Average NH_3 fluxes from water-holding structures at EST farms during the measurement periods are summarized in Table 2. The NH_3 flux results from all water-holding structures showed strong seasonal variation with significantly higher flux during the warm season than during the cold season at the EST farms. Seasonal differences in water-holding structure NH_3 fluxes are revealed from the composite hourly average fluxes measured at all of the EST farms, in which higher NH_3 fluxes with more clear diurnal variations were found during the warm season. Typical diurnal trends for the water-holding structure NH_3 fluxes showed low fluxes during the morning hours that increased with time during the early part of the day as the air and lagoon temperatures increased after sun rise, attaining maximum values around 3:00 p.m. and then decreasing during the evening hours. This trend was found to follow approximately the diurnal trends of air and lagoon temperatures at the experimental farms. An example of these patterns is shown in the composite hourly averaged NH_3 fluxes from the storage lagoons at Barham and Corbett #2 farms (Figure 9, a and b).

NH_3 Emissions from Water-Holding Structures

Average fluxes and total estimated emissions from water-holding structures are presented in Table 2. Flux measurements of NH_3 at the Barham farm were conducted from storage and overflow lagoons at the farm. For the April 2002 measurement campaign, the EST at the farm was not fully functioning and did not achieve steady state. The fluxes from the water-holding structures were found to be

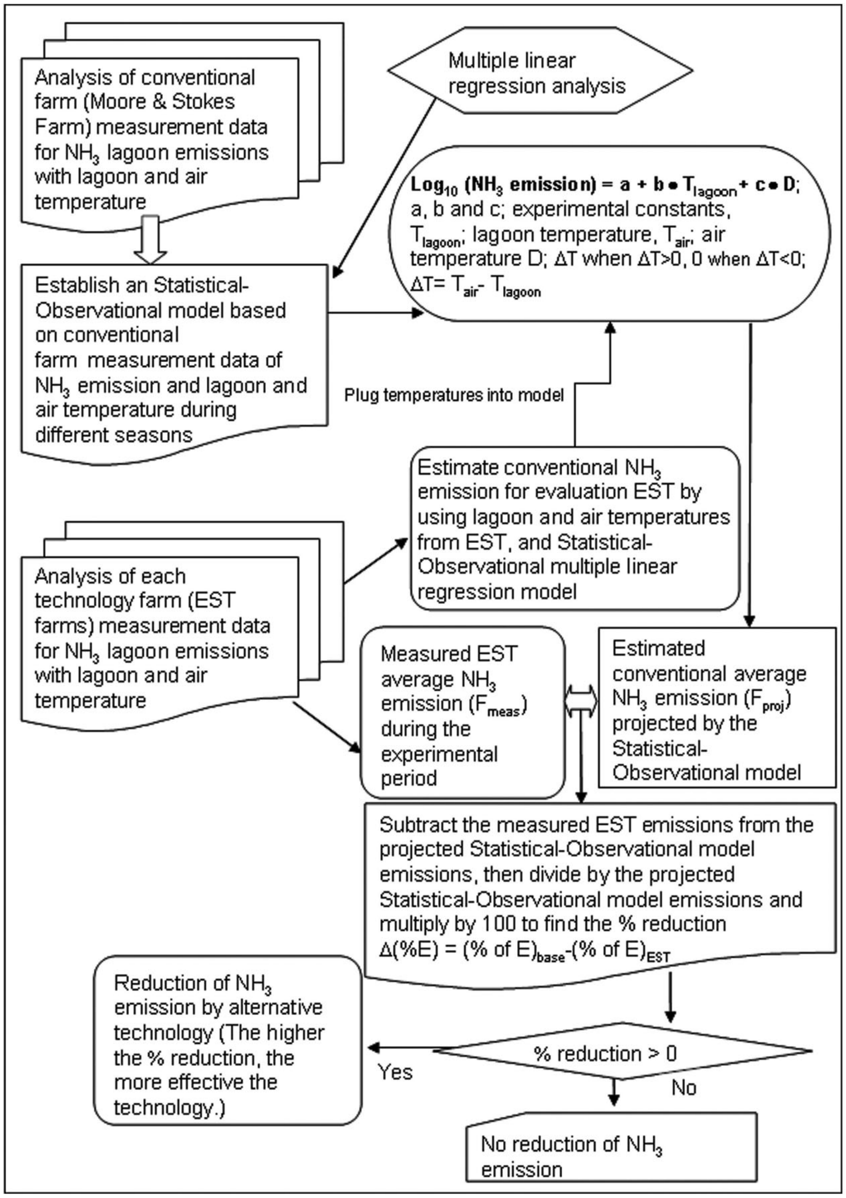

Figure 8. Algorithm flow chart for evaluation of EST NH_3 emissions from water-holding structures.

higher in the warm season than in the cold season. In the warm season, the overflow lagoon had a slightly higher flux, whereas in the cool season the storage lagoon had a higher flux. Overall, the weekly emissions were three to five times higher in the overflow lagoon than in the storage lagoon. This is a result of the overflow lagoon's area being approximately five times larger.

At BOC #93 farm, fluxes were measured from three water-holding structures: (1) the treated effluent lagoon, (2) the biosolids lagoon, and (3) and the equalization tank. In the warm season, the fluxes were higher for both the treated effluent lagoon and the biosolids lagoon than in the cool season, but the flux was lower in the warm season for the equalization tank. This is because the tank has a controlled temperature. For the cool season evaluation, the average fluxes from the three water-holding structures are very similar, with the treated effluent lagoon having the highest flux. Overall the emissions were highest from the biosolids lagoon, which had the largest surface area. The equalization tank had the smallest (negligible) emissions of the water-holding structures because of its small surface area.

At Carrolls farm, NH_3 fluxes were measured from the ABS lagoon, and from the east and west sides of the aeration lagoon. For both the warm season and the cool season, the ABS lagoon had the highest flux. Flux was higher in the warm season than the cool season for the ABS lagoon. A different pattern was observed for the aeration lagoon, where the fluxes were unusually higher in the cool season. Emissions followed the same pattern as fluxes, with the ABS having significantly larger emissions than the aeration lagoon.

Corbett #1 contained two water-holding structures: a stabilization lagoon and a feed tank. For the warm season evaluation, the flux was four times higher in the feed tank than in the stabilization lagoon; however, emissions were

Vestal August 2004	Aerobic digester	840.6 ± 284.8	1880.6	15.9	490.7	0.048	1.07
	polishing storage basin	2080.7 ± 340.8	22,636.0	474.8			

two orders of magnitude higher from the stabilization lagoon. This is likely due to the stabilization lagoon having a significantly larger surface area. For the December measurement period, measurements were only made at the stabilization lagoon. This was because of the malfunction of the dynamic flow-through chamber used for the feed tanks. This is not thought to be a problem because of the relatively small emissions observed in the October evaluation period. For the stabilization lagoon, the flux was lower in the cool season than in the warm season.

NH_3 fluxes at Corbett #2 farm were measured from the solid storage and the liquid storage lagoons. Emissions for both of these water-holding structures were lower in the cool season than the warm season. In the cool season, the liquid storage lagoon had the higher flux. Conversely, in the warm season, the solid storage lagoon had the higher flux. Both water-holding structures have similar surface areas, and therefore the same pattern was repeated for the emissions.

Vestal farm contained two water-holding structures, an aerobic digester, and a polishing storage basin. For the polishing storage basin, the flux was higher in the warm season than the cool season. This pattern was not observed for the aerobic digester, where the emissions in the digester were slightly lower in the warm season than in the cool season. The larger area of the polishing storage basin resulted in much higher emissions for both the cool and warm periods.

Total emissions (kg-N/1000 kg-lw/week), normalized by live animal mass at the farm, were calculated for each experimental period for each EST farm (see Table 2). The emissions for the cool season for all EST farms ranged from 0.07 to 0.39 kg-N/1000 kg-lw/week, with a mean value of 0.23 kg-N/1000 kg-lw/week. The emissions for

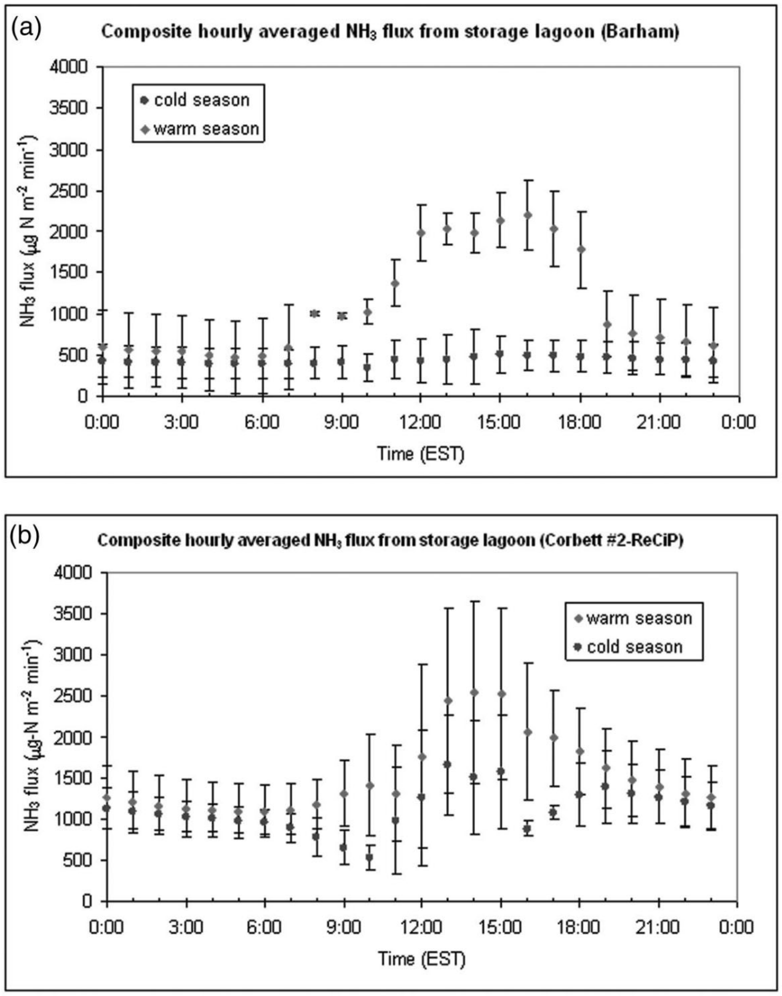

Figure 9. (a) Composite hourly averaged NH_3 flux from storage lagoon during April (warm season) and November (cold season), 2002 measurement periods at Barham farm. Error bar indicates ±1 standard deviation. (b) Composite hourly averaged NH_3 flux from storage lagoon during March (cold season) 2002 and June (warm season) 2003 measurement periods at Corbett #2 farm. Error bar indicates ±1 standard deviation.

the warm season for all EST farms ranged from 0.31 to 1.07 kg-N/1000 kg-lw/week, with an average value of 0.56 kg-N/1000 kg-lw/week. For all six EST farms, the total emissions were much higher in the warm season than the cold season, with the exception of the Carrolls farm where the seasonal difference was small.

NH_3 Emissions from Housing Units (Barns)

Table 3 shows the overall averages for the NH_3 emissions estimated by OP-FTIR measurements made during the sampling periods from the swine barns at the six EST farms. Emissions for the cool season for all of the EST farms ranged from 0.008 to 0.98 kg-N/1000 kg-lw/week, with an average value of 0.37 kg-N/1000 kg-lw/week. For the warm season, emissions ranged from 0.16 to 1.29 kg-N/1000 kg-lw/week, with a mean value of 0.70 kg-N/1000 kg-lw/week. Higher emissions from the barns were experienced during the warm period at five of six EST farms; the exception was the Barham farm. Emissions from naturally ventilated barns were noticeably lower on days when the curtains were closed to block the wind and maintain heat in the barn.

Evaluation of Total NH_3 Emissions from EST Farms

To calculate the total percent reduction, the sum of projected emissions and measured emissions were taken for

Notes: [a]NH_3 emission measured from barns at tunnel (fan) ventilated conventional farm (Moore farm) during October 2002; [b]NH_3 emission measured from barns at tunnel (fan) ventilated conventional farm (Moore farm) during February 2003; [c]NH_3 emission measured from barns at naturally ventilated conventional farm (Stokes farm) during January 2003. WHS = water-holding structures.

the water-holding structures and barns. These numbers were then used to calculate total percent reduction using the same process that was applied individually for water-holding structures and barns.

Table 4 shows the summary of the total NH_3 emissions measured from all six EST farms, along with the projected emissions from the LST farms and the percent reduction values for their evaluation of potential N reduction.

Out of six EST farms, five show percent reduction in NH_3 emissions for both experimental periods. The BEST technology used at Corbett #1 was the most successful, with a reduction of 71.8% in the warm season, and 66% in the cool season. The next largest percent reduction was the ISSUES-RENEW system used at Vestal farm, with percent reductions of 54 and 31.1% for cool and warm seasons, respectively. The next most effective was the EKO-KAN technology at BOC #93 farm, which had percent reductions of 23.5 and 43.3% for the cool and warm seasons, respectively. A further technology with reduction in both seasons was the ISSUES-PBS, which was located at Carrolls farm. There was a small reduction of 8.7% in the cool season, and a larger reduction of 49.5% in the warm season. The ReCip technology was only slightly effective, with small reductions in both seasons of 20.9 and 9.7%, respectively.

The technology at Barham farm was less effective with mixed results, reducing emissions slightly in one experimental period, but enhancing in the other. This could be the result of the EST at Barham farm not being fully functional. The technology did not achieve steady state until the April 2002 sampling period. However, this does not explain the insignificant percent reduction during the November 2002 experimental period.

CONCLUSIONS

A rational and functional approach to study NH_3 emissions at commercial-scale animal production agricultural farms was developed.

Six potential ESTs were evaluated to determine if they would substantially reduce atmospheric emissions of NH_3 at swine facilities from their estimated or projected emissions in comparison to what had been observed on two conventional LST swine farms during two different (warm and cold) experimental periods. Five of six farms showed varying amounts of percent reductions in NH_3 emissions for both experimental periods.

One of the five ESTs showed an appreciable percent reduction in NH_3 emissions for both periods. The technology used at Corbett #1 had the highest percent reductions of 71.8 and 66% for the warm and cool seasons, respectively.

However, on the basis of our evaluation results, analysis, and available information in the scientific literature, the evaluated alternative technologies may require additional technical modifications to be qualified as unconditional ESTs relative to NH_3 emissions reductions.

This study did not address the potential reductions in odor and pathogens by the potential ESTs. Other scientists in the OPEN project evaluated those environmental factors.

September 3, 2021

There is abundant scientific evidence that swine concentrated animal feeding operations (CAFOs) operated in North Carolina have adverse impacts on the environment. One of these well-documented impacts are emissions of ammonia (NH_3) from hog waste lagoons, spraying and fields where the waste is land-applied. The ammonia emitted by these sources also deposits on the ecosystem, including surface waters where it can cause increased oxygen demand and eutrophication and can impact aquatic ecosystems and harm fish and other aquatic organisms. Airborne ammonia also deposits on land, where it can overload soil with nitrogen and increase nitrate leaching into groundwater, and make well water unsafe to drink. There is a concern that swine-waste biogas production could exacerbate these problems by emitting more reactive nitrogen, including ammonia, into the atmosphere. This report considers this risk and concludes that storing digestate in open lagoons and land-applying it to field may increase ammonia emissions from hog CAFOs and contribute to further degradation of local air and water quality.

