICAL CHANGES

SECTION 1. Article 61 of Chapter 106 of the General Statutes reads as rewritten:

"Article 61.

"Agricultural Development and Preservation of Farmland.

…

"Part 2. Voluntary Agricultural Districts.

"§ 106-737. Qualifying farmland.

In order for farmland to qualify for inclusion in a voluntary agricultural district or an enhanced voluntary agricultural district under Part 1 or Part 2 of this Article, it must be real property that:

(1) ~~Is engaged in agriculture as that word is defined in G.S. 106-581.1.~~Is used for bona fide farm purposes, as that term is defined in G.S. 106-743.4(a) and G.S. 160D-903.

(2) Repealed by Session Laws 2005-390, s. 11 effective September 13, 2005.

(3) Is managed in accordance with the Soil Conservation Service defined erosion control practices that are addressed to highly erodable land; and

(4) Is the subject of a conservation agreement, as defined in G.S. 121-35, between the ~~county~~ local government administering the voluntary agricultural district program and the owner of such land that prohibits nonfarm use or development of such land for a period of at least 10 years, except for the creation of not more than three lots that meet applicable county and municipal zoning and subdivision regulations. The form of the conservation agreement shall be approved by the agricultural advisory board created under G.S. 106-739.

"§ 106-737.1. Revocation of conservation agreement.

By written notice to the ~~county,~~ local government administering the voluntary agricultural district program, the landowner may revoke this conservation agreement. Such revocation shall result in loss of qualifying farm status.

"§ 106-738. Voluntary agricultural districts.

(a) An ordinance adopted under this Part shall provide:

(1) For the establishment of voluntary agricultural districts ~~consisting initially of at least the number of contiguous acres of agricultural land, and forestland or horticultural land that is part of a qualifying farm or the number of qualifying farms deemed appropriate by the governing board of the county or city adopting the ordinance;~~upon the execution of a conservation agreement as provided in G.S. 106-737(4).

S605-V-7

(2) ~~For the formation of such districts upon the execution by the owners of the requisite acreage of an agreement to sustain agriculture in the district;~~

(3) ~~That the form of this agreement must be reviewed and approved by an agricultural advisory board established under G.S. 106-739 or some other county board or official;~~

(4) ~~That each such district have a representative on the agricultural advisory board established under G.S. 106-739.~~

(5) The minimum size, including acreage; number of tracts; and appropriate proximity of multiple tracts of agricultural land, forestland, or horticultural land that may comprise a voluntary agricultural district.

(b) The purpose of such agricultural districts shall be to increase identity and pride in the agricultural community and its way of life and to ~~increase protection from nuisance suits~~ decrease the likelihood of legal disputes, such as nuisance actions between farm owners and their neighbors, and other negative impacts on properly managed farms. The county or city that adopted an ordinance under this Part may take such action as it deems appropriate to encourage the formation of such districts and to further their purposes and objectives.

(c) A county ordinance adopted pursuant to this Part is effective within the unincorporated areas of the county. A city ordinance adopted pursuant to this Part is effective within the corporate limits of the city. A city may amend its ordinances in accordance with G.S. 160A-383.2 with regard to agricultural districts within its planning jurisdiction.

"§ 106-739. Agricultural advisory board.

(a) An ordinance adopted under this Part or Part 3 of this Article shall provide for the establishment of an agricultural advisory board, organized and appointed ~~as the county or city that adopted the ordinance shall deem appropriate.~~ by the board of county commissioners or the city council adopting the ordinance. The county or city that adopted the ordinance may confer upon this advisory board authority to:

(1) Review and make recommendations or decisions concerning the establishment and modification of agricultural ~~districts;~~districts. The board of county commissioners or the city council may make decisions regarding the establishment and modification of voluntary agricultural districts or may delegate that authority to the agricultural advisory board. If the authority is delegated to the agricultural advisory board, the agricultural advisory board's decisions shall be appealable to the board of county commissioners or city council by an owner of land that has been denied enrollment in a voluntary agricultural district or has been removed from a voluntary agricultural district by the agricultural advisory board.

(1a) Execute agreements with landowners necessary for enrollment of land in a voluntary agricultural district.

(2) Review and make recommendations concerning any ordinance or amendment adopted or proposed for adoption under this Part or Part 3 of this ~~Article;~~Article.

(3) Hold public hearings on public projects likely to have an impact on agricultural operations, particularly if such projects involve condemnation of all or part of any qualifying ~~farm;~~farm.

(4) Advise the governing board of the county or city that adopted the ordinance on projects, programs, or issues affecting the agricultural economy or way of life within the ~~county;~~county.

(5) Perform other related tasks or duties assigned by the governing board of the county or city that adopted the ordinance.

(b) The members of the agricultural advisory board shall be chosen to provide the broadest possible representation of the geographical regions of the local government and to represent, to the extent possible, all segments of agricultural production existing within the local government. A majority of the members of the agricultural advisory board shall be actively engaged in agriculture.

(c) The agricultural advisory board may, at the discretion of the board of county commissioners or the city council, utilize an existing local government agency for the purpose of administration, record keeping, and other related tasks or duties.

…

"§ 106-741. Record notice of proximity to farmlands.

(a) All counties shall require that land records include some form of notice reasonably calculated to alert a person researching the title of a particular tract that such tract is located within one-half mile of ~~a poultry, swine, or dairy qualifying farm or within 600 feet of any other qualifying farm or within one-half mile of a voluntary agricultural district.~~the property line of any tract of land enrolled in a voluntary agricultural district.

…

"§ 106-743. Local ordinances.

A county or a city adopting an ordinance under this Part or Part 3 of this Article may consult with the North Carolina Commissioner of Agriculture or ~~his~~ the Commissioner's staff before adoption, and shall record the ordinance with the Commissioner's office after adoption. Thereafter, the county or city shall submit to the Commissioner at least once a year, a written report including the status, ~~progress~~ progress, number of enrolled farms and acres, and activities of its farmland preservation program under this Part or Part 3 of this Article.

"Part 3. Enhanced Voluntary Agricultural Districts.

"§ 106-743.1. Enhanced voluntary agricultural districts.

(a) A county or a municipality may adopt an ordinance establishing an enhanced voluntary agricultural district. An ordinance adopted pursuant to this Part shall provide:

(1) For the establishment of an enhanced voluntary agricultural district that initially consists of at least the number of contiguous acres of agricultural land, and forestland and horticultural land that is part of a qualifying farm under G.S. 106-737 or the number of qualifying farms deemed appropriate by the governing board of the county or city adopting the ordinance.

(2) For the formation of the enhanced voluntary agricultural district upon the execution of a conservation agreement, as defined in G.S. 121-35, that meets the condition set forth in G.S. 106-743.2 by the landowners of the requisite acreage to sustain agriculture in the enhanced voluntary agricultural district.

(3) That the form of the agreement under subdivision (2) of this subsection be reviewed and approved by an agricultural advisory board established under G.S. 106-739, or other governing board of the county or city that adopted the ordinance.

~~(4) That each enhanced voluntary agricultural district have a representative on the agricultural advisory board established under G.S. 106-739.~~

(b) The purpose of establishing an enhanced voluntary agricultural district is to allow a county or a city to provide additional benefits to farmland beyond that available in a voluntary agricultural district established under Part 2 of this Article, when the owner of the farmland agrees to the condition imposed under G.S. 106-743.2. The county or city that adopted the ordinance may take any action it deems appropriate to encourage the formation of these districts and to further their purposes and objectives.

(c) A county ordinance adopted pursuant to this Part is effective within the unincorporated areas of the county. A city ordinance adopted pursuant to this Part is effective within the corporate limits of the city. A city may amend its ordinances in accordance with G.S. 160A-383.2 with regard to agricultural districts within its planning jurisdiction.

(d) A county or city ordinance adopted pursuant to this Part may be adopted simultaneously with the creation of a voluntary agricultural district pursuant to G.S. 106-738.
…."

ALLOW MAGISTRATES TO WAIVE TRIALS FOR STATE FOREST RULE OFFENSES

SECTION 2.(a) G.S. 7A-273 reads as rewritten:

"**§ 7A-273. Powers of magistrates in infractions or criminal actions.**

In criminal actions or infractions, any magistrate has power:

…

(2) In misdemeanor or infraction cases involving alcohol offenses under Chapter 18B of the General Statutes, traffic offenses, hunting, fishing, State park and recreation area rule offenses under Chapters 113 and 143B of the General Statutes, <u>State forest rule offenses under Articles 74 and 75 of Chapter 106 of the General Statutes, </u>boating offenses under Chapter 75A of the General Statutes, open burning offenses under Article 78 of Chapter 106 of the General Statutes, and littering offenses under G.S. 14-399(c) and G.S. 14-399(c1), to accept written appearances, waivers of trial or hearing and pleas of guilty or admissions of responsibility, in accordance with the schedule of offenses and fines or penalties promulgated by the Conference of Chief District Judges pursuant to G.S. 7A-148, and in such cases, to enter judgment and collect the fines or penalties and costs;

…."