I. Nitrogen cycle in North Carolina hog animal waste management systems

In North Carolina, Concentrated Animal Feeding Operations (CAFOs) are used extensively for meat production. Though the term Concentrated Animal Feeding Operation bears a technical definition under the Clean Water Act, here it is used to refer generally to a production model that raises large numbers of animals in confinement where they are fed and watered until they are slaughtered. Unlike traditional models of livestock husbandry, animals raised in CAFOs do not roam to forage and the feed is produced off-site. The CAFO model of production is used to produce beef, dairy, hogs, poultry, milk, and eggs. The majority of CAFOs in North Carolina produce are either broiler chickens or hogs.

North Carolina witnessed intense growth in its hog industry during the 1990s (Aneja et al., 2000). Due to the large number of animals raised in a concentrated location, CAFOs produce large volumes of waste (US EPA, 2004). In traditional animal production models, animal waste is deposited throughout the environment as the livestock forage. However, in the CAFO model of production, the waste accumulates within the barn. The most common system for disposing of this massive amount of waste is known as the lagoon and sprayfield system. In general, the floor of the swine barns is made of concrete with slats, allowing the urine and feces excreted by the hogs to fall into an underground storage pit below the barn. Depending on the design of the CAFO, the waste either remains in the pit for months before it is scraped out or is flushed out with lagoon water periodically. In North Carolina, there has been a significant shift towards flush systems that remove the waste from barns more frequently. At least three of the four hog operations at issue in this case use the flushing method of removing hog urine and feces from below the barn.[1]

In the conventional lagoon and sprayfield system, once waste is removed from the storage pit, it is transferred into an open-air retention pond or "lagoon" that stores millions of gallons of animal waste. This waste contains bacteria, nutrients such as phosphorus and nitrogen, and heavy metals including arsenic, cadmium, copper and zinc. The pH of waste in the lagoon is manipulated to favor bacteria that anaerobically digest the waste. The liquid waste rises to the top, and nutrient and elemental rich sludge forms at the bottom. The sludge is periodically removed and applied to land. The liquid waste is frequently applied as fertilizer to growing fields, known as spray-fields, via high-pressure sprayers. The waste may also be applied through other methods such as drag-hose application of waste to the surface of the land. Strategies such as injection, which incorporate the waste into the soil and help limit emissions, have not been widely adopted in North Carolina. The spray-fields grow crops such as hay and Bermuda grass in order to absorb the nutrients contained in the waste. In North Carolina, over 2,200 swine operations are permitted to use this kind of animal waste management system. Hog production in North Carolina is overwhelmingly centered in the Eastern Coastal Plain, particularly in Robeson, Columbus, Bladen, Sampson, Pender, Duplin, Onslow, Wayne, Lenoir, Greene, and Pitt counties.

One of the main drawbacks of managing waste in this manner is the effect on air and water quality. CAFOs are significant contributors to air pollution, which often disproportionately impacts low-income and minority communities (Wing et al., 2000). Hog barns, lagoons, land application (i.e. spraying) of animal waste, and land biogenic emissions all emit large quantities of ammonia and other pollutants into the atmosphere (Aneja et al. 2001, 2008, 2009).

Ammonia (NH3), a form of reactive nitrogen, is the most abundant gas-phase alkaline species in the atmosphere. Ammonia emissions from animal agriculture result from the degradation of urea by the ubiquitous enzyme urease, which results in ammonium (NH4+) formation Urea is mainly excreted in the animal urine and once it is hydrolyzed it is much more prone to ammonia emissions than organic nitrogen excreted in the feces.

Ammonia emitted by hog operations is transported and dispersed by wind and is deposited on surface waters or land through dry deposition or wet deposition (Figure 1) (Aneja et al., 2001). Multiple studies have modelled the dispersion patterns of ammonia from CAFOs in Eastern North Carolina (Walker et al., 2000; Costanza et al., 2008; Bajwa et al., 2008). These studies have established that ammonia produced by hog CAFOs deposits a significant amount of nitrogen into the Cape Fear River Basin.

When ammonia directly or indirectly deposits into surface waters it can cause algal blooms and eutrophication (Costanza et al., 2008; Aneja et al., 2001). These conditions in turn cause hypoxia—low oxygen levels—in rivers and streams that alters aquatic ecosystems and harms fish and other species (Costanza et al., 2008).

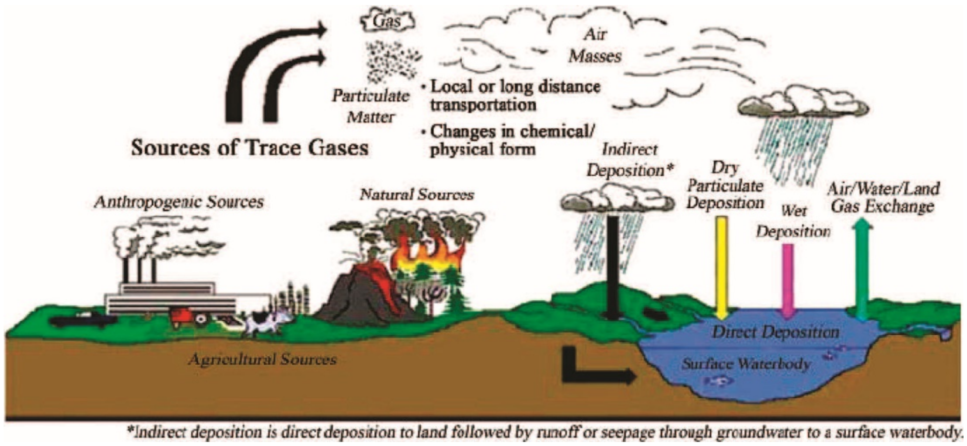

Fig. 1. Atmospheric emissions, transport, transformation and deposition of trace gases. (Aneja et al., 2001)

NH3 can neutralize sulfuric acid and nitric acid in the atmosphere to form fine particulate matter with an aerodynamic diameter <2.5 µm (PM2.5), which is closely linked to health and climatic effects. PM2.5 can penetrate deep into people's lungs and bloodstream and affect respiratory and cardiovascular health. PM2.5 exposure has been linked to a variety of health problems including heart attacks, irregular heartbeat, aggravated asthma, decreased lung function, premature death in people with heart or lung disease, and increased respiratory symptoms such as irritation of the airways, coughing, and difficulty breathing (EPA 2021). PM2.5 also has significant environmental effects, including formation of haze. PM2.5 can be carried over long distances by wind and settle on land or surface waters. When the PM2.5 containing ammonium/ammonia settles in surface waters it can increase the acidity or cause nutrient overloading, which leads to algal blooms and eutrophication.

High concentrations of ammonia, PM2.5, and other pollutants associated with hog CAFOs have a significant detrimental impact on the health and wellbeing of people living nearby. A study published by researchers from Duke University in 2018 found, after controlling for other factors, that for North Carolinians who live near hog CAFOs that use lagoons and sprayfields, mortality rates were substantially higher from causes such as anemia, kidney disease, tuberculosis, and lower birth rates than people who live further away from these operations (Kravchenko et al., 2018). Another recent study linked ammonia and particulate matter created by hog CAFOs to increased mortality rates in nearby communities (Domingo et al., 2021). CAFOs create areas of highly concentrated air pollution and odor that impairs the quality of life of nearby communities. Vulnerable populations are most at risk from the health impacts of CAFO-produced pollutants. Children, for instance, inhale 20-50% more air than adults, and air pollution can exacerbate existing health conditions in the elderly. In addition to affecting health, CAFO-produced pollution has substantial social impacts. Odor, for instance, may be detected several miles from CAFOs.

The waste treatment lagoons that CAFOs use to manage animal waste in North Carolina are a public hazard in times of extreme weather events e.g. hurricanes (Aneja et al., 2001). These events can cause lagoon overflows, which highly contaminate soil, surface water and groundwater used for wells with nutrients and pathogens impacting human health and the environment. Environmentally, these events cause extreme nutrient overload in waterways, which can have a negative impact on entire ecosystems by causing events like algae blooms.

II. Impact of retrofitting existing animal waste management systems to produce biogas on ammonia emissions

Anaerobic digestion (AD) is a method for converting biomass into bioenergy. Livestock manure is a commonly used biomass material for production of bioenergy.

Many livestock (hog and cattle) manure treatment systems rely on open lagoons where the CH_4, CO_2, NH_3 (ammonia) and other gases, such as reduced sulfur compounds, volatile organic compounds (VOCs) are emitted into the atmosphere. When these open systems are covered, gaseous emissions except ammonia are reduced, which results in the effluent leaving the anaerobic digester, known as digestate, with a modified chemical content (e.g. total solids, carbon, ammonia, ammonium (NH_4^+), and pH), relative to waste from a conventional open lagoon system. TAN content and pH in digested slurry are higher than in untreated slurry. Thus, potential for ammonia emissions during subsequent slurry storage are increased (Baines, 2021). The digestate contains more ammonium (NH_4^+) due to reduction in ammonia emissions from the anaerobic digester (i.e. covered lagoon) to the atmosphere, and has less degradable biomass carbon than the substrate in an open lagoon resulting in changes in GHG and NH_3 emissions (Baines, 2021).

The production of biogas through AD of livestock manure is a complex process. It involves a variety of physiological and biochemical metabolic pathways, the essence of which is the material and energy metabolism of microorganisms under anaerobic conditions. AD may be classified typically into three stages according to the utilization and transformation of organic matter (Baines, 2021):

1. Hydrolysis;

2. Acidogenesis; and

3. Methanogenesis.

In the hydrolysis step, macromolecular organic matters (fat, carbohydrate, protein, etc.) are hydrolyzed into small molecules such as monosaccharides, amino acids, fatty acids and so on by the action of extracellular enzymes. In the Acidogenesis step, the small molecule organic compounds are converted to a volatile organic acid, ethanol etc. by the acidified bacteria. H_2, CO_2 and acetic acid are then formed under the action of hydrogenic bacteria and acetogenic bacteria. Finally, in the Methanogenesis step, the methanogenic bacteria synthesize methane using acetic acid, H_2, CO_2 etc. in the methanogenesis stage.

In general, when the digestion process is complete, the pH of the digestate hovers between 7.5 and 8. The pH value in the course of anaerobic digestion is the result of the acid-alkali balance; the pH value decreasing with the increasing of organic acids, and increasing with the increases of Total Ammoniacal Nitrogen (TAN) (TAN = ammonium + ammonia), which is the product of the decomposition of nitrogenous organics (Lorimor and Sawyer, 2004; Grabow; Baines, 2021). The mass of total N is not significantly changed by anaerobic digestion, however the mass of organic nitrogen decreases and the mass of ammoniacal nitrogen increases. Organic N decreases as it is mineralized to TAN (Total Ammoniacal Nitrogen=NH4+N + NH3); i.e. NH3 N expressed as a percentage of TKN increases as manure is digested. Both the TAN and the mineral N (mineral N= TAN + NO3- N) increase. The impact of N transformations is to increase the fraction of total-N in the total ammoniacal form. This is important since the ammoniacal form is composed of both dissolved ammonium (NH4+) and ammonia (NH3) gas. Ammonia gas is emitted into the atmosphere from the open lagoon, i.e. secondary lagoon, during land application (i.e. spraying) of animal waste, and land biogenic emissions of the digested effluent. The amount of NH3 lost during land application of the digestate depends on multiple factors, including the method of application (generally high-pressure spray versus low pressure application or injection) and temperature. (Nyord et al. 2012; Dari et al., 2019).

Anaerobic digesters do not significantly change the nutrient quantity as nitrogen and phosphorus are retained, only the carbon is reduced through conversion and degassing of methane and carbon dioxide. The mass of organic nitrogen is decreased, and it is mineralized to TAN. Thus, ammonia and ammonium are found at higher concentrations in liquid digestates than raw manure (Nkoa, 2014). Therefore, anaerobic digestates stored in open secondary lagoons and land-applied to fields have higher NH3 emission potential than undigested animal manures and slurries (Aneja et al., 2008; Alburquerque et al., 2012; Nkoa, 2014) especially as the temperature increases. An increase in NH3 emissions during the summer from a secondary lagoon filled with digestate relative to conventional open lagoons was documented in North Carolina in 2008 as part of the North Carolina State University Animal and Poultry Waste Management Center's evaluation of potentially environmentally superior technologies. (Aneja 2008). Factors such as temperature and pH may alter the equilibrium between ammonia and ammonium. For example, increasing temperature and pH will enhance ammonia emissions. (Angelidaki et al., 2003; Weaver et al., 2012; Nkoa, 2014). Air movement across an open lagoon surface also enhances NH3 loss. (Dari et al., 2019).

Once digestate is removed from lagoons and applied to fields it has the potential to emit ammonia at a greater rate than conventional hog waste, as depicted in Figure 2. (Nyord et al., 2012). Most studies evaluating ammonia emissions from land-applied digestate have evaluated land-application methods such as drag-hose irrigation or injection. (Nyord et al. 2012; Chantigny et al. 2009). It is well-established that these methods of land-application produce substantially less ammonia emissions than high-pressure spray hoses, (Grabow 2007), which are the land-application method of choice on hog operations in North Carolina. Some studies evaluating ammonia emissions from land-applied digestate have also used data from much colder climates than North Carolina. (Chantigny et al. 2009). It is well-established that low temperatures inhibit NH3 volatilization. (Dari et al., 2019). Therefore, it is reasonable to believe that land-application of digestate effluent through spraying in North Carolina, particularly during the summer, is likely to cause greater ammonia emissions than documented in these studies.

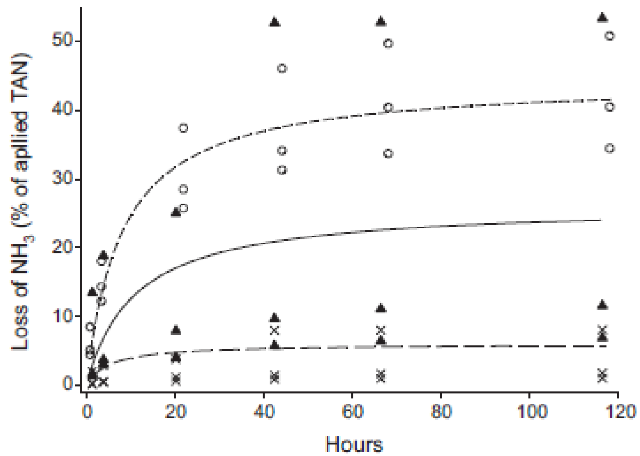

Fig. 3. Ammonia emissions 2008. Cumulative percentage loss of total applied TAN through emission over 116 h after application of pig slurry by trailing hoses. Regression lines and symbols represent cumulative losses of NH_3 emission from each measuring period; ---- and ○: digested slurry; — and ▲: untreated slurry; — — and ×: separated slurry.

Figure 2: Cumulative Ammonia loss by digestate, cattle, and pig slurry spread onto land under identical conditions (Nyord et al. 2012)

III. Impact of DEQ's issuance of permits to M-B to incorporate anaerobic digesters (covered lagoon) into the lagoon & sprayfield system

The permits issued by DEQ for the Waters, Kilpatrick, Benson, and Farm 2037/2038 hog operations authorize Murphy-Brown to modify its existing waste management systems to produce biogas, store digestate in open secondary lagoons, and apply digestate to fields. Instead of flushing hog urine and feces from barns into open lagoons the permits allow the hog operations to store the urine, feces, and water in covered lagoons where, as described in the previous section, biogas will be produced through the process of methanogenesis. The biogas along with other gases trapped under the lagoon cover will be siphoned off to be conditioned and then processed at a central plant.

The digestate will have a different composition from conventional waste, including a significantly higher concentration of NH3/NH4+. The digestate will be transferred to a secondary open lagoon. Ammonia emissions from the secondary lagoon are likely to exceed those expected from a similarly situated conventional lagoon system. (Aneja et al., 2008; Alburquerque et al., 2012; Nkoa, 2014). When the digestate effluent is land-applied, primarily through spraying, this higher rate of ammonia emissions is likely to continue. (Nyord et al., 2012).

The increased ammonia emissions from the secondary open lagoons and land-applied digestate effluent relative to a conventional lagoon and sprayfield system means that a technology intended to benefit the environment, biogas production and capture, may worsens air and water pollution coming from these four hog operations (Harper et al., 2010). The anticipated increase in ammonia emissions could cause more ammonia to be deposited onto nearby soil, where it can seep into groundwater or runoff into surface waters, and directly into surface waters, where it causes algal blooms, low oxygen conditions, and harms aquatic ecosystems.

IV. Availability of technology that mitigates ammonia emissions from lagoons & sprayfield system

Emissions of reactive nitrogen in animal waste can be reduced through various technologies and practices. (Aneja et al., 2009; Szogi et al., 2014). Farm-specific feed management practices cannot be enforced by regulators, but waste management technology requirements can. For example, in the Netherlands, Denmark, and UK, manure injection into soil, rather than spraying, has long been mandated to reduce ammonia emissions. However, technological fixes must be assessed for potential pollutant swapping, i.e., the increased emission of one pollutant resulting from abating another. One example of pollution swapping is increased nitrate leaching that may result from switching to manure injection without reducing the nitrogen application rate. (Aneja et al., 2009).

Over a decade ago, an engineered waste management system known as “Super Soils” was developed and tested in North Carolina. (Aneja et al., 2008). The system included a module that removed nitrogen from waste through a process known as nitrification-denitrification. The system reported a 73% reduction in ammonia emissions from hog operations. (Szogi et al., 2006). The Super Soils system also created an additional income stream for farmers by allowing them to sell concentrated nutrient byproducts of the system as fertilizer. The Super Soils technology has been improved upon twice. (Szogi et al., 2014). Though there is no lagoon in the Super Soil System for storage of the animal manure, the system’s modules have been adapted elsewhere to work alongside covered lagoons producing biogas. (Schmidt, 2009).

V. Conclusion

In sum, hog waste lagoons and sprayfields are a significant source of ammonia emissions, which harm local air and water quality and enhance formation of PM2.5, which is harmful to human health. The system permitted by DEQ, which includes a covered lagoon anaerobic digester, secondary uncovered lagoons that store digestate, and land application of the digestate through spraying, is likely to increase those ammonia emissions. The process of anaerobic digestion alters the composition of hog waste such that the digestate that comes out of the covered lagoon has a higher concentration of total ammoniacal nitrogen (TAN) than conventional waste. This change in composition increases ammonia emissions from lagoons and sprayfields fertilized with digestate relative to conventional lagoon and spray waste management systems. The expected increase in ammonia emissions, may in turn exacerbate air and water quality impacts. There are technologies available that reduce the nitrogen content of digestate and can therefore decrease ammonia emissions, avoiding significant environmental and public health impacts.

Received 18 November 1998; received in revised form 29 October 1999; accepted 29 October 1999

Abstract

Wet deposition and transport analysis has been performed for ammonium (NH_4^+) in North Carolina, USA. Multiple regression analysis is employed to model the temporal trend and seasonality in monthly volume-weighted mean NH_4^+ concentrations in precipitation from 1983 to 1996 at six National Atmospheric Deposition Program/National Trends Network (NADP/NTN) sites. A significant ($p < 0.01$) increasing trend beginning in 1990, which corresponds to an annual concentration increase of approximately 9.5%, is detected at the rural Sampson County site (NC35), which is located within a densely populated network of swine and poultry operations. This trend is positively correlated with increasing ammonia (NH_3) emissions related to the vigorous growth of North Carolina's swine population since 1990, particularly in the state's Coastal Plain region. A source–receptor regression model, which utilizes weekly NH_4^+ concentrations in precipitation in conjunction with boundary layer air mass back trajectories, is developed to statistically test for the influence of a particular NH_3 source region on NH_4^+ concentrations at surrounding NADP/NTN sites for the years 1995–1996. NH_3 emissions from this source region, primarily evolving from swine and poultry operations, are found to increase NH_4^+ concentration in precipitation at sites up to ≈ 80 km away. At the Scotland County (NC36) and Wake County (NC41) sites, mean NH_4^+ concentrations show increases of at least 44% for weeks during which 25% or more back trajectories are influenced by this source region.

Keywords: Ammonium; Ammonia; Multiple regression; Wet deposition; Back trajectories; Source–receptor

1. Introduction

1.1. Background

Interest in atmospheric ammonia (NH_3) has increased substantially over the past several years as its roles in both atmospheric chemistry and nutrient cycling have become better understood. Atmospheric NH_3 is an abundant alkaline responsible for the neutralization of a substantial fraction of strong acids in the atmosphere (Asman et al., 1982). The adverse effects of excess reduced nitrogen in forest systems are well documented (Nihlgard, 1985; Reuss and Johnson, 1986). Atmospheric NH_x (NH_x = ammonia + ammonium + amines) is now thought to be an important component of total atmospheric nitrogen (TAN) input to nitrogen-sensitive ecosystems such as coastal and estuarine waters (Aneja et al., 1998; Aneja, 1997). Such systems may receive nitrogen by direct wet and dry atmospheric deposition, as well as surface and ground water transport. North Carolina's Albemarle-Pamlico Sound system is one of many North American, European and Asian estuarine and coastal ecosystems impacted by atmospheric nitrogen deposition which are exhibiting advanced signs of eutrophication in the form of recurring toxic and non-toxic phytoplankton

blooms (Paerl, 1991,1995; Paerl et al., 1993). Such phytoplankton blooms are associated with varying degrees of oxygen depletion in water and fish losses (Paerl, 1995).

Atmospheric nitrogen deposition may be responsible for a substantial amount of nitrogen input across North Carolina's Coastal Plain region, owing to NH_3 emissions from the large number of animal operations across the region. Such sources will have a local impact on NH_3 and NH_4^+ deposition, and densely populated groups of such sources may have a regional influence on NH_4^+ deposition. The purpose of this study is to investigate the temporal characteristics of wet NH_4^+ deposition across North Carolina and to investigate the possible influence of NH_3 derived from a region of Coastal Plain animal operations on wet NH_4^+ deposition across the state. The analysis presented uses multiple linear regression to estimate the seasonality and long term trend in NH_4^+ concentration in precipitation at six National Atmospheric Deposition Program/National Trends Network (NADP/NTN) sites across North Carolina. Ammonium transport analysis is performed to investigate the influence of NH_3 emissions in southeastern North Carolina, where livestock population density is the largest, on NH_4^+ concentration in precipitation across the state. This is accomplished using boundary layer air mass back trajectory analysis coupled with multiple linear regression modeling. Incorporation of a weekly *influence factor* into a linear regression model allows for a formal statistical test of this source region's influence.

1.2. Ammonia emissions

Many studies have shown domestic animals to be the largest global source of atmospheric NH_3, with emission estimates ranging from 20–35 Tg N yr^{-1} (Schlesinger and Hartley, 1992; Warneck, 1988). Nitrogen emission estimates for the state of North Carolina (NC) show domestic animals to be the largest statewide contributor of NH_3, with swine operations present as the primary domestic animal source (Wooten, 1997; Aneja, 1997). Swine operations account for approximately 48% (68,450 t yr^{-1}, NH_3–N) of all North Carolina NH_3 emissions and approximately 21% of total nitrogen emissions.

Prior to 1990, the number of hogs in the state was relatively stable at near 2.5 million, however, this number began to rapidly increase within the period 1989–1990 (NCDA, 1998). In 1996, North Carolina contained approximately 9.3 million hogs, roughly 93% of which were located in the Coastal Plain region shown in Fig. 1. Area I in this figure, designated by shading, is defined as the six individual NC counties with the largest hog population densities. This collection of counties has an average hog population density of ~ 528 hogs km^{-2}. The average county hog population density for the remaining Coastal Plain is ~ 65 hogs km^{-2}. Area I contains approximately 66% of the Coastal Plain hog population and only 17% of the total Coastal Plain land area. Area I also contains approximately 68% of the Coastal Plain's domestic turkey population. These factors make area I a region of strong NH_3 emission relative to the rest of the state. Table 1 shows estimated area I NH_3 emissions by domestic animal type. Swine operations account for 77% of total NH_3 emissions from domestic animals within area I. Animal population statistics used in this study were supplied by the North Carolina Department of Agriculture (NCDA, 1998). Emissions are based on emission factors given by Battye et al. (1994).

1.3. Atmospheric ammonia

Estimates of the atmospheric lifetime of NH_3 range from approximately 0.5 h to 5 d (Fowler et al., 1997; Aneja et al., 1998). This short lifetime is the result of rapid gas-to-particle conversion of NH_3 to NH_4^+ and deposition of NH_3 to natural surfaces, particularly wet surfaces and vegetation which have low NH_3 compensation points. Once into the atmosphere, NH_3 which is not dry deposited or scavenged by raindrops will undergo conversion to NH_4^+ aerosol. The lifetime of NH_4^+ aerosol is typically 5–10 d (Crutzen, 1983). The rate of this conversion, which is largely unknown, will have an important bearing on the regional impact of NH_3 sources or source regions such as area I in this study. If this conversion proceeds slowly, area I emissions will primarily be deposited locally; thus, less NH_4^+ will be made available for long-range transport.

Conversion of NH_3 to NH_4^+ aerosol depends on the concentrations of strong acids and water vapor in the atmosphere. Ammonia reacts with sulfuric, nitric, and hydrochloric acids to form ammonium sulphate, ammonium bisulphate, ammonium nitrate and ammonium chloride aerosols (RGAR, 1997; INDTE, 1994; Finlayson-Pitts and Pitts, 1986). Ammonium aerosol formed in these reactions can exist as a solid particle or a liquid droplet depending on relative humidity (Finlayson-Pitts and Pitts, 1986). While the principal chemical transformation of NH_3 in the atmosphere is incorporation into NH_4^+ aerosol, approximately 10% is oxidized via the hydroxyl radical (OH) (Roberts, 1995).

1.4. Wet removal processes

The processes by which gases and aerosols are removed by precipitation can be divided into in-cloud and below-cloud regimes. The below-cloud processes include inertial removal by precipitation and diffusive removal on precipitation (Twomey, 1977). The in-cloud processes which govern wet deposition of aerosols and gases include inertial removal by cloud drops, nucleation, and diffusion to cloud drops (Twomey, 1977). It is generally agreed that in-cloud removal processes are more efficient

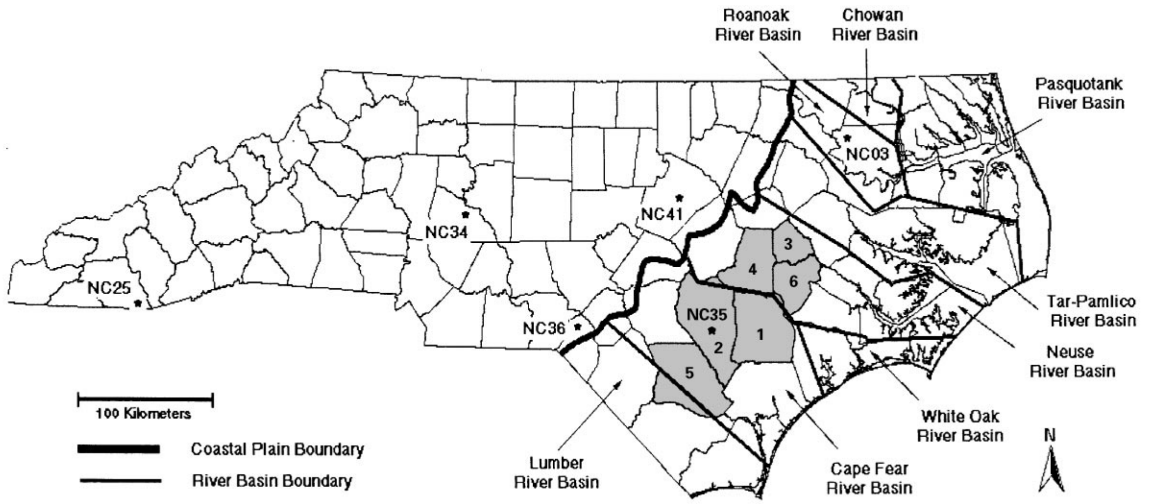

Fig. 1. NADP/NTN sites (*), area I NH_3 source region, and Coastal Plain river basins. The shaded area represents area I, a region defined as having an average hog population density of $\sim$ 528 hogs km^{-2}. Numbers within area I represent the following individual counties with corresponding estimated hog population densities (hogs km^{-2}): (1) Duplin County, 991; (2) Sampson County, 735; (3) Greene County, 503; (4) Wayne County, 349; (5) Bladen County, 316; and (6) Lenoir County, 274.

than below-cloud processes (Twomey, 1977; Asman, 1995). This is due to the large total surface area of droplets within the cloud compared to raindrops below cloud base. The contribution of below-cloud processes should not be ignored, however, especially in the case where the concentration of the compound of interest is larger in air below cloud base compared to the concentration within the cloud. It should be noted that some portion of the NH_4^+ measured in precipitation is the result of dry deposition of NH_4^+ aerosol to the precipitation collector. It is also important to point out that a fraction of the NH_4^+ measured in rainfall originates as NH_3 gas which is wet and dry deposited to the precipitation collector, resulting in the formation of NH_4^+ when NH_3 reacts with water (Warneck, 1988).

Table 1
Estimated area I NH_3–N emissions from domestic animals for the years 1996–1997[a]

Animal	NH_3–N emissions (t yr^{-1})
Hogs	47,679
Turkeys	9,585
Broilers	2,435
Cattle	2,154
All Chickens	181

[a] NH_3–N tons $= \frac{14}{17}$(NH_3 tons). Emissions calculated using emission factors given by Battye et al. (1994). Animal population statistics were provided by the North Carolina Department of Agriculture (NCDA, 1998). Calculations reflect hog population as of 1 December 1996; turkey population for 1996; cattle population as of 1 January 1997; broiler population for 1996; chicken population as of 1 December 1996. Emissions from turkeys and broilers were calculated by dividing the total population by the average number of flocks per year, 5.75 for broilers and 3.5 for turkeys.

2. Methods

2.1. Data selection

Precipitation chemistry data used in this study was provided by the National Atmospheric Deposition Program/National Trends Network, a nationwide precipitation collection network which began in 1978 and now operates over 200 sites (NADP/NTN, 1998). NADP/NTN samples are collected at 9:00 a.m. every Tuesday and sent to the Illinois State Water Survey, Central Analytical Laboratory (CAL) for chemical analysis (Peden, 1986). All samples are subject to the same field handling protocol and analytical procedures at CAL.