SECTION 2.(b) This section becomes effective December 1, 2021, and applies to offenses committed on or after that date.

EXEMPT CERTAIN FIRES FROM OPEN BURNING LAWS

SECTION 3.(a) G.S. 106-950 is amended by adding a new subsection to read:

"<u>(a2) Except in cases where the Commissioner has prohibited all open burning during periods of hazardous forest fire conditions or during air pollution episodes declared pursuant to Article 21B of Chapter 143 of the General Statutes, this Article does not apply to any fires started, or caused to be started, for cooking, warming, or ceremonial events, if the fire is confined (i) within an enclosure from which burning material may not escape or (ii) within a protected area upon which a watch is being maintained and which is provided with adequate fire protection equipment.</u>"

SECTION 3.(b) This section becomes effective December 1, 2021, and applies to offenses committed on or after that date.

FOREST SERVICE OVERTIME MODIFICATION

SECTION 4.(a) G.S. 106-903 reads as rewritten:

"**§ 106-903. Overtime compensation for forest fire fighting.**

The Department shall, within funds appropriated to the Department, provide <u>either monetary</u> overtime compensation <u>or compensatory leave at an hour-for-hour rate, at its discretion, </u>to the ~~professional~~ employees of the North Carolina Forest Service <u>who are exempt from the Fair Labor Standards Act and </u>involved in fighting forest ~~fires.~~<u>fires for overtime earned while conducting fire suppression duties as defined in G.S. 106-955. If the Department provides compensatory leave for overtime earned, it shall be provided in a manner consistent with the State's general compensatory time policy for exempt employees established by the Office of State Human Resources.</u>"

SECTION 4.(b) This section is effective when it becomes law and applies to overtime earned on or after that date.

INCREASE PUNISHMENT FOR TIMBER LARCENY AND INCREASE CIVIL PENALTIES FOR DAMAGING TIMBER OR AGRICULTURAL COMMODITIES

SECTION 5.(a) G.S. 14-135 reads as rewritten:

"**§ 14-135. ~~Cutting, injuring, or removing another's~~ Larceny of timber.**

(a) Offense. – Except as otherwise provided in subsection (b) of this section, a person commits the offense of larceny of timber if the person does any of the following:

(1) ~~If any person not being the bona fide owner thereof, shall knowingly and willfully cut down, injure or remove any standing, growing or fallen tree or log off the property of another, the person shall be punished the same as in G.S. 14-72.~~Knowingly and willfully cuts down, injures, or removes any timber owned by another person, without the consent of the owner of the land or the owner of the timber, or without a lawful easement running with the land.

(2) Buys timber directly from the owner of the timber and fails to make payment in full to the owner by (i) the date specified in the written timber sales agreement or (ii) if there is no such agreement, 60 days from the date that the buyer removes the timber from the property.

(b) Exceptions. – The following are exceptions to the offense set forth in subsection (a) of this section:

(1) A person is not guilty of an offense under subdivision (1) of subsection (a) of this section if the person is an employee or agent of an electric power supplier, as defined in G.S. 62-133.8, and either of the following conditions is met:

a. The person believed in good faith that consent of the owner had been obtained prior to cutting down, injuring, or removing the timber.

b. The person believed in good faith that the cutting down, injuring, or removing of the timber was permitted by a utility easement or was necessary to remove a tree hazard. For purposes of this sub-subdivision, the term "tree hazard" includes a dead or dying tree, dead parts of a living tree, or an unstable living tree that is within striking distance of an electric transmission line, electric distribution line, or electric equipment and constitutes a hazard to the line or equipment in the event of a tree failure.

(2) A person is not guilty of an offense under subdivision (2) of subsection (a) of this section if either of the following conditions is met:

a. The person remitted payment in full within the time period set in subdivision (2) of subsection (a) of this section to a person he or she believed in good faith to be the rightful owner of the timber.

b. The person remitted payment in full to the owner of the timber within the 10-day period set forth in subsection (c) of this section.

(c) Prima Facie Evidence. – An owner of timber who does not receive payment in full within the time period set in subdivision (2) of subsection (a) of this section may notify the timber buyer in writing of the owner's demand for payment at the timber buyer's last known address by certified mail or by personal delivery. The timber buyer's failure to make payment in full within 10 days after the mailing or personal delivery authorized under this subsection shall constitute prima facie evidence of the timber buyer's intent to commit an offense under subdivision (2) of subsection (a) of this section.

(d) Penalty; Restitution. – A person who commits an offense under subsection (a) of this section is guilty of a Class G felony. Additionally, a defendant convicted of an offense under subsection (a) of this section shall be ordered to make restitution to the timber owner in an amount equal to either of the following:

(1) Three times the value of the timber cut down, injured, or removed in violation of subdivision (1) of subsection (a) of this section.

(2) Three times the value of the timber bought but not paid for in violation of subdivision (2) of subsection (a) of this section.

Restitution shall also include the cost incurred by the owner to determine the value of the timber. For purposes of subdivisions (1) and (2) of this subsection, "value of the timber" shall be based on the stumpage rate of the timber.

(e) Civil Remedies. – Nothing in this section shall affect any civil remedies available for a violation of subsection (a) of this section."

SECTION 5.(b) G.S. 1-539.1 reads as rewritten:

"**§ 1-539.1. Damages for unlawful cutting, removal or burning of timber; misrepresentation of property lines.**

(a) Any person, firm or corporation not being the bona fide owner thereof or agent of the owner who shall without the consent and permission of the bona fide owner enter upon the land of another and injure, cut or remove any valuable wood, timber, shrub or tree therefrom, shall be liable to the owner of said land for ~~double~~ triple the value of such wood, timber, shrubs or trees so injured, cut or removed.

(b) If any person, firm or corporation shall willfully and intentionally set on fire, or cause to be set on fire, in any manner whatever, any valuable wood, timber or trees on the lands of another, such person, firm or corporation shall be liable to the owner of said lands for ~~double~~ triple the value of such wood, timber or trees damaged or destroyed thereby.

…."

SECTION 5.(c) G.S. 1-539.2B reads as rewritten:

"**§ 1-539.2B. ~~Double~~ Triple damages for injury to agricultural commodities or production systems; define value of agricultural commodities grown for educational, testing, or research purposes.**

(a) Any person who unlawfully and willfully injures or destroys any other person's agricultural commodities or production system is liable to the owner for ~~double~~ triple the value of the commodities or production system injured or destroyed.

…."

SECTION 5.(d) Subsection (a) of this section becomes effective December 1, 2021, and applies to offenses committed on or after that date. Subsections (b) and (c) of this section become effective December 1, 2021, and apply to civil actions filed on or after that date.

REQUIRE TIMBER BUYERS AND TIMBER OPERATORS TO PROVIDE A WOOD LOAD TICKET TO SELLERS OF CERTAIN WOOD PRODUCTS

SECTION 6.(a) Article 22 of Chapter 14 of the General Statutes is amended by adding a new section to read:

"**§ 14-135.1. Wood load tickets required for certain wood product sales; exceptions; penalties.**

(a) Definition. – For purposes of this section, the term "wood product" means trees, timber, wood, or any combination thereof.

(b) Requirement. – Except as provided in this section, whenever a timber buyer or timber operator purchases wood product by the load directly from a timber grower or seller and the load is sold by weight, cord, or measure of board feet, the timber buyer or operator shall furnish the timber grower or seller, within 30 days of the completion of the wood product harvest, a separate, true, and accurate wood load ticket for each load of wood product removed from the timber grower's or seller's property. At a minimum, each wood load ticket shall include all of the following information provided by the timber grower or seller who sold the wood product:

(1) The name of the timber grower or seller.

(2) The county from which the wood product was severed.

(3) The amount of wood product severed.

(4) The date the wood product was delivered to the timber buyer or timber operator.

(c) Applicability. – The provisions of this section do not apply to the following:

(1) The sale of wood for firewood only.

(2) A landowner harvesting and processing their own timber.

(3) Bulk or lump sum sales for an agreed total price for all timber purchased and sold in one transaction.

(d) Punishment. – Any person who violates this section is guilty of a Class 2 misdemeanor."

SECTION 6.(b) This section becomes effective December 1, 2021, and applies to offenses committed on or after that date.

EXPAND THE LAWS ENFORCED BY DEPARTMENT OF AGRICULTURE AND CONSUMER SERVICES LAW ENFORCEMENT OFFICERS

SECTION 7.(a) G.S. 106-897 reads as rewritten:

"**§ 106-897. Forest laws defined.**

The forest laws consist ~~of:~~of all of the following:

(1) ~~G.S. 14-136 to G.S. 14-140;~~G.S. 14-135 to G.S. 14-140.1.