Only species concentrations in precipitation were used in this study. The term precipitation includes liquid, solid and mixed phase. Additionally, only samples that were considered valid and complete by NADP/NTN standards were used. Information on the data validation and completeness criteria used in this analysis can be found at the NADP/NTN website: *http://nadp.sws.uiuc.edu* (NADP/NTN, 1998). This study also employed the use of NADP/NTN daily precipitation information. The Rowan County (NC34) and Wake County (NC41) sites should be considered suburban. The remaining sites are located in rural areas. Fig. 1 shows the general location of the six NADP/NTN sites used in this study.

2.2. Trends analysis

Given the drastic increase in NH_3 emissions within area I beginning during the period 1989–1990, we hypothesize that a positive trend in NH_4^+ concentration in precipitation should be present at site NC35, located within area I, beginning in 1990 and that this trend may also be present at additional sites. To test this hypothesis, multiple linear regression is used to illustrate seasonality and trend in 14 yr worth of monthly volume-weighted mean NH_4^+ concentrations in precipitation. The 14 yr record is split into two periods. Period 1 includes the years 1983–1989 and period 2 includes the years 1990–1996. This was done in an effort to facilitate the correlation of any increasing NH_4^+ trends during period 2 with the growth of the North Carolina swine industry and the resulting increase in area I NH_3 emissions beginning in 1990. Complete analyses were performed for both periods at all sites.

Multiple linear regression analysis to investigate the temporal variation of precipitation chemistry has been widely used in the past (Buishand et al., 1988; Dana and Easter, 1987; MAP3S/RAINE, 1982). The present analysis employs the following regression model for separate analysis of both 7 yr periods at all sites:

$$Y_i = a_0 + a\cos(2\pi i/12 - \phi) + bi + cP_i + e_i,$$
$$i = 1, \ldots, 12N. \tag{1}$$

where N represents the number of years in the time series ($N = 7$). In this case, Y_i is the natural logarithm of the volume-weighted mean NH_4^+ concentration (mg l^{-1}) in precipitation for the ith month. The use of the natural log transform of concentrations has proven useful in improving the fit of parametric models such as the one above (Dana and Easter, 1987). The approximate lognormal distribution of species concentrations in precipitation has been illustrated (MAP3S/RAINE, 1982). Sirois (1991) points out that this transformation will help to achieve the regression modeling assumption of constant error variance. The term a_0 represents the intercept.

P_i represents the natural logarithm of the precipitation amount (ml) for the ith month. The inverse relationship between precipitation amount and concentration of ammonium in precipitation, which is the result of several processes occurring simultaneously, is well illustrated by Prado-Fiedler (1990). It should be pointed out that the use of volume-weighted concentrations will effectively reduce the amount of variation imposed on the concentration by precipitation amount. The precipitation term in the presently addressed regression model is included to capture remaining precipitation effects.

The term bi, where i (month) goes from 1 to $12N$, represents the monotonic trend in NH_4^+ concentration in precipitation over time. It should be pointed out that a systematic trend in precipitation amount will have some degree of collinearity with the trend term for concentration, thus the precision in the estimate of the trend magnitude will be reduced. Additionally, the assumption of a linear trend will simplify the structure of the actual trend which may have non-linear characteristics. In addressing the detectability of possible trends in the 7 yr records analyzed, emphasis was placed on the value of b in Eq. (1) for which the null hypothesis H_0: $b = 0$ is rejected with 80% probability. Buishand et al. (1988) used this approach in addressing the detectability of NH_4^+ trends in 5 yr records of monthly bulk precipitation samples.

The probability of detecting a trend, or power, is a function of degrees of freedom v, significance level (SL), and the noncentrality parameter δ where

$$\delta = b/\sigma_b. \tag{2}$$

Power increases with δ and v, though power varies minimally above $v = 30$. Power has a much stronger relationship with δ, which is a function of trend magnitude. Note that $v = n - c$ where n is the total number of observations and c is the number of regression coefficients in the model. As pointed out by Buishand et al. (1988), it is usually necessary to have at least 10 degrees of freedom in order to obtain a powerful t-test. For this reason it is advantageous to use monthly concentration values in this analysis rather than annual values. Another way to increase the power of trend detectability is to reduce the error (e_i) standard deviation. This illustrates the usefulness of adding additional explanatory variables, such as precipitation amount, to regression models designed to detect trend and seasonality. In this analysis, adding explanatory variables such as concentrations of other analytes (NO_3^- and SO_4^{2-}) resulted in a reduction of error standard deviation at the cost of severe multicollinearity among model independent variables. To avoid such multicollinearity, only the most parsimonious group of variables was chosen for the final model.

The use of a cosine or sine term to model the annual cycle in concentrations is well documented (Buishand et al., 1988; MAP3S/RAINE, 1982). The cosine term in model (1) represents the seasonal component of the variation in concentration where a is the amplitude and ϕ is the phase angle. This term achieves a maximum at $i \approx 6\phi/\pi$, thus the location of the maximum in the annual cycle of concentration can be readily identified. It should be noted that the seasonality term will have some degree of collinearity with seasonality present in the precipitation term.

To test the hypothesis that presence of seasonality and trend in precipitation amount exist, the following regression model was used for analysis of both periods at all sites:

$$P_i = a_0 + a\cos(2\pi i/12 - \phi) + bi + e_i, \quad i = 1, \ldots, 12N. \tag{3}$$

P_i represents the natural logarithm of precipitation amount and bi is the trend term. The cosine term models the seasonal cycle in precipitation amount.

2.2.1. Reparameterized models

To facilitate the estimation of the coefficients $a_0, a, b, c,$ and ϕ following Buishand et al. (1988), the final form of model (1) becomes

$$Y_i = a_0 + \alpha\cos(2\pi i/12) + \beta\sin(2\pi i/12) + bi + cP_i + e_i,$$

$$i = 1, \ldots'' \, 12N \tag{4}$$

where $\alpha = a\cos\phi$ and $\beta = a\sin\phi$. The cosine term in Eq. (1) is thus decomposed into the cosine and sine terms in Eq. (4) to determine a and ϕ. Using the Proc Reg procedure within SAS® statistical analysis software, estimates $\hat{a}_0, \hat{\alpha}, \hat{\beta}, \hat{b}$, and $\hat{c}$ of the regression coefficients in Eq. (4) were calculated by the method of ordinary least squares (SAS Institute Inc., 1990). It follows that estimates of a and ϕ can be derived from the relations:

$$\hat{a} = \sqrt{\hat{\alpha}^2 + \hat{\beta}^2}, \tag{5}$$

$$\hat{\phi} = \begin{cases} \arctan(\hat{\beta}/\hat{\alpha}) & \text{if } \hat{\alpha} \geqslant 0, \\ \arctan(\hat{\beta}/\hat{\alpha}) + \pi & \text{if } \hat{\alpha} < 0. \end{cases} \tag{6}$$

Proc Reg also provides estimates of the standard errors of the above regression coefficients as well as an estimate of σ_e. Buishand et al. (1988) give the following relationships for $\hat{a}$ and $\hat{\phi}$ which are derived from a Taylor expansion of Eqs. (5) and (6):

$$\sigma^2(\hat{a}) = \operatorname{var}\hat{a} \approx (\alpha^2/a^2)\operatorname{var}\hat{\alpha} + (\beta^2/a^2)\operatorname{var}\hat{\beta} + 2(\alpha\beta/a^2)\operatorname{cov}(\hat{\alpha}, \hat{\beta}), \tag{7}$$

$$\sigma^2(\hat{\phi}) = \operatorname{var}\hat{\phi} \approx (\beta^2/a^4)\operatorname{var}\hat{\alpha} + (\alpha^2/a^4)\operatorname{var}\hat{\beta} - 2(\alpha\beta/a^4)\operatorname{cov}(\hat{\alpha}, \hat{\beta}). \tag{8}$$

Estimated values of the variances and covariances of $\hat{\alpha}$ and $\hat{\beta}$ are calculated by Proc Reg. By using estimates of a, α and β on the right-hand sides of (7) and (8), the standard errors $\hat{\sigma}(\hat{a})$ and $\hat{\sigma}(\hat{\phi})$ can be calculated.

The final form of model (3) is:

$$P_i = a_0 + \alpha\cos(2\pi i/12) + \beta\sin(2\pi i/12) + bi + e_i,$$

$$i = 1, \ldots, 12N. \tag{9}$$

Model variables are defined as in model (3). Estimates of a, α, β, ϕ and b and their standard errors are obtained as in model (4).

The Student's t-statistic is used to test the statistical significance of the regression coefficients in the model under the null hypothesis (H_0) that the regression coefficient being tested is zero. Probability values (p-values) are also calculated for each coefficient. A small p-value suggests a disagreement between the data and the null hypothesis. In this study, the significance level SL $= 0.1$ is chosen as the value above which a given p-value results in failure to reject H_0.

The validity of the t-test is subject to the basic assumptions of the linear regression model. These assumptions are that the errors (e_i): have constant variance; are uncorrelated with each other in time; and have a normal distribution. The Durbin–Watson test was used to test for first-order autocorrelation among the residuals. At sites where the correlation assumption was violated or considered inconclusive, a regression technique, Proc Autoreg, which accounts for correlation in residuals was used to estimate regression coefficients. The validity of the normality assumption was assessed by visual inspection of residual frequency distributions and quantile–quantile (Q–Q) plots of ordered residuals against normal quantiles. In observing Q–Q plots, a linear relationship suggests a normal population of residuals. For a more detailed treatment of residual frequency distributions and Q–Q plots, the reader is referred to *SAS® System for Statistical Graphics* (1991).

In this analysis, outliers that were not considered influential were left in the model. The level of outlier influence was estimated by using the difference in fits (DFFITS) and difference in beta (DFBETAS) statistics produced by the Proc Reg procedure. The commonly used cutoff value of 2 was used for both statistics (Bowerman and O'Connell, 1990). When the value of DFFITS exceeds 2, removing the corresponding observation from the data set substantially changes the point prediction of Y_i (model (4)). If the value of DFBETAS exceeds 2, then removing the corresponding observation from the data set substantially changes the point estimate of the corresponding regression coefficient. Those observations with DFFITS and DFBETAS values less than 2 after the initial model run were retained.

2.3. Source–receptor analysis

The source–receptor analysis developed here combines air mass back trajectory analysis with multiple linear regression to investigate the influence of area I NH_3 emissions on NH_4^+ concentration in precipitation at surrounding NADP/NTN sites. An air mass trajectory within the boundary layer which arrives at a site after having traversed any portion of area I for any duration of time is considered to possibly contain elevated concentrations of NH_3 and NH_4^+, and is consequently labeled as influenced. The distances of individual sites from the perimeter of area I are listed in Table 2. All sites in

Table 2
Distance from the perimeter of area I to NADP sites

Site	Distance (km)
NC41	56
NC03	76
NC36	60
NC34	170
NC25	387

Fig. 1 except site NC35 are included in the source–receptor analysis. This analysis uses weekly NH_4^+ concentrations in precipitation and daily precipitation information. The period of analysis includes the years 1995 and 1996.

Back trajectory models are commonly used to link receptors to source regions in wet deposition studies (Billman-Stunder et al., 1986; Moody and Samson, 1989; Henderson and Weingartner, 1982; Ruijgrok and Romer, 1993; RGAR, 1997). Such studies typically utilize chemistry data from samples collected on an event basis. This analysis uses weekly concentration values and back trajectories for days on which precipitation was measured. Therefore, a weekly sample can be comprised of a maximum of seven separate precipitation events.

Back trajectories were calculated using version 4 of the Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) model developed by the National Oceanic and Atmospheric Administration's Air Resources Laboratory (NOAA/ARL). The model was accessed and run from the World Wide Web at *http://www.arl.noaa.gov/ready/hysplit4.html* (HYSPLIT4, 1997). The HYSPLIT model calculates three-dimensional trajectories from previously gridded horizontal (u and v) and vertical (ω) wind fields output and archived every 2 h from NOAA's National Center for Environmental Prediction's Nested Grid Model (NGM) (Draxler, 1997). The trajectories in this analysis used the vertical motion prescribed by the NGM and are therefore kinematic.

A single 24 h back trajectory starting at 2300 h was run for each day on which precipitation was measured at the NADP/NTN site. Given its distance from area I, 36 h back trajectories were calculated for site NC25. When initial trajectories exhibited significant curvature, additional trajectories were also run at 1800 and 1200 h. The trajectory level was chosen as 150 m. The 150 m level is expected to be within the boundary layer even during stable nocturnal conditions, when boundary layer depth is typically 100–200 m (Arya, 1998). The HYSPLIT wind fields at this level are interpolated from the nearest NGM sigma level. There are about 4 NGM sigma levels within the boundary layer (Draxler, 1996).

In our analysis it is assumed that most of the NH_3 emitted at ground level within area I will likely arrive at surrounding NADP/NTN sites, aside from NC25, via transport within the boundary layer. We are, by consequence, characterizing flow conditions which result in the wet deposition of area I NH_3 and NH_4^+ at a site via below-cloud mechanisms. Only when the cloud-level trajectory is the same as the 150 m level will we describe those conditions which result in wet deposition of NH_3 or NH_4^+, which has originated from area I, by both in-cloud and below-cloud mechanisms.

The methodology presented here also assumes that the 150 m trajectory characterizes the general flow of the boundary layer. Within the well-mixed daytime boundary layer, trajectories at different levels should not deviate from each other significantly. Arya (1988) points out that wind direction across the moderately unstable and convective boundary layer typically changes by less than 15°. Under stable conditions, the horizontal deviation of trajectories at different heights in the boundary layer will be greater. The largest change in trajectory imposed by diurnal variation in boundary layer stability may take place in the transition from unstable daytime conditions to more stable nighttime conditions. In this case however, the layers that begin to form and fan out as stratification proceeds will roughly have the same concentration of NH_3 or NH_4^+, a result of the uniform concentration within the well-mixed daytime boundary layer.

During the time required for transport from area I to NC25, a considerable amount of NH_4^+ may make it out of the boundary layer and into clouds associated with precipitating systems transported by synoptic scale flow. For this reason, a 2000 m trajectory was calculated in addition to the 150 m trajectory.

In order to facilitate the use of daily back trajectories with weekly NADP samples, an influence factor (I) is introduced. I is defined as the ratio of the number of influenced trajectories during week i to the total number of trajectories during week i. Note that $I = 1$ when all the trajectories during a week are considered influenced. The maximum possible number of trajectories for a week is 7.

We hypothesize that area I NH_3 emissions may be influencing NH_4^+ concentrations at NADP sites surrounding area I. To set up this hypothesis, we first use the non-parametric Wilcoxon Rank Sums (WRS) test to compare the average concentration for weekly samples where $I \geqslant 0.25$ to the average concentration of those weeks where $I < 0.25$. $I \geqslant 0.25$ represents a week during which 25% or more of all back trajectories were considered to be influenced. H_0 for the WRS test is that the means of the groups being compared are equal. The WRS test is also performed to test for the equality of mean precipitation amounts of the two I groups. If the two group mean precipitation amounts are equal, then the physical meaning of different group mean NH_4^+ concentrations is maximized with respect to the dependence of concentration on I. Using the information gained in this means comparison as the foundation for our hypothesis, we then use regression analysis to conduct a formal hypothesis test.