(2) Articles 74 through 84 of this ~~Chapter;~~Chapter.

(3) G.S. 77-13 and ~~G.S. 77-14;~~G.S. 77-14.

(4) Other statutes enacted for the protection of forests and woodlands from fire, insects, or disease and concerning obstruction of streams and ditches in forests and ~~woodlands; and~~woodlands.

(5) Regulations and ordinances adopted under the authority of the above statutes."

SECTION 7.(b) This section becomes effective December 1, 2021, and applies to offenses committed on or after that date.

REQUIRE PRODUCTION OF ELECTRONIC RECORDS FOR DEPARTMENT OF AGRICULTURE AND CONSUMER SERVICES RECORD AUDITS

SECTION 8.(a) G.S. 106-92.8 reads as rewritten:

"**§ 106-92.8. Tonnage fees: reporting system.**

For the purpose of defraying expenses connected with the registration, inspection and analysis of the materials coming under this Article, each manufacturer or registrant shall pay to the Department of Agriculture and Consumer Services tonnage fees in addition to registration fees as follows: for agricultural liming material, fifty cents (50¢) per ton; for landplaster, fifty cents (50¢) per ton; excepting that these fees shall not apply to materials which are sold to fertilizer manufacturers for the sole purpose for use in the manufacture of fertilizer or to materials when sold in packages of 10 pounds or less.

Any manufacturer, importer, jobber, firm, corporation or person who distributes materials coming under this Article in this State shall make application for a permit to report the materials sold and pay the tonnage fees as set forth in this section.

The Commissioner of Agriculture shall grant such permits on the following conditions: The applicant's agreement ~~that he will~~ to keep such records as may be necessary to indicate accurately the tonnage of liming materials, etc., sold in the State and ~~his~~ the applicant's agreement for the Commissioner or ~~this~~ the Commissioner's authorized representative to examine such records to verify the tonnage statement. If the records are available electronically, the electronic records shall be made available to the Commissioner or the Commissioner's authorized representative. The registrant shall report quarterly and pay the applicable tonnage fees quarterly, on or before the tenth day of October, January, April, and July of each year. The report and payment shall cover the tonnage of liming materials, etc., sold during the preceding quarter. The report shall be on forms furnished by the Commissioner. If the report is not filed and the tonnage fees paid by the last day of the month in which it is due, or if the report be false, the amount due shall bear a penalty of ten percent (10%) which shall be added to the tonnage fees due. If the report is not filed and the tonnage fees paid within 60 days of the date due, or if the report or tonnage be false, the Commissioner may revoke the permit and cancel the registration."

SECTION 8.(b) G.S. 106-277.12 reads as rewritten:

"**§ 106-277.12. Records.**

All persons transporting or delivering for transportation, selling, offering or exposing for sale agricultural or vegetable seeds if their name appears on the label shall keep for a period of two years a file sample and a complete record of such seed, including invoices showing lot number, kind and variety, origin, germination, purity, treatment, and the labeling of each lot. The Commissioner or ~~his~~ the Commissioner's duly authorized agents shall have the right to inspect such records in connection with the administration of this Article at any time during customary business hours. If the records are available electronically, the electronic records shall be made available to the Commissioner or the Commissioner's authorized representative."

SECTION 8.(c) G.S. 106-284.40(c)(2) reads as rewritten:

"(2) Keep such records as may be necessary or required by the Commissioner to indicate accurately the tonnage of commercial feed distributed in this State, and the Commissioner or ~~his~~ the Commissioner's duly designated agent shall have the right to examine such records during normal business hours, to verify statements of tonnage. If the records are available electronically, the electronic records shall be made available to the Commissioner or the Commissioner's authorized representative. Failure to make an accurate statement of tonnage or to pay the inspection fee or comply as provided herein shall constitute sufficient cause for the cancellation of all registrations on file for the distributor."

SECTION 8.(d) G.S. 106-671(b) reads as rewritten:

"(b) Reporting System. – Each manufacturer, importer, jobber, firm, corporation or person who distributes commercial fertilizers in this State shall make application to the Commissioner for a permit to report the tonnage of commercial fertilizer sold and shall pay to the North Carolina Department of Agriculture and Consumer Services an inspection fee of fifty cents (50¢) per ton. The Commissioner is authorized to require each such distributor to keep such records as may be necessary to indicate accurately the tonnage of commercial fertilizers sold in the State, and as are satisfactory to the Commissioner. Such records shall be available to the Commissioner, or ~~his~~ the Commissioner's duly authorized representative, at any and all reasonable hours for the purpose of making such examination as is necessary to verify the tonnage statement and the inspection fees paid. If the records are available electronically, the electronic records shall be made available to the Commissioner or the Commissioner's authorized representative. Each registrant shall report monthly the tonnage sold to non-registrants on forms furnished by the Commissioner. Such reports shall be made and inspection fees shall be due and payable monthly on the fifteenth of each month covering the tonnage and kind of commercial fertilizers sold during the past month. If the report is not filed and the inspection fee paid by the last day of the month it is due, the amount due shall bear a penalty of ten percent (10%), which shall be added to the inspection fee due. If the report is not filed and the inspection fee paid within 60 days of the date due, or if the report or tonnage be false, the Commissioner may revoke the permit."

TOBACCO TRUST FUND COMMISSION ADMIN EXPENSES

SECTION 9. G.S. 143-717(i) reads as rewritten:

"(i) Limit on Operating and Administrative Expenses. – All administrative expenses of the Commission shall be paid from the Fund. No more than ~~three hundred fifty thousand dollars ($350,000)~~ three hundred seventy-five thousand dollars ($375,000) may be used each fiscal year for administrative and operating expenses of the Commission and its staff, provided that the Commission may annually adjust the administrative expense cap imposed by this subsection, so long as that any cap increase does not exceed the amount necessary to provide for statewide salary and benefit adjustments enacted by the General Assembly."

WORKERS' COMPENSATION DEFINITION CLARIFICATION

SECTION 10. G.S. 97-2 reads as rewritten:

"**§ 97-2. Definitions.**

When used in this Article, unless the context otherwise requires:

(1) Employment. – The term "employment" includes employment by the State and all political subdivisions thereof, and all public and quasi-public corporations therein and all private employments in which three or more employees are regularly employed in the same business or establishment or in which one or more employees are employed in activities which involve the use or presence of radiation, except agriculture and domestic services, unless 10 or more full-time nonseasonal agricultural workers are regularly employed by the employer and an individual sawmill and logging operator with less than 10 employees, who saws and logs less than 60 days in any six consecutive months and whose principal business is unrelated to sawmilling or logging. For purposes of this section, "agriculture" has the same meaning as in G.S. 106-581.1.

…."

CREATE A NEW GENERAL PERMIT FOR FARMS WITH FARM DIGESTER SYSTEMS

SECTION 11.(a) G.S. 143-213 reads as rewritten:

"**§ 143-213. Definitions.**

Unless the context otherwise requires, the following terms as used in this Article and Articles 21A of this Chapter are defined as follows:

…

(5a) The terms "animal waste" and "animal waste management system" have the same meaning as in G.S. 143-215.10B.

…

(12a) The term "farm digester system" means a system, including all associated equipment and lagoon covers, by which gases are collected and processed from an animal waste management system for the digestion of animal biomass for use as a renewable energy resource. A farm digester system shall be considered an agricultural feedlot activity within the meaning of "animal operation" and shall also be considered a part of an "animal waste management system" as those terms are defined in G.S. 143-215.10B.

(12b) The term "lagoon cover" means a structure or material that covers a lagoon receiving animal waste as part of an animal waste management system. For purposes of this subdivision, the term "lagoon" includes a lagoon as defined in G.S. 106-802(1) or a storage pond.

…

(14a) The term "renewable animal biomass energy resource" means any renewable energy resource, as defined in G.S. 62-133.8(a)(8), that utilizes animal waste as a biomass resource, including a farm digester system.

…."

SECTION 11.(b) G.S. 143-215.10C reads as rewritten:

"**§ 143-215.10C. Applications and permits.**

(a) No person shall construct or operate an animal waste management system for an animal operation or operate an animal waste management system for a dry litter poultry facility that is required to be permitted under 40 Code of Federal Regulations § 122, as amended at 73 Federal Register 70418 (November 20, 2008), without first obtaining an individual permit or a general permit under this Article. The Commission shall develop a system of individual and general permits for animal operations and dry litter poultry facilities based on species, number of animals, and other relevant factors. <u>The Commission shall develop a general permit for animal operations that includes authorization for the permittee to construct and operate a farm digester system.</u> It is the intent of the General Assembly that most animal waste management systems be permitted under a general permit. The Commission, in its discretion, may require that an animal waste management ~~system~~ <u>system, including an animal waste management system that utilizes a farm digester system,</u> be permitted under an individual permit if the Commission determines that an individual permit is necessary to protect water quality, public health, or the environment. <u>After the general permit for animal operations that includes authorization for the permittee to construct and operate a farm digester system has been issued, the decision to require an individual permit shall not be based solely on the fact that the animal waste management system utilizes a farm digester system.</u> The owner or operator of an animal operation shall submit an application for a permit at least 180 days prior to construction of a new animal waste management system or expansion of an existing animal waste management system and shall obtain the permit prior to commencement of the construction or expansion. The owner or operator of a dry litter poultry facility that is required to be permitted under 40 Code of Federal Regulations § 122, as amended at 73 Federal Register 70418 (November 20, 2008), shall submit an application for a permit at least 180 days prior to operation of a new animal waste management system.

…

(c) The Commission shall act on a permit application as quickly as possible and may conduct any inquiry or investigation it considers necessary before acting on an application.

<u>(c1) Failure of the Commission to make a final permitting decision involving a notice of intent for a certificate of coverage under a general permit for animal operations that includes authorization for the permittee to construct and operate a farm digester system within 90 days of the Commission's receipt of a completed notice of intent shall result in the deemed approval of coverage under the permit. If the Commission fails to act within 90 days of the Commission's receipt of a completed notice of intent, the permittee may request that the Commission provide written confirmation that the notice of intent is deemed approved. Failure to provide this written confirmation within 10 days of the request shall serve as a basis to seek a contested case hearing pursuant to Article 3 of Chapter 150B of the General Statutes. Unless all parties to the case agree otherwise in writing, the administrative law judge shall issue a final decision or order in the contested case no later than 120 days after its commencement pursuant to G.S. 150B-23; provided that, upon written request of the administrative law judge or any party to the hearing, the Chief Administrative Law Judge may extend this deadline for good cause shown, no more than two times, for not more than 30 days per extension. Upon review of a failure to act on a notice of intent, the administrative law judge may either (i) direct the Commission to issue a written certificate of coverage under the general permit or (ii) deny the petition.</u>

…."

SECTION 11.(c) For purposes of this section, the following definitions apply:

(1) "Certificate of coverage" means an approval granted to a person who meets the requirements of coverage under a general permit as provided in 15A NCAC 02T .0111 (Conditions for Issuing General Permits).

(2) "Commission" means the Environmental Management Commission.

(3) "Notice of intent" means a request for coverage under a general permit using forms approved by the Division of Water Resources of the Department of Environmental Quality.

SECTION 11.(d) The Commission shall immediately initiate the process of developing and issuing a general permit for animal operations that includes authorization for the permittee to construct and operate a farm digester system. In addition to conditions required to describe and authorize the construction, monitoring, and proper operation of farm digester systems, the general permit shall contain the same conditions that are included in the currently existing general permits for animal operations. The general permit shall become effective no later than 12 months after the effective date of this section and shall expire on the later of September 30, 2024, or the effective date of the next version of the currently existing general permit for animal operations.

SECTION 11.(e) Until the general permit issued under subsection (d) of this section becomes effective, any animal operation that holds a general or individual permit that (i) is in effect on the effective date of this section and (ii) authorizes the construction and operation of a farm digester system may construct and continue to operate the farm digester system as authorized by that permit. For any animal operation that holds a general or individual permit that is in effect on the effective date of this section, but that does not authorize the construction and operation of a farm digester system, an operator may submit a notice of intent to be covered under the general permit to be developed under subsection (d) of this section. If the submitted notice of intent is incomplete, the Commission shall notify the applicant of the deficiency in the notice of intent. When an operator submits a completed notice of intent, the Commission shall, within 90 days of receipt of the completed notice of intent, either issue a certificate of coverage allowing the operator to construct and operate the farm digester system or notify the operator of the basis for the denial of the certificate of coverage. If the Commission fails to take action on the notice of intent within 90 days, authorization to construct and operate a farm digester system under the existing general permit shall be deemed approved.

SECTION 11.(f) Nothing in this section shall apply to permits for facilities that are required to be permitted under 40 C.F.R. § 122, as amended at 73 Federal Register 70418 (November 20, 2008).

SECTION 11.(g) G.S. 106-806 reads as rewritten:

"**§ 106-806. Construction or renovation of swine houses at preexisting swine farms.**

(a) As used in this section, the following definitions apply:

(1) "Farm digester system" means a farm digester system as defined in G.S. 143-213(12a).

(2) "New swine farm" means any swine farm the operations of which were sited on or after October 1, 1995. "New swine farm" does not include any preexisting swine farm, even if a subsequent site evaluation is performed on or after October 1, 1995, at the preexisting swine farm.

~~(2)~~(3) "Preexisting swine farm" means any swine farm either the operations of which were begun prior to October 1, 1995, or the site evaluation of which was approved prior to October 1, 1995, by the Department of Environmental Quality under Part 1A of Article 21 of Chapter 143 of the General Statutes.

~~(3)~~(4) "Renovation or construction," "renovated or constructed," and any similar phrase mean any activity to renovate, construct, reconstruct, rebuild, modify, alter, change, restructure, upgrade, improve, enlarge, reduce, move, or otherwise perform construction work on a swine house that is a component of a swine farm.

…

(e) Notwithstanding any other provision of this Article, a farm digester system that is a component of a preexisting swine farm may be constructed or renovated if the construction or renovation of the farm digester system satisfies all of the following requirements:

(1) The construction or renovation of the farm digester system does not result in an increase in the permitted capacity of the swine farm, as measured by the annual steady state live weight capacity of the swine farm.

(2) The construction or renovation of the farm digester system does not result in requiring an increase in the total permitted capacity of the animal waste management system or systems located at the swine farm.

(3) The construction or renovation of the farm digester system shall comply with the siting requirements set out in G.S. 106-803 to the maximum extent practicable. Except as provided in subsection (c) of this section, construction or renovation of the farm digester system shall not result in any portion of the constructed or renovated farm digester system being located closer to the building, property, or well that is the object of the siting requirement than any existing component of the animal waste management system that fails to meet the siting requirements of G.S. 106-803.

(4) Renovation or construction of a farm digester system shall not be allowed in the 100-year floodplain."

SECTION 11.(h) G.S. 105-275(8) is amended by adding a new sub-subdivision to read:

"a2. Notwithstanding sub-subdivision a1. of this subdivision, sub-subdivision a. of this subdivision applies to a farm digester system as defined in G.S. 143-213(12a)."

SECTION 11.(i) This section is effective when it becomes law.

CLARIFY THE DURATION OF DRIVERS LICENSES FOR H-2A WORKERS

SECTION 12.(a) G.S. 20-7(f)(3) reads as rewritten:

"(3) Duration of license for certain other drivers. – The durations listed in subdivisions (1), (2) and (2a) of this subsection are valid unless the Division determines that a license of shorter duration should be issued when the applicant holds valid documentation issued by, or under the authority of, the United States government that demonstrates the applicant's legal presence of limited duration in the United States. In no event shall a license of limited duration expire later than the expiration of the authorization for the applicant's legal presence in the United States. A drivers license issued to an H-2A worker expires three years after the date of issuance of the H-2A worker's visa; provided, if at any time during that three-year period an H-2A worker's visa duration is not extended by United States Citizenship and Immigration Services, the license expires on the date the H-2A worker's visa expires. For purposes of this subdivision, the term "H-2A worker" means a foreign worker who holds a valid H-2A visa pursuant to the Immigration and Nationality Act (8 U.S.C. § 1101(a)(15)(H)(ii)(a)) and who is legally residing in this State."

SECTION 12.(b) This section is effective when it becomes law and applies to applications for licenses submitted on or after that date.

AG COST SHARE TECHNICAL CORRECTION

SECTION 13A. G.S. 106-850(b)(2) reads as rewritten:

"(2) The program shall ~~initially include the present 16 nutrient sensitive watershed counties and 17 additional counties.~~include the entire State."

SEVERABILITY CLAUSE AND EFFECTIVE DATE

SECTION 14.(a) If any provision of this act or the application thereof to any person or circumstances is held invalid, such invalidity shall not affect other provisions or applications of this act that can be given effect without the invalid provision or application, and, to this end, the provisions of this act are declared to be severable.

SECTION 14.(b) Except as otherwise provided, this act is effective when it becomes law.

In the General Assembly read three times and ratified this the 30th day of June, 2021.