In order to formally test for a statistically significant influence of area I NH_3 emissions on NH_4^+ concentration in precipitation collected at sites other than NC35, the influence factor (I) is incorporated into the following source–receptor regression model:

$$Z_i = a_0 + \alpha\cos(2\pi i/52) + \beta\sin(2\pi i/52) + dP_i + fI_i + e_i, \quad i = 1,\ldots,52N. \tag{10}$$

In this model, Z_i represents the natural logarithm of NH_4^+ concentration in precipitation ($mg\,l^{-1}$) for the ith week, P_i is the precipitation amount (ml) for the ith week, and I_i represents the influence factor for the ith week. The sine and cosine terms model the annual cycle which may be present in the weekly concentration values. Coefficients α, β, and corresponding phase angle ϕ are described in Section 2.2.1. $N(N = 2)$ represents the number of years present in the time series. This model was used to perform separate analyses at each site for the entire 2 yr period. Tests for regression coefficients, recognition of model assumptions and treatment of outliers are described in Section 2.2.1.

3. Results and discussion

3.1. Trends analysis

Table 3 summarizes the results of the trends analysis [model (4)]. The average R^2 for all sites is 0.45, meaning that the collection of variables in the regression model explains about 45% of the variation in the monthly volume-weighted mean NH_4^+ concentrations in precipitation. Mean observed concentration values for time period 1 range from 0.16 to 0.28 $mg\,l^{-1}$, and from 0.15 to 0.31 $mg\,l^{-1}$ for period 2. Mean predicted concentrations for time period 1 range from 0.11 to 0.24 $mg\,l^{-1}$, and from 0.11 to 0.26 $mg\,l^{-1}$ during period 2. The two highest concentration values, both observed and predicted, for period 1 are found at the two suburban sites, NC34 and NC41. It should be noted that NH_4^+ concentrations at NC34 and NC41 are likely influenced by NH_3 emissions from local livestock throughout both periods. The highest value for period 2 is shared by site NC35, located within area I, and NC41. The mean predicted value is an average of 0.045 $mg\,l^{-1}$ lower than the corresponding mean observed value at all sites during both periods. Precipitation amount is a significant predictor variable at several sites.

Table 3 shows a statistically significant (SL = 0.01) seasonal cycle at all sites, with maximum NH_4^+ concentrations in precipitation occurring in the summer, except for a spring maximum at site NC25 during period 1. Figs. 2 and 3 illustrate the typical seasonal cycle. Standard deviations of the phase angle, which illustrate the accuracy of i_{max}, range from 6.6 to 16.6°, or approximately 1 to 2.5 weeks (Table 3).

The increased ambient concentration of NH_4^+ during summer comes partly from the fact that mineralization in soil, which drives natural production of NH_3, is governed partially by temperature dependent microbial activity. A 10°C increase in soil temperature approximately doubles the rate of ammonification (Addiscott, 1983). As pointed out by Davies et al. (1986,1991), seasonality in

Table 3

Estimated regression coefficients in model (4), multiple coefficients of determination (R^2), and mean volume-weighted monthly NH_4^+ ion concentrations in precipitation for all sites. Time period 1: 1983–1989. Time period 2: 1990–1996. The value i_{max} is the month corresponding to the seasonal maximum ($i_{max} = 1$ corresponds to January). The phase angle $\hat{\phi}$ and its standard deviation (SD) are in degrees. $\hat{y}$ and y represent predicted and observed concentrations ($mg\,l^{-1}$), respectively

Site	Period	$\hat{a}$	SD $\hat{a}$	$\hat{\phi}$	SD $\hat{\phi}$	i_{max}	$\hat{b}$	$\hat{c}$	R^2	mean $\hat{y}$	$\bar{y}$

Seasonality and insignificant trend ($p > 0.10$) in the natural log (log NH_4^+) of monthly volume-weighted NH_4^+ concentration in precipitation (mg l^{-1}) at Sampson County site NC35 during period 1. Solid dots (●) represent observed values. The solid and dashed lines respectively represent predicted values and estimated trend given by model (4).

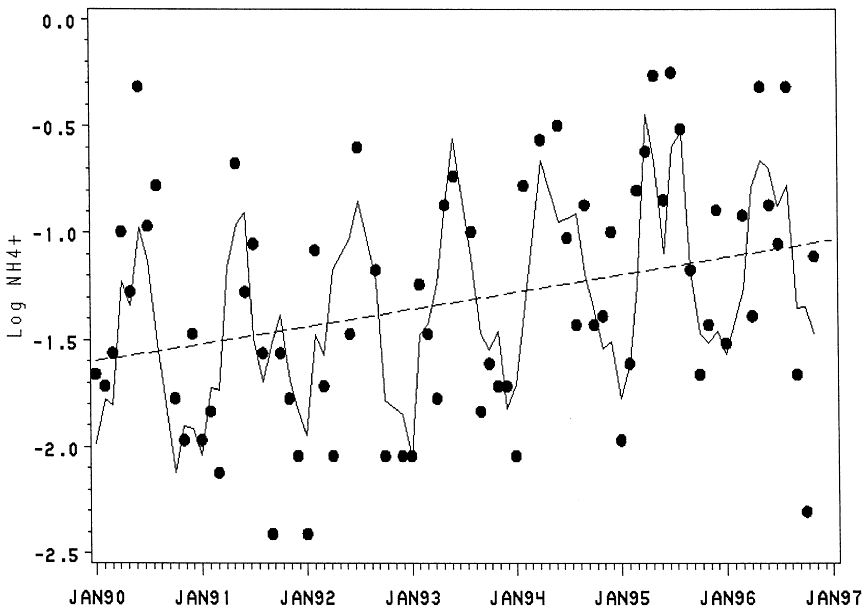

Fig. 3. Seasonality and significant trend ($p < 0.01$) in the natural log (log NH_4^+) of monthly volume-weighted NH_4^+ concentration in precipitation (mg l^{-1}) at Sampson County site NC35 during period 2. Solid dots (●) represent observed values. The solid and dashed lines respectively represent predicted values and estimated trend given by model (4).

synoptic scale meteorological conditions may also influence the seasonal pattern of NH_4^+ concentration in precipitation. This may involve a seasonal redistribution of upwind sources due to changing prevailing flow regimes and seasonal changes in precipitation characteristics such as intensity and duration.

As mentioned above, area I is believed to be a significant source of atmospheric NH_3 in the North Carolina Coastal Plain region. Harper and Sharpe (1997) have shown that volatilization of NH_3 from waste lagoons has a positive correlation with lagoon surface temperature, thus such sources will have peak emission strengths during summer. This may contribute to the summertime maximum NH_4^+ concentration in precipitation at sites such as NC35 which are located within a dense population of swine operations. These sources are randomly located among croplands, thus increased concentrations of NH_4^+ in rainfall during summer may also be related to emissions of NH_3 resulting from summer fertilizer application.

It is hypothesized that seasonal patterns in precipitation may have some influence on NH_4^+ concentration in precipitation. The use of regression model (9) to detect seasonal patterns in precipitation amount revealed statistically significant (SL $= 0.05$) annual cycles during period 1 at all sites except NC25. Maximum values of precipitation amount occurred during the summer in all cases. Significant annual cycles during period 2 were found at NC36, NC35 and NC03. Maximum precipitation amounts were again found during the summer at all sites. The inverse relationship between precipitation amount and NH_4^+ concentration in precipitation suggests that the summer maximum in NH_4^+ concentration is unrelated to the seasonal pattern in precipitation amount.

As stated earlier, the hypothesis behind the trends analysis is that increasing NH_3 emissions in area I may be imposing a positive trend in NH_4^+ concentrations in precipitation at site NC35, located within area I, and that this trend may also be present at additional sites. The trends should follow the temporal pattern of NH_3 emissions related to the NC hog industry growth which was generally stable within the period 1983–1989 (period 1) and has experienced drastic growth during the period 1990–1996 (period 2). Regression analysis shows a highly significant (SL $= 0.01$) increasing trend present at Sampson County site NC35 during period 2 (Table 3) and lack of trend during period 1. Figs. 2 and 3 show predicted value trendlines for both periods at NC35. The estimated monthly increase in NH_4^+ concentration in precipitation during period 2 corresponds to an annual increase of approximately 9.5%. The location of site NC35 among such a large number of animal operations and the correlation of the NH_4^+ trend with hog population growth suggests that the increasing magnitude of local NH_3 emission is the most likely explanation for the positive NH_4^+ trend. Furthermore, Cornelius (1997) showed that hog population density may be a significant predictor of NH_4^+ concentration in precipitation for sites within densities > 140 hog mi^{-2} such as area I. Site NC35 is specifically included in his analysis. It is important to realize that the trend model addressed here and the analytical methods employed by Cornelius (1997) do not identify sources of NH_4^+ in precipitation. This analysis illustrates the apparent correlation between the increasing trend in NH_4^+ concentration in precipitation at site NC35 and the increase in local NH_3 emissions resulting from rapid growth in the number of neighboring swine operations. A less significant (SL $= 0.1$) trend is found at site NC34 for period 2 (Table 3) and is most likely related to the increase in NH_3 emissions associated with a 33% countywide (Rowan County) increase in the cattle population for the period. The remaining sites, NC03, NC41, NC36, and NC25 do not show significant temporal trends during either period (Table 3).

Buishand et al. (1988) show that $\delta = 2.85$ for an 80% chance of rejecting H_0: $b = 0$ where $v > 30$ (two-sided test at the 5% level). In this analysis, $v = n - 5$, where the average n for all sites is ≈ 69. It follows from Eq. (2) that $b_{80} = 2.85\sigma_{\hat{b}}$. Using this relationship, the estimate of b for site NC34 during period 2 falls slightly below $b_{80} = 0.006$. At site NC35 for period 2, $b_{80} = 0.005$ and $b_{90} = 0.007$, indicating that the estimated trend ($b = 0.0079$) was detected with 80 and 90% probability.

In this analysis it is found that precipitation volume has a statistically significant inverse relationship with monthly volume-weighted NH_4^+ concentration at some sites. Any trend in precipitation volume over time may then impose a trend of opposite sign in NH_4^+ concentration. Regression model (9) was used to test the hypothesis of no trend in precipitation amount at each site. A single significant ($p < 0.05$) positive trend at site NC41 was found during period 2. This trend was not strong enough to impose a significant decreasing trend in NH_4^+ concentration in precipitation during the period. No other trends were detected at any site during either period.

During the analyses of concentrations [model (4)] and precipitation amount [model (9)], no departures from normality were detected in residuals. The number of influential outliers was less than 5 in all cases.

3.2. Source–receptor analysis

Table 4 shows the results of the Wilcoxon rank sums (WRS) test. At site NC36, the mean NH_4^+ concentration in precipitation for weeks where $I \geqslant 0.25$ is approximately 0.08 mg l^{-1} or 44% higher than the mean value for weeks where $I < 0.25$. The WRS test suggests that these means are significantly different at SL $= 0.10$. It is important to understand that the difference between these means could be entirely due to differences in group mean precipitation amounts. However, the WRS test for equality of mean precipitation amounts fails to show unequal means for the two I groups at the 10% level. This suggests that the difference in mean NH_4^+ values is likely not arising simply from a difference in group mean precipitation amounts. At site NC41, the mean NH_4^+ concentration in precipitation for weeks where $I \geqslant 0.25$ is approximately 0.17 mg l^{-1} or 50% higher than the

Table 4
Group means for weekly NH_4^+ (mg l^{-1}) concentrations in precipitation and precipitation amount (ml) and p-values (Prob. $> |Z|$) for the Wilcoxon Rank Sums test. $\mu_{1NH_4^+}$ is the mean of the observed weekly NH_4^+ values for which $I < 0.25$. $\mu_{2NH_4^+}$ is the mean of the observed weekly NH_4^+ values for which $I \geqslant 0.25$. p-value$_A$ is the probability of falsely rejecting H_0 for the WRS test for equality of $\mu_{1NH_4^+}$ and $\mu_{2NH_4^+}$. μ_{1P} is the mean observed precipitation amount of weekly samples with $I < 0.25$. μ_{2P} is the mean observed precipitation amount of weekly samples with $I \geqslant 0.25$. p-value$_B$ is the probability of falsely rejecting H_0 for the WRS test for equality of μ_{1P} and μ_{2P}

Site	$\mu_{1NH_4^+}$	$\mu_{2NH_4^+}$	p-value$_A$	μ_{1P}	μ_{2P}	p-value$_B$
NC03	0.24	0.31	0.1600	1608	2437	0.1525
NC36	0.18	0.26	0.0586[a]	2033	2395	0.6411
NC41	0.34	0.51	0.0747[a]	1560	2337	0.0621[a]

[a]Significant at the 10% level, but not at the 5% or 1% levels.

mean value for weeks where $I < 0.25$. Here the group mean concentrations are again deemed significantly different at SL = 0.10. The mean precipitation amounts are also significantly different at SL = 0.10. The higher mean precipitation value for $I \geqslant 0.25$ shows that in spite of the inverse relationship between precipitation amount and concentration, the concentration for those weeks where $I \geqslant 0.25$ is still greater than those weeks where $I < 0.25$. At NC03, the mean NH_4^+ concentration for weeks where $I \geqslant 0.25$ is approximately 0.07 mg l^{-1} or 29% higher than the mean value for weeks where $I < 0.25$. In this case the results were not statistically significant (SL < 0.20). The mean precipitation amounts for this site where not shown to be significantly different (SL = 0.10). It should be noted that first order autocorrelation between NH_4^+ concentration and I was found at both NC41 and NC36 ($\rho < 0.24$ in both cases). For this reason the p-values used to test H_0 in the WRS test should be used with caution, since the WRS test assumes independence in the data. The WRS was chosen here for its resistance to outliers in comparing means.

Table 5 summarizes the results of model (10) in the source–receptor analysis. The average R^2 is 0.45, meaning that precipitation amount and boundary layer air mass transport explain approximately 45% of the variation in weekly NH_4^+ concentration in precipitation. The influence of precipitation amount is highly significant ($p < 0.01$) at all sites. Statistically significant ($p < 0.01$) annual cycles are also found at all sites. The cycles reach a maximum during the summer at all sites, showing good agreement with the cyclic pattern predicted by the trends model for monthly values. An important result from this analysis is the sitewise estimates of f. Statistically significant ($p < 0.10$) positive values of $\hat{f}$ are found for NC03, NC36 and NC41. A positive value of $\hat{f}$ suggests that NH_4^+ concentration in precipitation increases with the percentage of influenced trajectories during a week. These results suggest that transport of NH_4^+ and or NH_3 originating from area I is detected for distances up to approximately 80 km. The influence of area I NH_3 emissions on NH_4^+ concentration in precipitation at sites greater than approximately 80 km away was not detected. We do not wish to suggest that the spatial extent of wet deposited NH_3 and NH_4^+ originating from area I is limited to 80 km. A larger data set is needed to provide more information for sites NC34 and NC25. The average number of observations used in this analysis for all sites is 80. Q–Q plots and frequency distributions of residuals suggest that the normality assumption was satisfied at all sites.

Table 5
Influence factor regression coefficients ($\hat{f}$) and multiple coefficients of determination (R^2) for model (10). Number of influenced trajectories and percent of total back trajectories (BT) labeled as influenced for the entire period are included for each site

Site	$\hat{f}$	R^2	No. influenced BT	% influenced BT
NC03	0.441[a]	0.52	53	22.0
NC25	− 1.475[b]	0.32	11	4.0
NC34	− 0.579[a]	0.39	29	9.0

[a]Significant at the 10% level, but not at the 5 or 1% levels.
[b]Significant at the 5% level, but not at the 1% level.