ABSTRACT

The need for developing environmentally superior and sustainable solutions for managing the animal waste at commercial swine farms in eastern North Carolina has been recognized in recent years. Program OPEN (Odor, Pathogens, and Emissions of Nitrogen), funded by the North Carolina State University Animal and Poultry Waste Management Center (APWMC), was initiated and charged with the evaluation of potential environmentally superior technologies (ESTs) that have been developed and implemented at selected swine farms or facilities. The OPEN program has demonstrated the effectiveness of a new paradigm for policy-relevant environmental research related to North Carolina's animal waste management programs. This new paradigm is based on a commitment to improve scientific understanding associated with a wide array of environmental issues (i.e., issues related to the movement of N from animal waste into air, water, and soil media; the transmission of odor and odorants; disease-transmitting vectors; and airborne pathogens). The primary focus of this paper is on emissions of ammonia (NH_3) from some potential ESTs that were being evaluated at full-scale swine facilities. During 2-week-long periods in two different seasons (warm and cold), NH_3 fluxes from water-holding structures and NH_3 emissions from animal houses or barns were measured at six potential EST sites: (1) Barham farm—in-ground ambient temperature anaerobic digester/energy recovery/greenhouse vegetable production system; (2) BOC #93 farm—upflow biofiltration system—EKOKAN ; (3) Carrolls farm—aerobic blanket system—ISSUES-ABS; (4) Corbett #1 farm—solids separation/gasification for energy and ash recovery centralized system—BEST; (5) Corbett #2 farm—solid separation/reciprocating water technology—ReCip; and (6) Vestal farm—Recycling of Nutrient, Energy and Water System—ISSUES-RENEW. The ESTs were compared with similar measurements made at two conventional lagoon and spray technology (LST) farms (Moore farm and Stokes farm). A flow-through dynamic chamber system and two sets of open-path Fourier transform infrared (OP-FTIR) spectrometers measured NH_3 fluxes continuously from water-holding structures and emissions from housing units at the EST and conventional LST sites. A statistical-observational model for lagoon NH_3 flux was developed using a multiple linear regression analysis of 15-min averaged NH_3 flux data against the relevant environmental parameters measured at the two conventional farms during two different seasons of the year. This was used to

IMPLICATIONS

Current estimates indicate that atmospheric NH_3 emitted from North Carolina swine facilities account for approximately 46% of the state's atmospheric NH_3 emission. As part of an agreement between the state of North Carolina and two animal production agriculture companies, some potential ESTs were evaluated for NH_3 emissions. This paper describes the evaluation of six potential ESTs using the statistical-observational model developed for NH_3 emissions from the conventional LST currently in use for managing swine waste. The evaluated alternative technologies may require additional technical modifications to be qualified as unconditional ESTs relative to NH_3 emissions reductions.

compare the water-holding structures at ESTs with those from lagoons at conventional sites under similar environmental conditions. Percentage reductions in NH_3 emissions from different components of each potential EST, as well as the whole farm on which the EST was located were evaluated from the estimated emissions from water-holding structures, barns, etc., all normalized by the appropriate nitrogen excretion rate at the potential EST farm, as well as from the appropriate conventional farm. This study showed that ammonia emissions were reduced by all but one potential EST for both experimental periods. However, on the basis of our evaluation results and analysis and available information in the scientific literature, the evaluated alternative technologies may require additional technical modifications to be qualified as unconditional ESTs relative to NH_3 emissions reductions.

INTRODUCTION

The scientific attention given to atmospheric ammonia (NH_3) and its roles in both atmospheric chemistry and eutrophication of ecosystems has grown during the last decade.[1–7] It has been recognized that NH_3 is responsible for neutralizing the acids produced by the oxidation of sulfur (S) and nitrogen (N). This neutralization process results in the formation of atmospheric aerosol containing ammonium (NH_4^+), which may be of concern in increasing fine particulate matter concentration.[8–12] Swine farms are a significant source of NH_3 in eastern North Carolina. Lagoon and spray technology (LST) is the conventional and current system used in North Carolina to manage swine waste. It consists of anaerobic lagoons that store and biologically treat the swine waste (~98% liquid), and the effluent from these lagoons is periodically pumped and sprayed as a nutrient source on surrounding crop fields.[1] Many sensitive ecosystems lie within approximately 100 km of NH_3 area sources in North Carolina. Ecosystems in proximity to high NH_3 emission sources and NH_3/NH_4^+ deposition are subject to potential environmental consequences, including aquatic eutrophication and soil acidification.

The need for developing environmentally superior and sustainable solutions for the management of animal waste is vital for the future of animal farms in North Carolina, the United States, and the world. In addressing that need, the North Carolina Attorney General initiated the development, implementation, and evaluation of environmentally superior swine waste management technologies (ESTs) that would be appropriate to each category of swine farms in North Carolina. This evaluation was done through agreements between the Attorney General of North Carolina with Smithfield Foods, Inc. and Premium Standard Farm, Inc. Those agreements provided funds for research to develop and evaluate ESTs through the Animal and Poultry Waste Management Center (APWMC) at North Carolina State University, Raleigh, NC.[13] The agreements define “Environmentally Superior Technology or Technologies” as any technology, or combination of technologies that (1) is permittable by the appropriate governmental authority; (2) is determined to be technically, operationally, and economically feasible for an identified category or categories of farms (to be described in a technology determination); and (3) meets the following performance standards:

- Eliminates the discharge of animal waste to surface waters and groundwater through direct discharge, seepage, or runoff;
- Substantially eliminates atmospheric emission of NH_3;
- Substantially eliminates the emission of odor that is detectable beyond the boundaries of the parcel or tract of land on which the swine farm is located;
- Substantially eliminates the release of disease-transmitting vectors and airborne pathogens; and
- Substantially eliminates nutrient and heavy metal contamination of soil and groundwater.

Program OPEN (Odor, Pathogens, and Emissions of Nitrogen) was initiated as an integrated study of the emissions of NH_3, odor and odorants, and pathogens from potential ESTs for swine facilities. Its main purpose was to evaluate potential ESTs that have been developed and implemented under an agreement between the North Carolina Attorney General and the participating companies that own approximately 10% of the swine farms in North Carolina, using the conventional LST. Under this program, ESTs implemented at selected swine facilities were evaluated to determine if they would be able to substantially reduce atmospheric emissions of NH_3, odor, and pathogens. This study focuses on the emissions of N in the form of NH_3 from different components/processes involved in swine waste handling and treatment, including waste storage lagoons, swine houses, and spray fields at six selected EST sites. These are described below in the following format: name of the farm where the potential EST was used, type of technology, and brand name where applicable.

(1) Barham farm: in-ground ambient temperature anaerobic digester/energy recovery/greenhouse vegetable production system;
(2) BOC #93 farm: upflow biofiltration system—EKOKAN;
(3) Carrolls farm: aerobic blanket system—ISSUES-ABS;
(4) Corbett #1 farm: solids separation/gasification for energy and ash recovery centralized system—BEST;
(5) Corbett #2 farm: solid separation/reciprocating water technology—ReCip;
(6) Vestal farm: Recycling of Nutrient, Energy and Water System—ISSUES-RENEW.

These potential ESTs were evaluated during two seasons (cool and warm), and the results are compared and contrasted with data from two conventional LST swine farms (Moore farm and Stokes farm), which have been described in the companion paper.[1] The evaluation of two other potential ESTs, qualified as unconditional ESTs relative to NH_3 emissions reductions, are described in another paper.[14]

NH_3 fluxes from water-holding structures and other area sources and NH_3 emissions from animal houses at all of the ESTs and conventional farms were measured by a dynamic flow-through chamber system and open-path Fourier transform infrared (OP-FTIR) spectroscopy.

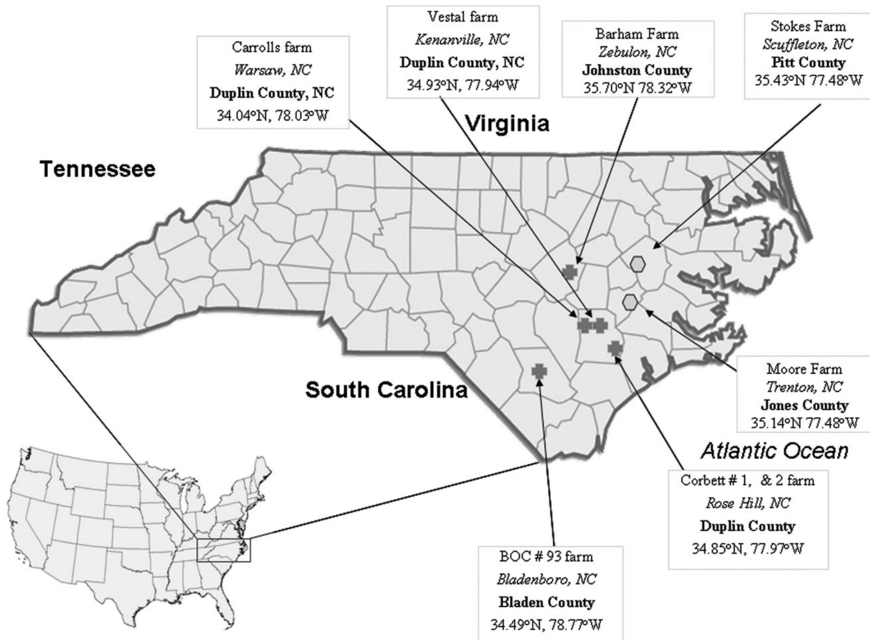

Figure 1. Map of North Carolina indicating the location of the ESTs and LSTs.