4. Conclusions

In this study, multiple linear regression has been used to illustrate the temporal characteristics of NH_4^+ concentration in precipitation at six North Carolina NADP/NTN sites. Seasonality, with maximum concentrations during warm months, is observed at all sites. A significant ($p < 0.01$) increasing trend in NH_4^+ concentration in precipitation beginning in 1990 is found at site NC35. This trend, which corresponds to an average annual increase in NH_4^+ concentration in precipitation of 9.5%, is correlated with the increasing number of local swine operations since 1990. A less significant trend at Rowan County site NC34 is found, which is also likely the result of increasing local NH_3 emissions and not the result of increasing area I emissions.

A source–receptor relationship has been developed for five NADP/NTN sites surrounding an area of strong NH_3 emission located over southeast North Carolina. For this analysis, boundary layer air mass back trajectories based on daily precipitation information are used in conjunction with weekly NH_4^+ concentrations in precipitation. This information is incorporated into a source–receptor regression model to test for the dependence of weekly NH_4^+ concentration in precipitation on the percentage of back trajectories during a week which are possibly influenced by this area of strong NH_3 emission.

Results show that NH_4^+ concentration in precipitation is positively correlated with the percentage of influenced trajectories during a week at sites up to approximately 80 km away. For those weeks during which 25% or more boundary layer air mass trajectories traversed area I, NH_4^+ concentration in precipitation at Scotland County site NC36 is approximately 44% higher than other weeks. At Wake County site NC41, NH_4^+ concentration in precipitation is at least 50% higher for those weeks during which 25% or more trajectories traversed area I.

Results from this analysis show that NH_3 emitted from area I is being transported over distances which would allow direct wet deposition as NH_4^+ or NH_3 to nitrogen sensitive coastal and estuarine waters. This also suggests that NH_3 emitted from area I is being wet deposited as NH_4^+ or NH_3 to all river basins in the North Carolina Coastal Plain region.

The swine industry accounts for roughly 21% of all NC nitrogen emissions and 93% of the total hog population resides in the Coastal Plain region of the state. The fraction of TAN being deposited to NC coastal and estuarine waters which can be attributed to agricultural NH_3 emissions over the southeast part of the state may therefore be significant. This study points to the need for broader regulations governing nitrogen emissions. As Paerl (1995) points out, atmospheric nitrogen emissions have increased in a largely unregulated manner globally over the last four decades. In the US, nitrogen emission restrictions primarily consist of NO_x regulations. Over the past several years it has become apparent that excess nitrogen can have acute and chronic detrimental effects on coastal and estuarine ecosystems. In coastal states such as North Carolina, whose NH_3 emissions represent a significant portion of overall nitrogen emissions, regulations on primary NH_3 sources, in addition to NO_x restrictions, may be warranted. In the future, it may be possible for us to mitigate the influence of ammonia emissions through chemical or physical process controls.

Abstract Concentrated animal feeding operations (CAFOs) are the principal means of livestock production in the USA and Europe, and these industrial-scale facilities have a high potential to pollute nearby waterways. Chemical and biological stream water quality of a swine and poultry CAFO-rich watershed was investigated on 10 dates during 2013. Geometric mean fecal coliform counts were in the thousands at five of seven sites, especially in locations near swine waste sprayfields. Nitrate concentrations were very high and widespread throughout the watershed, with some individual samples yielding >10 mg-N/L. Ammonium concentrations were likewise high, but greatest near swine waste sprayfields, ranging up to 38 mg-N/L. Five-day biochemical oxygen demand (BOD5) concentrations exceeded 10 mg/L in 11 of 70 stream samples, reaching as high as 88 mg/L. BOD5 concentrations were significantly correlated with components of animal waste including total organic carbon, ammonium, and phosphorus, as well as the nutrient response variable chlorophyll *a*. The degree of nutrient and fecal contamination did not significantly differ between rainy and dry periods, indicating that surface and groundwater pollution occurs independently of stormwater runoff. This research shows that industrial-scale swine and poultry production leads to chronic pollution that is both a human health and ecosystem hazard. There are approximately 450,000 CAFOs currently operating in the USA, with the majority located in watersheds feeding major riverine and estuarine systems with known water quality problems. Current US waste management protocols for this widespread system of livestock production fail to protect freshwater and estuarine ecosystems along the US Mid-Atlantic, Southeast and Gulf coasts, and expansion into industrializing nations will likely bring severe pollution with it.

Keywords CAFO · Nutrients · Fecal bacteria · BOD · Algal blooms

1 Introduction

Industrial-scale livestock production is the most common and widespread means of swine and poultry production in the USA and Europe (Thu and Durrenberger 1998; Thorne 2007) and occurs within facilities known as concentrated, or confined, animal feeding operations (CAFOs). The USEPA (2014) defines large CAFOs as containing ≥1000 head of beef cattle, 2500 swine >25 kg, 10,000 swine <25 kg, 125,000 chickens, 82,000 laying hens, or 55,000 turkeys. Large-scale production of livestock in CAFOs involves shipping in vast quantities of feed from elsewhere (often from other states) which results in the deposition of large amounts of excretory nitrogen, phosphorus, organic matter, and fecal microbes in the watershed where the CAFO is located (Cahoon et al. 1999; Mallin and Cahoon 2003). Waste generated by swine in CAFOs is hosed

e-mail: mallinm@uncw.edu

through slats in the floor of confinement buildings and is drained or pumped outdoors into a cesspit which the industry calls a "lagoon." Periodically, the liquid waste supernatant of lagoons is pumped out and sprayed onto surrounding fields (i.e., sprayfields), which are planted with a cover crop such as Bermuda grass to absorb excess nutrients. Poultry waste is usually collected as dry litter, mixed with straw, and spread on neighboring fields; some CAFOs containing laying hens use the lagoon system. However, the production of vast quantities of animal manure within watersheds can overload the ecosystem's capacity to dilute and process such waste (Carpenter et al. 1998; Weldon and Hornbuckle 2006). According to the USEPA (2014), there are approximately 450,000 CAFOs in the USA, unevenly distributed with the vast majority concentrated in a few states. While inventory and sales vary year to year, the largest swine-producing states include Iowa, North Carolina, Minnesota, Illinois, and Nebraska; the largest broiler chicken producers include Arkansas, Alabama, Mississippi, North Carolina, and Texas; and the largest turkey producers include North Carolina, Arkansas, Minnesota, Missouri, and South Carolina (USDA 2014a). This investigation did not include cattle CAFOs; however, cattle production is especially large in Texas, Nebraska, Kansas, Oklahoma, Iowa, Mississippi, and Wisconsin (USDA 2014a). The CAFO system has currently expanded beyond the USA and northern Europe into Eastern Europe and South America (Thorne 2007).

Serious human health (Cole et al. 2000; Wing and Wolf 2000) and environmental impacts (Campagnolo et al. 2002; Burkholder et al. 2007) of industrial animal production have been documented by researchers, including water quality impacts. The acute polluting impacts of large-scale accidents and hurricanes involving CAFO waste on freshwater streams and estuaries have been well documented (Burkholder et al. 1997; Mallin 2000; Mallin et al. 1999). The location of many CAFOs on river and stream floodplains renders receiving water vulnerable to such accidents, especially during major storms (Wing et al. 2002). CAFOs have been cited as supplying excessive nitrate to Midwestern streams in Ohio and Iowa (Weldon and Hornbuckle 2006; Hoorman et al. 2008). Karr et al. (2001) were able to trace nitrogen that was derived from CAFOs several kilometers downstream using isotopic techniques. A broad-scale study found that streams whose watersheds contained swine and poultry CAFOs had significantly higher concentrations of ammonium, nitrate, and total N than streams whose watersheds lacked CAFOs (Harden 2015). Additionally, the deposition of manure and urine in storage lagoons and on surrounding fields has caused ammonium and/or nitrate pollution of groundwater on or near production facilities (Ritter and Chirnside 1990; Westerman et al. 1995; Liebhardt et al. 1979).

However, chronic pollution of surface waters by a suite of potential pollutants has not been comprehensively assessed for a CAFO-rich watershed. This research investigated physical, chemical, and biological pollution of stream waters in a watershed containing numerous swine and poultry CAFOs while lacking industrial or municipal point sources of pollution and containing little traditional crop agriculture. The degree of pollution was determined from two perspectives: first, since this stream consists of public waters, it was of interest to investigate whether or not these waters were impaired based on state chemical and biological standards. Second, comparative water quality conditions based on parameter concentrations were made using the published literature on coastal plain streams as well as broad-scale literature analyses of streams in general.

Stocking Head Creek (Fig. 1) is a second-order blackwater stream located in the Northeast Cape Fear River basin in eastern North Carolina. Catchment area is 1980 ha (4893 acres), and stream length to where it enters the Northeast Cape Fear River is 22.1 km (13.7 mi). The watershed soils are dominated by Noboco loamy fine sand, Johns fine sandy loam, Autryville loamy fine sand, Pactolus fine sand, Lumbee sandy loam, and Marvyn and Gritney soils (NRCS 2014a). There is some traditional row crop agriculture within this watershed, but aerial photography indicates that coverage by such is small in comparison to CAFO sprayfields and forest cover. The Northeast Cape Fear River is a fifth-order tributary of the sixth-order Cape Fear River, the watershed of which contains approximately half of the 9,000,000 plus swine in North Carolina as well as vast numbers of confined poultry. Cahoon et al. (1999) estimated that the Cape Fear River basin annually received 82,700 metric tons of nitrogen and 26,000 metric tons of phosphorus as animal waste in this watershed from CAFOs alone. Thus, CAFO-rich subwatersheds are likely to be sources of considerable nutrient pollution to larger rivers and estuaries (Mallin and Cahoon 2003; Burkholder et al. 2007). As such, our primary objective was to investigate potential environmental impacts to a stream draining a swine and poultry

CAFO-rich watershed. From July to October 2013, we sampled four main channels and three tributary stations for a broad selection of physical, chemical, and biological water quality parameters.

The location of swine CAFOs and the permitted numbers of swine for each are available from the North Carolina Department of Environment and Natural Resources, and we used these data to map and enumerate swine CAFOs. However, the N.C. Department of Agriculture and Consumer Services (NCDA & CS) does not provide such watershed-specific information on poultry CAFOs to the public or other agencies, although counts of each type of livestock are available on a county-by-county basis from NCDA & CS. Thus, a second objective was to obtain the locations of poultry CAFOs within this basin and estimate poultry numbers confined within them using alternative GIS and aerial photography-based techniques.

2 Methods

2.1 Sample Locations and Frequency

Seven stations were sampled, four on the main stream and two on first-order tributaries (Table 1, Fig. 1). The seventh station (MC-50) was collected on second-order Maxwell Creek, which joins lower Stocking Head Creek before it enters the Northeast Cape Fear River. The Maxwell Creek watershed also contains CAFOs, but they are not as concentrated near stream waters as those in the Stocking Head Creek watershed and they are not quantified in this investigation; MC-50 is used as a comparison site herein. All sites were sampled from bridges on public right-of-ways. The sampling design included five sample trips each taken during two different 30-day periods, one in mid-summer and one in fall. This was planned in accordance with the North Carolina Department of Environment and Natural Resources (NCDENR)'s protocol for fecal coliform sampling for assessment of whether a given stream supported its designated use or if it belongs on the state's 303(d) list for impaired waters. Sampling of Stocking Head Creek occurred during both dry and wet periods. Rainfall data were obtained from the NC CRONOS data set, using Station #319026 Wallace, latitude 34.72, longitude 77.97778, in Duplin County. Rainfall amount was computed for the day of sampling, the day of sampling plus the previous 24-h period, and the day of sampling plus the previous 48-h period.

2.2 Sample Parameters and Methodology

To obtain a full perspective of the stream's physical and chemical qualities, a suite of parameters was sampled. Field measurements were made on-site using YSI field meters calibrated and checked according to standard procedures for water temperature, pH, dissolved oxygen, turbidity, and specific conductance. Samples were collected from surface waters by bucket haul and distributed into pre-cleaned bottles for nutrient (ammonium, nitrate, total nitrogen, orthophosphate, total phosphorus), total suspended solids (TSS), chlorophyll *a*, and 5-day biochemical oxygen demand (BOD5) analyses. Samples were kept on ice and delivered to the laboratory for subsequent analysis within proper holding times. Chain of custody records was maintained.

Analytical methods used (see APHA 1995; USEPA 1983, 1997) were as follows: TSS, SM 2540D; ammonium, EPA 350.1; nitrate+nitrite, EPA 353.2; TKN, EPA 351.2, total nitrogen as calculation of TKN+nitrate; orthophosphate, SM 4500PE; total phosphorous, SM 4500 PE; BOD5, SM 5210B; and fecal coliform bacteria, SM 9222D MF. Total organic carbon concentrations (TOC) were obtained during the fall sampling in an effort to better understand causes of high BOD5 levels that were seen in the summer; the analytical method used for TOC was SM 5310B. Chlorophyll *a* measurements were performed using EPA method 445.0, based on the Welschmeyer (1994) fluorometry method.

2.3 Statistical Analyses

Summary statistics were derived for each parameter (means, standard deviations, medians, minimum, maximum for all data, also geometric means for fecal coliform analysis). Data were tested for normality using the Shapiro-Wilk test, with most chemical and biological parameters requiring log-transformation prior to further statistical analysis. An important consideration was whether or not the pollutant concentrations measured in Stocking Head Creek were the result of acute stormwater-driven surface runoff into the creek or a result of chronic, long-term pollution impacting groundwater as well as surface waters. As such, we analyzed whether or not rainfall produced higher pollutant

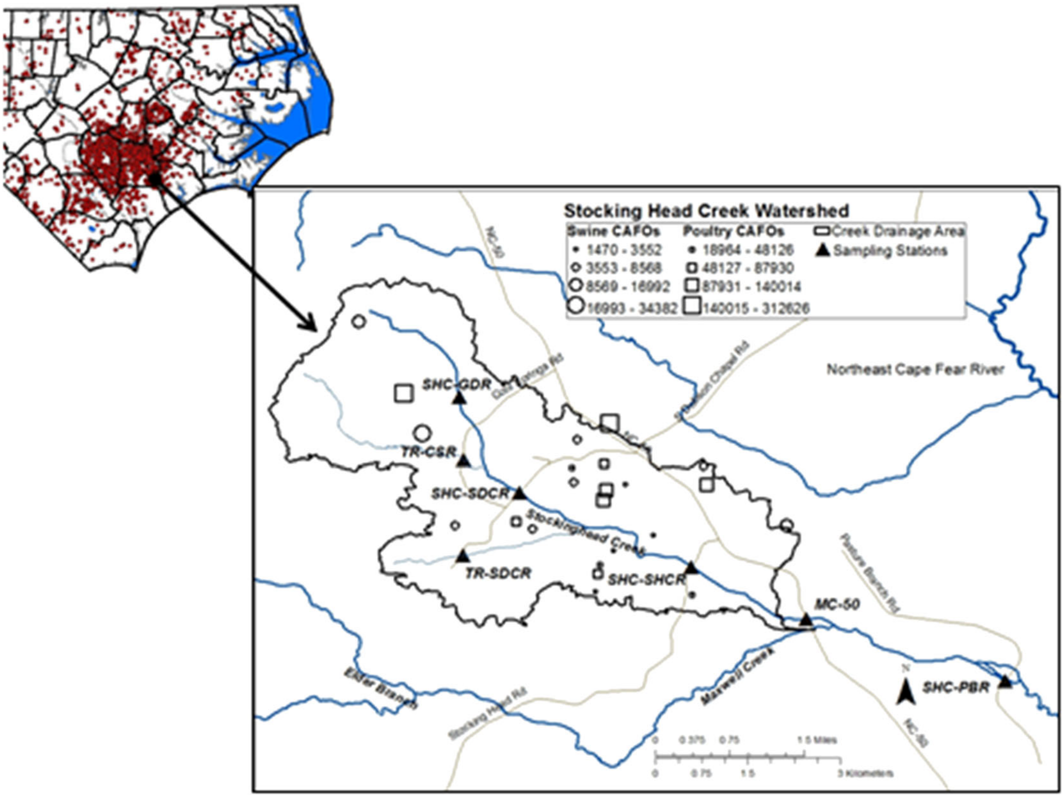

Fig. 1 Map of the Stocking Head Creek watershed, eastern North Carolina, USA, including streams, roads, sampling sites, and swine and poultry CAFOs sorted by size groups. *Inset* is the North Carolina Coastal Plain with *red dots* indicating location of swine CAFOs

parameter concentrations than occurred on non-rain periods. Measurable rainfall occurred either on the day of sampling or within the 48 h preceding the sample day on five of 10 sampling occasions. They were August 1 and 13, September 24, and October 8 and 10. *T* tests were used to test selected parameter concentrations between wet and dry periods (α=0.05). Parameters tested for wet-dry differences included ammonium, nitrate, and fecal coliform bacterial concentrations. To assess potential chemical and biological parameters influencing BOD, correlation and regression analyses were performed using SAS (Schlotzhauer and Littell 1987).