Recent studies, using a mass balance approach to estimate NH_3 emission rates, found that swine houses represent a more significant source than previously hypothesized.[15] On the basis of a review of published data, the loss of NH_3 from swine houses was estimated to be around 15% of total N excreted.[16] Griffing et al.[17] used the mass balance method to estimate that approximately 80% of NH_3 loss was due to volatilization from liquid waste storage systems. In this study also, the mass balance approach was used to estimate NH_3-N emissions from different components of the EST and LST farms, as well as N excretion rates, on the basis of swine population and feed data. Normalizing emissions by N excretion rate, percentage reductions in NH_3-N emissions are determined for water-holding structures, barns, and the whole farm for each EST facility from their estimated values for the appropriate LST farm.[1]

EXPERIMENTAL SETUPS AT EST SITES

Sampling Sites and Periods

NH_3 flux measurements were conducted during two different seasons (warm and cool) at eight swine farms (two conventional sites and six EST sites) in eastern North Carolina (for location see Figure 1). Two conventional sites (Stokes farm and Moore farm, i.e., LSTs) are also referred to as "baseline" sites for comparison with EST sites. The six EST sites were Barham, BOC #93, Carrolls, Corbett #1, Corbett #2, and Vestal farms, respectively. Aneja et al.[1] have given a detailed description of the two baseline farms with LST, as well as instrumentation and sampling techniques and scheme, therefore this information will not be repeated.

OP-FTIR measurements were conducted to measure the NH_3 flux from the ventilation systems at the swine houses. Of the swine houses measured, there were two different types of ventilation systems, namely, mechanical or tunnel ventilation and natural ventilation. At the Barham, BOC #93, and Carrolls farms, mechanical ventilation was used. At the Corbett #1 and #2 farms and the Vestal farm, the swine houses had natural ventilation. The methodologies for the measurement of NH_3-N emissions from the swine barns are described in Aneja et al.[1]

A brief description of each of the potential ESTs that have been evaluated is provided here. Williams,[18] and Williams,[19] contain more detailed information including site plans, design schematics, and projected operational characteristics.

Barham Farm. Barham Farm (35.70 °N, 78.32 °W, 130 m mean sea level [MSL]) is located near Zebulon, NC, in Johnston county. Field campaigns were conducted during April 1–12, 2002 and November 11–22, 2002, at this farm site. However, during the first measurement period in April we were notified that the EST was not fully functioning as designed, because the biofilters were not operational during that time. A schematic layout of the EST at Barham farm including the various sampling locations is given in Figure 2. This potential EST has an in-ground ambient digester comprised of a covered anaerobic waste lagoon. The primary lagoon was covered by an impermeable layer of 40-mm thick high-density polypropylene that prevented gaseous methane and other gases and odor from escaping into the atmosphere during the digestion process. Methane gas that is produced during the digestive process was extracted and burned into a biogas generator to produce electricity. Heat from the generator was captured and used to produce hot water that was used by the farm in its production activities. Effluent from the digester (covered lagoon) flowed into a storage pond with a surface area of 4459 m^2. This storage pond was formerly part of the primary anaerobic lagoon before the digester was built. A portion of this effluent was further treated via biofilters, the purpose of which was to convert NH_4^+ to nitrate in the effluent. This nitrified effluent was then used to flush out the swine production facilities, and the

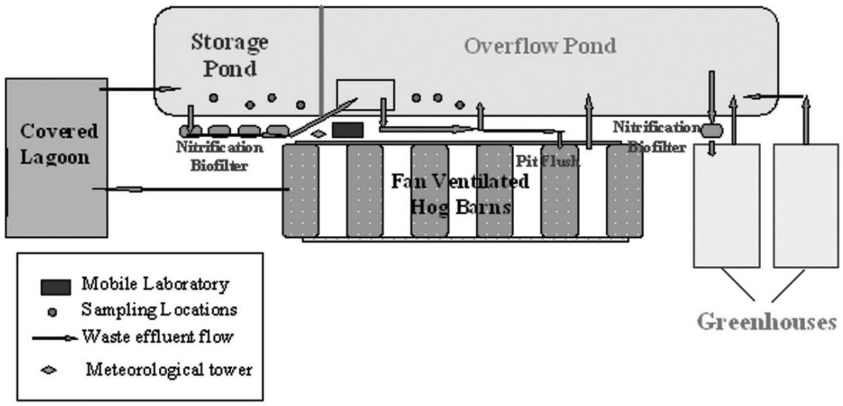

Figure 2. A schematic layout of the EST at Barham farm.

excess effluent was channeled into the larger overflow pond with a surface area of 19,398 m^2. A heavy polymer baffle separated the overflow and storage ponds. The overflow pond was used to store rainwater and overspills from the storage pond. Water from the overflow pond was also pumped into a nitrification biofiltration system where the nutrients in the treated effluent were used to fertilize vegetables grown in greenhouses adjacent to the swine production facility.

In this study NH_3 flux measurements were made from the surfaces of the storage pond, the overflow pond, and from the covered anaerobic primary lagoon. Average NH_3 concentrations were measured using the OP-FTIR spectroscopy system across the forced ventilation fan openings, as well as along the sides of swine houses (barns) to estimate barn emissions during the experimental periods.

BOC #93 Farm. BOC #93 farm (34.49 °N, 78.77 °W) is located near Bladenboro, NC, in Bladen county. NH_3 measurements were conducted on March 31, April 11, 2003, and June 16–27, 2003. A schematic layout of the EST at BOC #93 farm including the various sampling points is given in Figure 3.

The EKOKAN waste treatment system consisted of solids/liquid separation and biofiltration of the liquid with upflow aerated biological filters. Five finishing barns were connected to the waste treatment system, and the barn pits were emptied automatically in sequence. Wastewater from the barn pits was released to a solids separation unit. Coarse solids were separated from the wastewater using a screen separator (TR separator). After the solids/liquid separation process, the liquid was pumped to a 40,000-gal equalization tank. Liquid flowed from the equalization tank by gravity and passed through first- and second-stage aerated biofilters connected in series (two sets). Wastewater flowed upward through the biofilters, and air was supplied at the bottom of each biofilter with blowers. The biofilter tanks were covered, and air and any excess foam from the aerated treatment were routed through polyvinyl chloride pipes to exit points over an anaerobic lagoon. The biofilters were backwashed periodically to remove excess biosolids. Treated effluent from the biofilters flowed by gravity to a storage basin, with a portion of the treated effluent being recycled to the solids separation basin, from which it was pumped to the equalization tank, which had a surface area of 28.3 m^2. Water was pumped from the storage basin to the barns to refill the pits. At this site, the anaerobic lagoon that received manure from 10 barns was partitioned using plastic curtains into three sections, with one section much larger than the other two. The larger section received manure from five barns not connected to the EKOKAN treatment system. One of the smaller sections received any overflow from the solids separation basin, the separated solids, and

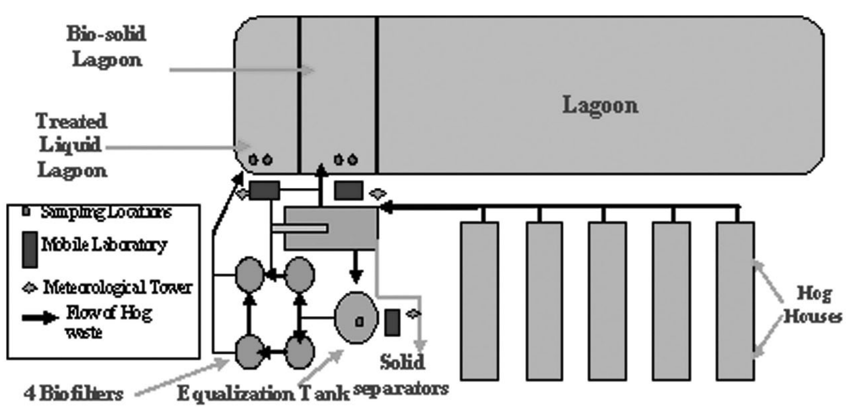

Figure 3. A schematic layout of the potential EST at BOC #93 farm.

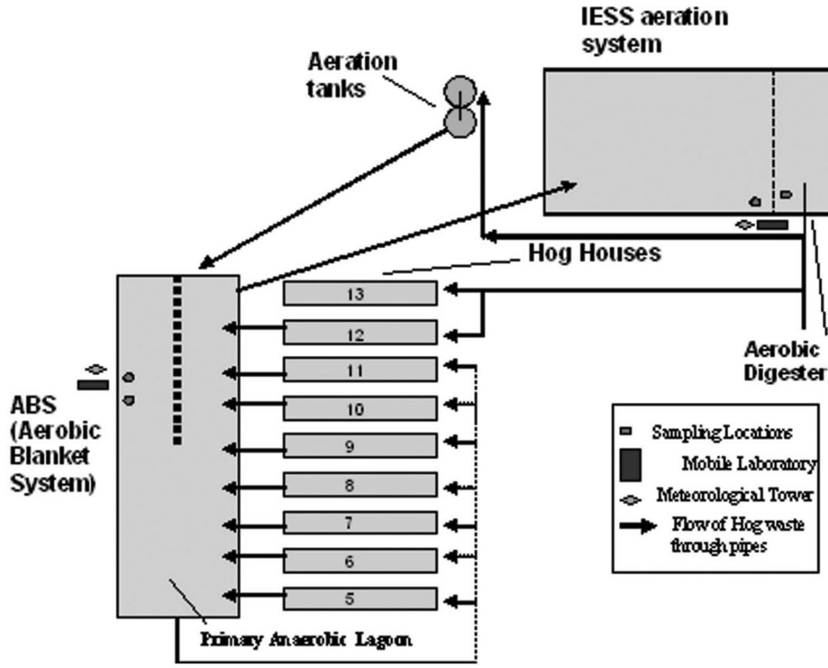

Figure 4. A schematic layout of the potential EST at Carrolls farm.

the backwashed biosolids that were removed from the biofilters. This was known as the biosolids lagoon and had a surface area of 3229.2 m^2. The other small section received the treated effluent from the biofilters. This was known as the treated effluent lagoon and had a surface area of 1614.6 m^2. NH_3 fluxes were measured from the treated effluent storage, the biosolids storage lagoon, and the equalization tank during the experimental periods.

Carrolls Farm. Carrolls (34.04 °N, 78.03 °W) is located near Warsaw, NC, in Duplin county. NH_3 flux measurements were conducted on this farm from March 29 to April 2, 2004 and from June 28 to July 2, 2004, respectively. A schematic layout of the EST at Carrolls farm including the various sampling points is given in Figure 4.

The waste stream in the proposed EST flows from the houses to a primary anaerobic lagoon equipped with the ABS. This is known as the ABS lagoon and has a surface area of 3304.8 m^2.

The ABS consists of a fine mist of treated swine waste that is applied every 15 min to the surface of the anaerobic lagoon. During both evaluation periods, only half of the anaerobic lagoon was being treated by the ABS. The treated swine waste arises from an aeration treatment that takes place in an adjoining water-holding structure (aerobic digester). Waste from the anaerobic lagoon flows into an aerobic digester (IESS aeration system). This is referred to as the west side of the aerated lagoon and has a surface area of 5068.8 m^2. This portion of the basin is sectioned off with a plastic barrier. The aerated waste eventually flows into the sectioned-off portion of the aeration treatment basin. This is known as the east side of the aerated lagoon, and has a surface area of 6010.2 m^2. The waste is then used to flush the animal houses and supplies the treated water for the ABS. During the first evaluation period, the IESS aeration system was not functioning and treated waste for the ABS was derived by using two aeration treatment tanks. For the second evaluation, the aeration treatment basin was operating as designed. Only waste from finishing houses 5–13 flowed into the ABS-equipped anaerobic lagoon. Waste from the remaining farrow and weaning houses flowed into a separate lagoon. These houses and their accompanying lagoon were not included in the evaluation of the EST.

Corbett #1 Farm. Corbett #1 farm (34.85 °N, 77.97 °W) is located near Rose Hill, NC, in Duplin county. NH_3 flux measurements were conducted during October 1–8, 2003, and December 4–7, 2003, respectively. A schematic layout of the EST at Corbett #1 farm including the various sampling points is given in Figure 5.

Manure flushed from the barns flows first to a collection pit, then to an aboveground feed tank, and then to a screw-press separator on a raised platform. The separator has a screen with 0.25-mm openings. The liquid that flows through the screw-press separator screen flows to a second feed tank, which has a surface area of 27.1 m^2, and then to two tangential-flow gravity settling tanks sited parallel to each other. Each tangential-flow settling system consists of a 2.2-m diameter tank with a cone bottom followed by a 1.2-m diameter sludge thickening tank, also with a cone bottom. Tangential flow in the first tank causes solids to concentrate in the center of the tank and settle down to the bottom. This settled slurry is then pumped to the second tank for sludge thickening. For approximately 10 min every hour the settled slurry from the second tangential-flow settling tank is pumped back to the tank that feeds the screw-press separator, where the settled slurry is combined with the flushed manure that is being pumped to the screw-press separator. The treated

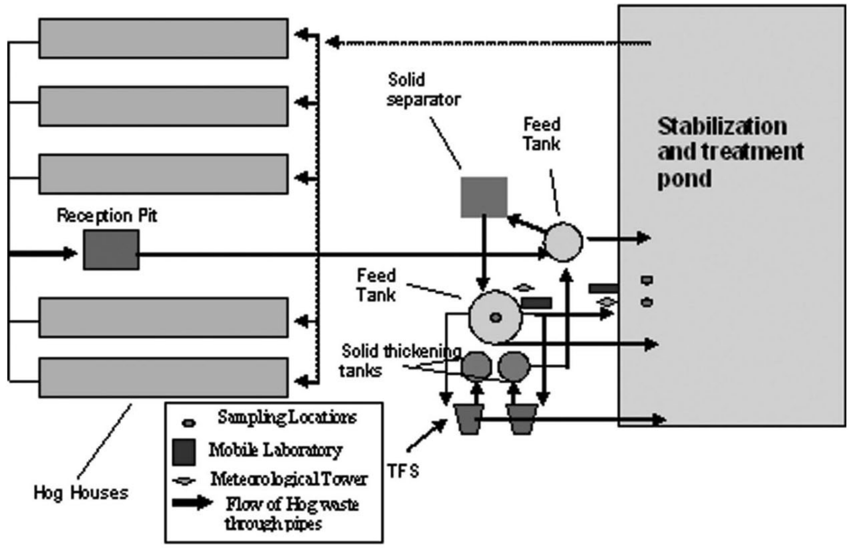

Figure 5. A schematic layout of the potential EST at Corbett #1 farm.

waste and any overflow go to a stabilization and treatment pond, which has an area of 8291.9 m^2.

Corbett #2 Farm. Corbett #2 farm (34.84 °N, 77.96 °W) is located near Rose Hill, NC, in Duplin county. Measurement campaigns were conducted during March 10–21 and June 2–13, 2003 at this farm site. A schematic layout of this potential EST including locations of flux measurements is given in Figure 6.

The ReCip encompasses two cells, or treatment basins, filled with media (proprietary technology), that would alternately drain and fill on a cyclic basis. The draining and filling cycles created aerobic, anaerobic, and anoxic conditions within the cells, providing both biotic and abiotic treatment processes to promote nitrification and denitrification. The treatment process was preceded by a solids separation step. The solid waste and the treated liquid waste went into individual lagoons, which had surface areas of 2601 m^2 and 2717 m^2, respectively. The ReCip project at the evaluation time was designed to treat only the liquid portion of the swine waste.

Vestal Farm. Vestal farm (34.93 °N, 77.94 °W) is located near Kenansville, NC, in Duplin county. NH_3 flux measurements were conducted during March 16–18, 2004, and August 4–12, 2004, respectively. A schematic layout of the EST at the Vestal Farm including the various sampling points is given in Figure 7.