2.4 CAFO Map Construction

A digital elevation model was downloaded from the USGS geospatial portal and used as the data input to delineate the watershed boundaries of Stocking Head Creek. The ArcMap 10.1 Hydrology toolset was utilized, and the catchment area of Stocking Head Creek system was identified. A shapefile including all of the documented animal operations from the NC OneMap geospatial portal was clipped to only display those CAFOs within the newly defined watershed area. After establishing these boundaries and existing CAFOs (primarily swine operations), 2012 orthophotography from the North Carolina OneMap service was analyzed for undocumented CAFOs. The signature shape of the farm buildings (long rectangles side by side) was used to identify these locations, which were presumed to be poultry CAFOs. These were manually digitized as polygons superimposed on the aerial photos, and added to the existing CAFO location data to provide a more accurate assessment of the total number of animal operations within the Stocking Head Creek watershed. Besides the lack of inclusion on the NCDENR database, other characteristics that distinguish North Carolina poultry from swine CAFOs from the air include a lack of waste lagoons for poultry (all swine CAFOs contain waste lagoons but few poultry CAFOs do—egg-laying facilities only). Also, based on aerial photography, poultry CAFO structures are generally longer than swine

Table 1 Description and location of sampled sites, roughly in descending order from headwaters downstream in Stocking Head Creek. See Fig. 1 for locations, nearby roads, and CAFOs

SHC-GDR (Stocking Head Creek at Graham Dobson Road): N 34.91197, W 77.94507. This location collects the uppermost branch of Stocking Head Creek; a swine CAFO and sprayfields are present several hundred of meters upstream from the sampling site. Aerial photos indicate that this stream initiates in what is now a swine CAFO sprayfield.

TR-CSR (unnamed first-order tributary at Cool Springs Road): N 34.90279, W 77.94440. This site had no immediately adjoining CAFOs or sprayfields, but the GIS map (Fig. 1) indicates a large swine CAFO and a large poultry CAFO upstream.

TR-SDCR (unnamed first-order tributary entering Stocking Head Creek at South Dobson Chapel Road): N 34.88878, W 77.94453. Grazing cattle were occasionally present upstream within 75 m of this site, and waste spraying equipment was stationed within 50 m upstream on several sampling dates.

SHC-SDCR (Stocking Head Creek at South Dobson Chapel Rd.): N 34.89796, W 77.93628. Numerous CAFOs, sprayfields, and grazing cattle were located within 200 m of the stream at this site.

SHC-SHCR (Stocking Head Creek at Stocking Head Road): N 34.88710, W 77.91124. A large CAFO sprayfield was located within 50 m of the stream, with a ditch carrying sprayfield runoff that emptied directly into the stream at this location.

MC-50 (Maxwell Creek at SR 50): N 34.87950, W 77.89438. This sampling site adjoined a wetland area which was hydrologically connected to Stocking Head Creek. The Maxwell Creek watershed also contains CAFOs, although fewer than those in Stocking Head Creek watershed (Fig. 1).

SHC-PBR (Stocking Head Creek at Pasture Branch Road): N 34.87043, W 77.86539. This location was the farthest downstream site sampled. This downstream area also likely receives inputs from CAFOs in the Maxwell Creek drainage. There was also an adjoining forested wetland that supplied flow to the stream here.

CAFOs and have the feeding silo located at the building midpoint, while swine CAFOs have feeding silos located at the building's end.

The dimensions of each poultry building were computed from the digitized aerial photographs. Maximum bird (considered as broiler chickens) populations per building were estimated by assuming 743 cm^2 (0.80 ft^2) of space allotted per bird as is standard for a major poultry producer (Sanderson Farms 2007). The United Egg Producers (2010) recommend 436–557 cm^2 (0.47 to 0.60 ft^2) of space per egg-laying chicken; thus, we feel our counts are conservative. As there is no way to distinguish chicken from turkey operations from the air, for the purposes of this study, we assumed all broiler chickens. As a comparative reference regarding livestock manure production, the National Resources Conservation Service within the US Department of Agriculture uses animal units, i.e., 1 cow=9 hogs=455 broiler chickens=67 turkeys (NRCS 2014b).

3 Results

The Stocking Head Creek watershed (excluding Maxwell Creek) contains 13 swine CAFOs that are permitted by NCDENR for collectively 108,068 heads of swine. This watershed also contains 11 poultry CAFOs, consisting of a total of 42 individual buildings. Average poultry house size was approximately 2323 m^2 (25,000 ft^2), with an average capacity of 31,250 birds. Thus, the watershed can house a maximum of 1,312,500 broiler chickens or equivalent turkeys using the animal unit conversions above. Grazing cattle were visibly present in this watershed (with some photographed grazing directly under swine waste sprays), but an accurate count is beyond the capability of this study. Confined swine, poultry, and cattle produce large quantities of manure; conversion factors of excreted waste into total nitrogen, phosphorus, and fecal bacteria for these three livestock types can be found in Mallin and Cahoon (2003). While the local human population relies on septic systems for sewage treatment, aerial photography revealed only 67 human dwellings in the watershed, yielding a scant 0.03 septic systems/ha.

Summer water temperatures ranged between 22.0 and 28.0 °C, and fall water temperatures ranged from 16.1 to 22.6 °C. Most sampling events reflected neutral stream pH conditions ranging from 6.5 to 7.3. Dissolved oxygen concentrations ranged from mildly hypoxic (3.5 mg/L) to supersaturation (17.0 mg/L) during an algal bloom. Average turbidity by station ranged from 1.1 to 21.0 NTU (nephelometric turbidity units). Total suspended solids (TSS) in most cases were less than 25 mg/L (Table 2). Elevated TSS concentrations occurred a few times primarily at the tributary station TR-SDCR.

Ammonium in Stocking Head Creek during the 10 sample trips ranged from the detection limit (0.05 mg/L) to 37.8 mg/L (Table 2). Highest ammonium concentrations were found at station TR-SDCR, followed by station SHC-SHCR. These stations are both within 50 m of swine CAFO sprayfields (Table 1, Fig. 1). Nitrate concentrations in Stocking Head Creek were very high (Table 2). Whereas the highest ammonium

Table 2 Water quality parameter concentrations in Stocking Head Creek, 2013, given as mean±standard deviation/median/range; fecal coliforms as geometric mean/range. n=70, except for TOC where n=35

concentrations were found at the two sites located closest to waste sprayfields, several sites showed high nitrate, including sites distant from sprayfields (Table 2; Fig. 1). Concentrations ranged from 0.08 to 13.60 mg-N/L, with station means ranging from 0.30 to 7.94 mg-N/L. Particularly high nitrate concentrations were documented at these four sites: SHC-GDR, TR-CSR, SHC-SDCR, and SHC-SHCR. On 12 of 70 sampling occasions, stream nitrate concentrations exceeded 8 mg-N/L. Total nitrogen (TN) concentrations ranged from 0.11 to 46.70 mg-N/L, while highest individual station average TN concentrations occurred at TR-SDCR, TR-CSR, and SHC-SHCR. The TN values in this stream were dominated by inorganic nitrogen (i.e., nitrate and ammonium) rather than organic nitrogen, with average percent inorganic N ranging from 80 to 100 % of TN, depending upon station.

Orthophosphate concentrations in Stocking Head Creek ranged from 0.04 to 5.45 mg-P/L, with station means ranging from 0.11 to 1.78 mg-P/L (Table 2). Highest concentrations were found at station TR-SDCR, followed by SHC-SHCR. Total phosphorus ranged from 0.040 to 10.70 mg-P/L, and station means ranged from 0.15 at SHC-GDR to 2.83 mg-P/L at TR-SDCR, with SHC-SHCR second highest at 0.50 mg-P/L (Table 2). Most TOC concentrations were in the 10–20 mg/L range; however, higher TOC concentrations occurred at TR-SDCR and SHC-SHCR, the stations nearest to sprayfields (Table 2).

Chlorophyll *a* represents the amount of suspended live microalgal biomass found in a sample of water (Wetzel 2001). Elevated chlorophyll *a* concentrations (algal blooms) occurred at TR-SDCR on July 29 (40 μg/L) and at this same site on September 18 (44 μg/L), with smaller blooms occurring several times at other sites. Thus, algal blooms occurred within Stocking Head Creek, but were inconsistent in time and among sampling sites (Table 2).

Biochemical oxygen demand (BOD) is a measure of the organic matter available for consumption by the bacteria in a body of water during respiration; excessive BOD can lead to hypoxia. Five-day BOD (BOD5) varied widely (Table 2), from background concentrations of 1.0 mg/L up to high values of 21 mg/L at MC-50, 25 mg/L at SHC-SHCR, and the maximum of 88 mg/L at station TR-SDCR. That station maintained the highest overall BOD5 concentrations (Table 2), reaching 10 mg/L or more on six of 10 dates, while station SHC-SHCR exceeded 10 mg/L on three dates. The stream stations with highest average BOD concentrations were those in closest proximity to swine waste sprayfields (Table 1; Fig. 1).

North Carolina uses fecal coliform bacteria counts as a proxy for potentially pathogenic bacteria in fresh water bodies; this standard is commonly used throughout the southeast of the USA (EPA Region 4) for freshwater contact. The NC protocol (NCDENR 1999) for sampling and the means for determining fecal impairment of a water body state that fecal coliform counts shall not exceed a geometric mean of 200 CFU/100 mL based on at least five consecutive samples during any 30-day period nor exceed 400 CFU/100 mL in more than 20 % of the samples examined during such period. Fecal coliform counts for Stocking Head Creek were generally very high (Fig. 2). During summer 2013, the upper five stations exceeded 400 CFU/100 ml on 100 % of the time sampled, and the geometric means for all seven stations exceeded 200 CFU/10 mL for five samples in 30 days. Fecal coliform counts for Stocking Head Creek in fall 2013 were even higher than those in summer; the upper five stations exceeded 400 CFU/100 ml on 96 % of the time sampled, and the geometric means for six of the seven stations exceeded 200 CFU/10 mL for five samples in 30 days. During both the summer and the fall sampling periods, fecal coliform criteria for impaired waters were well exceeded. Elevated fecal coliform counts occurred during both wet and dry periods. Highest fecal coliform counts occurred at TR-SDCR and SHC-SHCR, the stations nearest to sprayfields. Most other stations also had high counts, with geometric means exceeding 1000 CFU/100 mL (Table 2, Fig. 2). While lower Maxwell Creek (MC-50) maintained the lowest counts, it still exceeded state criteria for impaired waters.

An important consideration is whether or not the high pollutant values measured in Stocking Head Creek were the result of acute stormwater-driven surface runoff into the creek or a result of chronic, long-term pollution impacting groundwater as well as surface waters. As such, we analyzed whether or not rainfall produced higher pollutant parameter concentrations than occurred

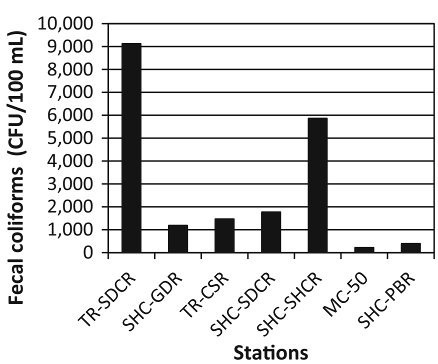

Fig. 2 Fecal coliform bacteria counts (as colony-forming units/100 mL) for Stocking Head Creek watershed sampling sites, presented as geometric mean of 10 samples per site. Note that the NC freshwater recreational standard is 200 CFU/100 mL

on non-rain periods. For all non-rain sample dates and stations, the fecal coliform geometric mean was 1455 CFU/100 mL, and counts exceeded 200 CFU/100 mL on 31 of 35 samples with 89 % exceedence of the state standard. For all rain periods and stations combined, the fecal coliform geometric mean was 1467 CFU/100 mL, and counts exceeded 200 CFU/10 mL on 30 of 35 samples with 86 % exceedence of the state standard. *T* test results showed no significant difference in means between wet and dry periods (p=0.49; df=68). Thus, fecal coliform pollution of Stocking Head Creek was not rain dependent; rather, fecal coliform pollution was a *chronic* condition.

Ammonium concentrations during non-rain periods were 2.67±7.59 mg-N/L (mean±standard deviation) vs. rain period concentrations of 1.56±4.65 mg-N/L. *T* test results on log-transformed data showed no significant difference in means (p=0.64; df=68). Nitrate concentrations during non-rain periods were 4.45±3.68 mg-N/L vs. rain concentrations of 3.82±3.56 mg-N/L. *T* test on log-transformed nitrate data showed no significant difference in means (p=0.38, df=68). Thus, inorganic nitrogen concentrations were not increased by rainfall-driven surface runoff, but instead they were a chronic condition in Stocking Head Creek, indicating groundwater pollution.

4 Discussion

Ammonium is a reduced form of inorganic nitrogen that is a major component of fresh human sewage or animal excreta (Clark et al. 1977). It is readily used by algae and bacteria, and an overabundance of ammonium can stimulate eutrophication (Wetzel 2001). Research in coastal plain blackwater streams and rivers has indicated that ammonium concentrations of 0.5 mg/L (ppm) or higher can stimulate algal blooms (Mallin et al. 2004). Additionally, ammonium exerts a significant chemical oxygen demand in sewage treatment plant discharges (Clark et al. 1977), as it is oxidized to nitrate. Thus, excess ammonium can lead to aquatic ecosystem deterioration through more than one pathway. The ammonium concentrations found in Stocking Head Creek, particularly at the sites nearest to sprayfields, greatly exceeded ammonium concentrations typically found in other coastal plain streams and rivers (Smock and Gilinsky 1992; Mallin et al. 2004, 2006). Previously, only during swine or poultry lagoon breaches have such concentrations been found in receiving streams in this region (Burkholder et al. 1997; Mallin 2000).