The RENEW system uses a mesophilic digester as well as aeration and wastewater filtering and disinfection systems. This project also incorporated a microturbine generator. For this system, the waste first flows from the pig

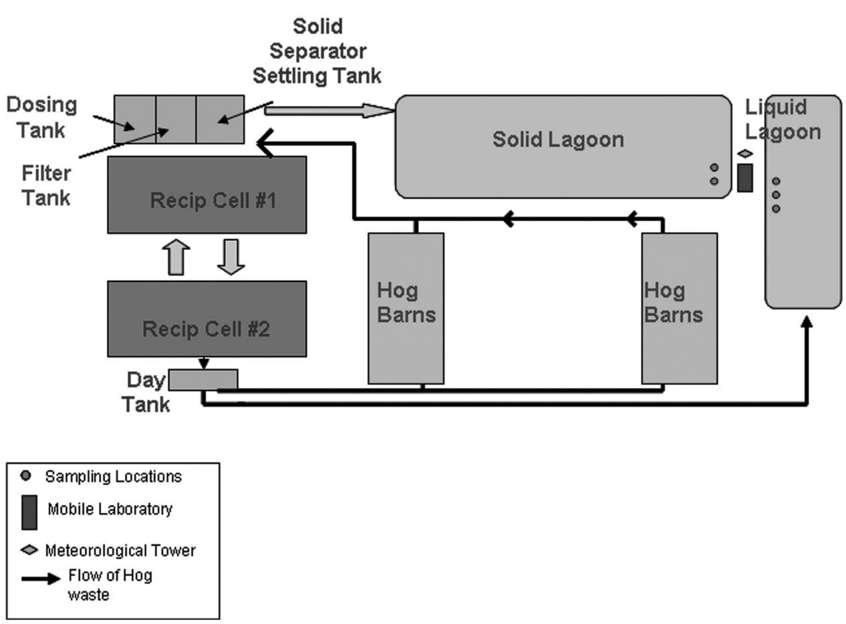

Figure 6. A schematic layout of the EST at Corbett #2 farm.

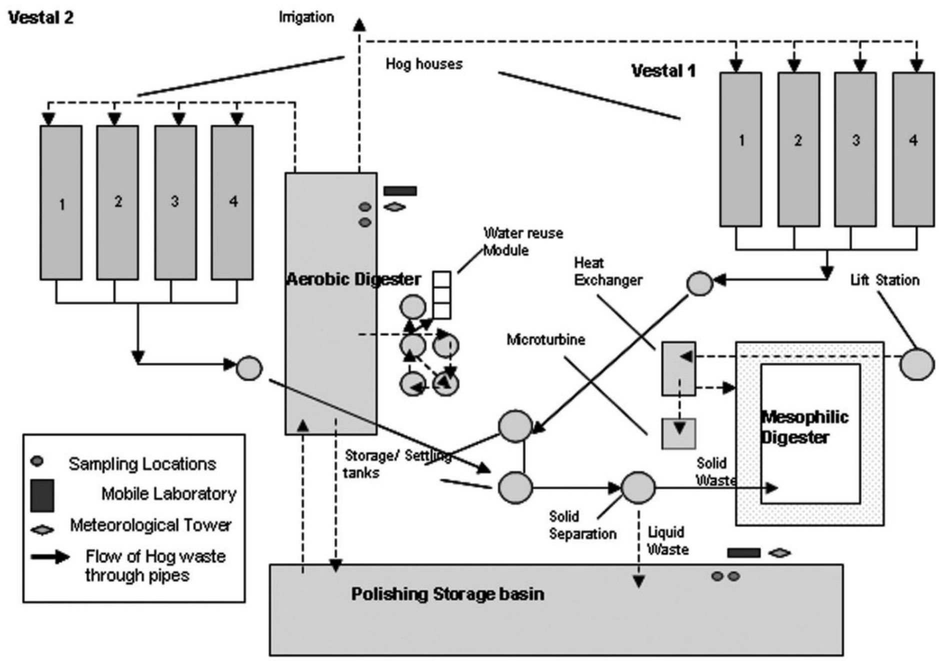

Figure 7. A schematic layout of the potential EST at Vestal farm.

barns to equalization and concentrator tanks, which serve to produce a thickened liquid. This liquid then flows to a mesophilic digester. The digester, which operates at a temperature of 95 °F, produces biogas, which is used to fuel the microturbine generator. The generator produces electricity, which is sold and used on the electric power grid. The waste stream then flows to a polishing storage basin, which has a surface area of 22,636 m^2, and then to an aerobic digester, also called a nitrification pond, which has a surface area of 1880.6 m^2. A portion of the waste stream then flows back to the polishing storage basin where it is used to flush the pig barns and is sprayed on cropland if necessary. The remaining portion of the waste stream flows through a filtration system. The filtration system consists of sand carbon filters and reverse osmosis. The water is then disinfected using ozonation and ultraviolet light. Filtered and disinfected water is then returned to the pig barns where it is used as drinking water for the pigs.

Approach to Evaluate NH_3 Emissions Reduction at EST Farms

At each EST and conventional site, the monitoring of NH_3 emissions were limited to about two 2-week periods, representing both a warm and a cool season. It was suggested that the estimated emissions from an EST for each measurement period be compared with the estimated emissions from conventional sites. However, because measurements at different sites were made at different times of the year, environmental conditions are likely to be different at different sites, even during a representative warm or cool season. Thus, there is a need for accounting for these differences in our relative comparisons of the various alternative and conventional technologies.

A rational basis for this adjustment for somewhat different environmental conditions is the development of a statistical-observational model based on multiple regression. This is developed between NH_3 emissions and measured environmental parameters at the two conventional sites.[1] Such a comparison does not require highly uncertain extrapolations of emissions at EST sites beyond the two measurement periods. It also provides a sound basis for ranking the various ESTs on the basis of their comparisons with conventional sites for each of the warm and cold seasons.

Relationships between NH_3 flux and lagoon temperature, pH, and TKN, as well as certain environmental parameters were examined in the accompanying paper, Aneja et al.[1] over a relatively wide range of lagoon temperatures (~2–35 °C) and lagoon air temperature differences that were observed during the fall and winter field campaigns at both conventional farms.

The multiple regression equation based on flux measurement data from two conventional farms is given by Aneja et al.[1]

$$\mathrm{Log}_{10}\mathrm{F} = 3.8655 + 0.04491(\mathrm{T}_1) - 0.05946(D). \quad (1)$$

Here, F denotes the average NH_3-N emission from the conventional lagoon in $\mu g \cdot min^{-1}$/1000 kg-lw (lw = live weight), where T_l is the lagoon temperature in °C, and D is a hot-air variable that is equal to zero if lagoon is warmer than air, but is equal to $\Delta T = T_a - T_l$ when $T_a > T_l$ and T_a is air temperature in °C at 10-m height. This statistical-observational model was used to estimate the projected NH_3-N flux from lagoons at the LST baseline farms to compare with the measured NH_3-N flux from water-holding structures at an EST site, for the average values of T_l and D observed at the latter.

Aneja et al.[1] describes the development of the statistical-observational model in more detail.

Table 1. The summary of animal mass, feed consumed, N content, and N excretion at EST farms.

Farm Information	Number of Pigs	Average Pig Mass (kg/pig)	Total Pig Mass (kg)	Feed Consumed (kg/pig/week)	N Content (%)	*E* (kg-N/week/1000 kg-lw)
Barham						
April 2002	4,000	238.1	952,560	12.84	2.25[a]/3.09[b]	1.65
November 2002	4,000	238.1	952,560	15.92	2.38[a]/3.43[b]	1.77
BOC #93

August 2004	10,248	44.7	458,086	11.02	3.17	5.47

Notes: All farms are finishing operations except Barham farm, which is a farrow-to-wean operation with a mixture of sows and mature pigs. [a]N content of the feed in gestation houses; [b]N content of the feed in farrowing houses.

Estimated NH_3 emission from animal houses at a potential EST were compared with the estimated NH_3 emissions from similar houses at a conventional farm (either Moore farm—tunnel ventilated, or Stokes farm—naturally ventilated), depending on the type of the house ventilation used at the EST farm, for the same season.

Both EST emissions and conventional NH_3 emissions were normalized by the N excretion rate (E) for the farm, and are called %E. On the basis of the N mass balance equation with the given animal feed information (Table 1), E in units of kg-N week^{-1} (1000 kg-lw)$^{-1}$ was determined using the following equation:

$$E = \frac{F_c \times N_f \times (1 - e_r)}{\bar{w}} \times 1000, \qquad (2)$$

where F_c is the feed consumed (kg pig^{-1} · week^{-1}), N_f is the fraction of N content in feed, e_r is the feed efficiency rate (ratio of average gain of N to N intake),[20] and $\bar{w}$ is the average live animal mass (kg/pig). The N excretion data are presented in Table 1. N excretion and NH_3-N emissions at each farm was calculated in the same units (kg-N · week^{-1} (1000 kg-lw)$^{-1}$) , thus, %E represents the loss rate of NH_3 from a source as a percentage of N-excretion rate. A potential EST was evaluated by comparison of %E value from the EST (%E_{EST}) farm to %E value from a baseline conventional farm (%E_{CONV}), and percent reduction of NH_3-N can be estimated as

$$\%\ reduction = \frac{(\%E_{CONV} - \%E_{EST})}{\%E_{CONV}} \times 100 \qquad (3)$$

Such percentage reductions can be estimated, separately for water-holding structures, animal houses/barns, etc., as well as for the whole EST farm. An algorithmic flow diagram for the evaluation of NH_3 emissions from water-holding structures at the EST farms is shown in Figure 8.

RESULTS AND DISCUSSION

Temporal Variations of Lagoon NH_3 Fluxes