Ammonium pollution from CAFOs is not limited to runoff or seepage entering waterways. Volatilization of ammonia from CAFOs releases vast amounts of inorganic nitrogen to the atmosphere. On the North Carolina Coastal Plain alone, annual ammonia emissions from swine and poultry have been estimated as 73,500 and 22,900 metric tons (Costanza et al. 2008). Regionally, ammonia volatilization from waste lagoons, sprayfields, and litterfields carries ammonia well outside of the watershed of origination (Walker et al. 2000; Costanza et al. 2008) and is reflected in elevated ammonium concentrations in rainfall measurements downwind (Willey et al. 2006). In a study of the two most CAFO-rich North Carolina watersheds, ammonium concentrations were found to have increased approximately 500 % in the Neuse River and 315 % in the Northeast Cape Fear River between 1995 and 2005 (Burkholder et al. 2006).

Ammonium at the concentrations found in Stocking Head Creek can have other impacts besides increasing algal blooms and chemical oxygen demand. Recent studies (see review by Glibert et al. 2015) have indicated that ammonium at these concentrations can stimulate cyanobacterial production as well as increase the production of toxic microcystin, while suppressing growth of diatoms which are generally benign organisms that support the higher trophic levels. Ammonium has been found to preferentially enhance cyanobacterial growth in locales as diverse as San Francisco Bay (Glibert et al. 2014) to the South Carolina Coastal Plain (Siegel et al. 2011). Interestingly, in July 2011, an unprecedented (during 23 years of monitoring) bloom of cyanobacteria (mostly *Anabaena planctonica*) occurred in the blackwater Northeast Cape Fear River downstream from its confluence with Stocking Head Creek (and several other CAFO-impacted watersheds). The bloom lasted for several weeks and, upon decomposition, resulted in a BOD that decreased river DO from 5.3 to 0.7 mg/L (S. Petter Garrett, NCDENR, personal communication August 4, 2011).

Nitrate is likewise readily used by visible plants and algae for growth. It is mobile in soils and readily moves through the water table to enter streams (Keeney 1986). Average nitrate concentrations at six of seven stations well exceeded levels known to stimulate algal production and lead to elevated BOD in blackwater streams (Mallin et al. 2004). Nitrate concentrations in this stream were well in excess of those reported from other streams in the southeast USA (Edwards and Meyer 1987; Smock and Gilinsky 1992; Mallin et al. 2004, 2006; Carey et al. 2007), but in line with nitrate concentrations reported from Ohio watersheds impacted by runoff from combined row crop and dense CAFO presence (Hoorman et al. 2008). Regarding human health, there is a US EPA drinking well nitrate standard of 10 mg-N/L to prevent blue baby syndrome (also called methemoglobinemia). It is notable that on three occasions, even the 10-mg/L standard for drinking well water was exceeded, and in seven of 70 samples collected, stream nitrate concentrations exceeded 9 mg/L, close to the methemoglobinemia standard.

There are no point-source discharges entering this creek. The local human population uses septic systems, but the 67 human dwellings in the watershed are spaced well away from the creek, with sprayfields located between human dwellings and riparian areas. Thus, the principal sources of nitrate are swine CAFO waste (either runoff from sprayfields, or subsurface movement into the stream), poultry litter spread on fields, and cattle manure deposited on land. Nitrate concentrations of similar magnitude have been documented from subsurface waters draining sprayfields and surface streams passing through or near swine sprayfields (Evans et al. 1984; Stone et al. 1995). Total nitrogen concentrations in Stocking Head Creek were very high compared to available data from other blackwater coastal plain streams (Smock and Gilinsky 1992; Mallin et al. 2004, 2006). To provide a wider perspective, using a large data set of 1070 streams, Dodds et al. (1998) determined that average TN concentrations >1.5 mg/L were characteristic of eutrophic conditions; this level was well exceeded according to average station TN at six of the seven sites (Table 2).

Orthophosphate is the most common form of inorganic phosphorus directly used by algae. It is not very mobile in soils and adsorbs readily to soil particles (Wetzel 2001). Orthophosphate station means were generally 2–10 times the average levels found in a selection of less-impacted blackwater coastal plain streams (Edwards and Meyer 1987; Mallin et al. 2004, 2006; Carey et al. 2007). Average orthophosphate concentrations in Stocking Head Creek were similar to those in streams draining mixed row crop and CAFO watersheds in Ohio (Hoorman et al. 2008).

Concentrations of TP≥0.50 mg-P/L or greater can increase BOD in blackwater streams by serving as a substrate assimilated by ambient bacteria (Mallin et al. 2004). In the present study, TP was higher than 0.50 mg-P/L in 11 of 70 samples. Using data from 1366 streams, Dodds et al. (1998) concluded that TP concentrations >0.075 mg/L were characteristic of eutrophic streams; average TP at all sites exceeded this threshold (Table 2). Additionally, a study of soils in eastern North Carolina using a soil phosphorus index developed by the N.C. Division of Agronomy found that the soils in counties where CAFOs were abundant (including Duplin County) contained excessively high index values (Cahoon and Ensign 2004). We note that besides direct eutrophication impacts, highly variable nutrient ratios (such as seen with this impacted stream) can lead to changes in taxonomic structure for resident phytoplankton and higher trophic levels (Glibert et al. 2015).

Bacteria require phosphorus both structurally and energetically (Kirchman 1994), and fecal bacteria growth in stream sediments can be stimulated by inputs of phosphate (Toothman et al. 2009). Also, fecal coliform bacteria within the water column can be significantly stimulated by additions of organic or inorganic P inputs >0.100 mg/L, increasing survival and reproduction (Chudoba et al. 2013). Mean and median concentrations of TP in all Stocking Head Creek stations exceeded 0.100 mg-P/L. The data suggest that high phosphorus inputs to stream waters polluted by fecal bacteria can magnify human health risks, as well as ecosystem impacts.

BOD5 concentrations at times were very high in Stocking Head Creek (Table 2). Comparison of BOD5 from many streams and rivers in coastal North Carolina indicates that concentrations of 1 to 2 mg/L are background for minimally impacted streams (Mallin et al. 2006). Elevated BOD can be stimulated by several causes. One common cause of elevated BOD is the introduction of organic materials such as human sewage or animal waste into the water; thus, dissolved organic carbon, if labile, can stimulate BOD (Clark et al. 1977). Another cause is algal blooms, which upon death and decay create a source of labile organic matter available for bacterial consumption. In a variety of coastal plain freshwater streams, tidal creeks, and lakes, Mallin et al. (2006) found strong statistical correlations between BOD and chlorophyll *a*. Ammonium pollution can exert a significant chemical oxygen demand in waterways, and elevated phosphorus concentrations can lead to elevated BOD by directly stimulating bacteria growth. In Stocking Head Creek, BOD5 was positively correlated with TOC (r=0.833. p<0.0001), ammonium (r=0.666, p<0.0001), TP (r=0.626, p<0.0001), orthophosphate (r=0.569, p<0.0001), chlorophyll a (r=0.316, p=0.008), and TN (r=0.284, p=0.017). Multiple regression analyses indicated that the best predictive linear model for BOD5 in this stream was (as log-transformed data)

$$\mathrm{BOD5} = 0.952(\mathrm{TOC}) + 0.367(\mathrm{AMM})–3.961,\ r^2 = 0.85,\ p < 0.0001$$

Thus, the high BOD in Stocking Head Creek is directly related to common components of animal waste (TOC, ammonium, phosphorus) as well as to chlorophyll a, a response variable to nutrient inputs. As mentioned, the lower Cape Fear River and its estuary are on the 303(d) list due to DO violations. Stocking Head Creek enters the Northeast Cape Fear River, which enters the lower Cape Fear River at Wilmington. The high levels of BOD observed in Stocking Head Creek as well as the high nitrate, ammonium, and fecal bacteria loads contribute to the low DO concentrations frequently occurring in summer in the Northeast Cape Fear River.

Most troublesome from a human health perspective is the data indicating that Stocking Head Creek is highly polluted by fecal bacteria, by both measures of the NC criteria for impaired waters. The upper five stations exceeded 400 CFU/100 ml on 96–100 % of the time sampled, and six of seven stations exceeded a geometric mean of 200 CFU/10 mL for five samples in both 30-day periods. Importantly, elevated fecal coliform counts occurred during both wet and dry periods; this creek is chronically polluted by fecal bacteria. The stimulatory effect of phosphorus loading on fecal bacteria (Chudoba et al. 2013) further exacerbates the potential human health issues. Fecal bacteria generated by livestock within the watershed are not confined to the immediate watershed but are likely to be carried downstream into higher order streams. A bacterial source-tracking study using molecular techniques demonstrated swine waste contamination at Cape Fear River system sites well downstream from swine CAFOs (Arfken et al. 2013).

In addition to surface waters, groundwater under and near swine and poultry CAFOs can contain very high inorganic nitrogen concentrations. Ritter and Chirnside (1990) found ammonium concentrations up to 960 mg-N/L and nitrate up to 50 mg-N/L in test wells in close proximity to swine waste lagoons on the Delmarva Peninsula. In North Carolina, Westerman et al. (1995) analyzed seepage from two swine waste lagoons and found ammonium concentrations in nearby wells averaged more than 50 mg-N/L, with nitrate of 6–15 mg-N/L. In other areas, it has also been observed that both spreading and spraying of livestock waste on the landscape will lead to excessive nitrate in groundwater (Liebhardt et al. 1979).

The water table in this area varies seasonally but is relatively near the land surface on average. No groundwater level monitoring wells are immediately on-site, but the US Geological Survey operates a well 10 km southwest at Rose Hill (Well DU-157). At that well, annual average depth to the surficial water table from 2004 to 2014 ranged from 1.3 to 2.7 m, with an average of 2.2 m. The North Carolina Division of Water Resources operates a monitoring well 10 km southeast at Chinquapin (Well W29D9), and 2013 data showed depth to surficial water table ranging from 1.4 to 1.8 m below the land surface. The local predominating sandy loam soils (NRCS 2014a) have moderate to rapid permeability with permeability rates of 0.5–1.5 m/day and 1.5–3.0 m/day, respectively (USDA 2014b). Thus, following a swine waste spray event, nitrate (and likely some portion of the fecal bacteria load) could migrate into the water table in as little as a day or two and from there move laterally to the nearest stream. Thus, groundwater in a CAFO-rich watershed such as that of Stocking Head Creek is a source of nitrogen and fecal bacterial pollution to the stream waters, and continual (including non-storm event) groundwater inputs into the stream at selected locations results in chronic pollution. Simply considering overland runoff will underestimate the N flux to aquatic systems as this ignores infiltration and leaching (Carpenter et al. 1998). The lack of concentration differences in fecal coliform, ammonium, and nitrate concentrations between rainy and dry periods shows that the stream pollution is chronic and a result of normal CAFO operations and presently accepted waste disposal techniques.

This research has demonstrated that drainage basins rich in CAFOs cause chronic pollution that has both human health and ecosystem impacts. However, the scope of US confined animal operations is nationwide. Many CAFO-rich watersheds pollute freshwater streams and rivers, which eventually enter estuaries located on the Atlantic and Gulf coasts. For instance, poultry CAFO-rich Delaware, Maryland, and Virginia, and poultry and swine CAFO-rich North Carolina drain into middle-Atlantic estuaries. Major swine, poultry, and cattle-producing states such as Arkansas, Alabama, Iowa, Illinois, Minnesota, Missouri, and Texas in the Mississippi River drainage feed the Gulf of Mexico. As such, Weldon and Hornbuckle (2006) determined that for four major agricultural watersheds in Iowa, nitrate was strongly correlated with CAFO densities, and these watersheds made an outsized contribution to nitrate loading to the Mississippi River.

An extensive study covering 90 % of estuarine surface area in the USA (Bricker et al. 1999) concluded that severe eutrophication conditions (toxic algal blooms, bottom-water hypoxia, losses of submersed aquatic vegetation) were most prevalent along the middle Atlantic and Gulf Coast estuaries. Howarth et al. (2012) have demonstrated that estuarine nitrogen discharge from a wide selection of rivers in Europe and North America is positively correlated with net watershed nitrogen inputs. That study showed that for watersheds that have positive increases in animal feed from outside the system, there is a strong correlation with riverine N flux. Many of those rivers drain watersheds rich in poultry CAFOs, swine CAFOs, or both. The magnitude of industrial livestock production indicates that not only are immediate watersheds severely polluted but the collective impacts of the numerous subwatersheds draining CAFO-rich areas contribute to major ecosystem impacts far downstream as well. As the magnitude of the CAFO style of industrial livestock production grows beyond the USA and Europe into developing nations (Thorne 2007), highly concentrated nutrient and fecal microbial pollution from these sources will similarly expand.

Acknowledgments For funding, we thank the Waterkeeper Alliance. We thank Mary Grace Lemon and Rena Turner for the laboratory help. For project facilitation, we thank Kelly Hunter Foster and Larry Baldwin of Waterkeeper and Kemp Burdette, Cape Fear Riverkeeper. For review comments, we thank Drs. JoAnn Burkholder and Lawrence B. Cahoon.

Introduction

The Cape Fear River Animal Feeding Operations Monitoring Study (CFRAFOMS) is an ongoing surface water quality monitoring study that evaluates water quality in watersheds adjacent to high concentrations of permitted animal feeding operations utilizing lagoon and spray fields for waste management. This report evaluates the analytical data obtained from water samples collected from surface water quality monitoring stations. The data presented in this report is from eleven monitoring stations in Duplin and Pender Counties (see Figure 1 and Table 1) and represents monitoring results from April 2018 to October 2019. Ten of the eleven monitoring stations are test stations located in Duplin County in watersheds with high concentrations of animal feeding operations. The monitoring station in Pender County is a reference/background station and no registered animal feeding operations are present in the drainage area of this station.

The CFRAFOMS was conducted as part of a settlement agreement between North Carolina Department of Environmental Quality (NCDEQ) and multiple parties that include the North Carolina Environmental Justice Network (NCEJN), The Rural Empowerment Association for Community Help (REACH), and The Waterkeeper Alliance, Inc. The CFRAFOMS was intended to provide NCDEQ an opportunity to evaluate surface water conditions in areas with a high concentration of animal feeding operations, and if surface water impacts were found, then to evaluate potential sources. The study also helps the NCEJN, REACH, and Waterkeeper Alliance Inc. to evaluate the terms discussed in the settlement agreement (Settlement Agreement.pdf).

Program Background

Animal waste management systems in North Carolina (NC) are regulated by the Animal Feeding Operations (AFO program in the Department of Environmental Quality's. The AFO Program is responsible for issuing permits and enforcing compliance activities on animal feeding operation facilities across the state. Animal operations are defined by General Statute 143-215.10B as feedlots involving more than 250 swine, 100 confined cattle, 75 horses, 1,000 sheep, or 30,000 poultry with a liquid waste management system. NCDEQ AFO Program has some of the most stringent permit requirements for AFOs in the country and is one of the few states that requires annual inspections of every permitted facility. Permitting requirements for animal feeding operations in North Carolina can be found at:
/about/divisions/water-resources/water-resources-permits/wastewater-branch/animal-feeding-operation-permits/permits.

The majority of NC swine AFOs are covered by the N.C. Swine State General Permit. The general permit contains performance standards, operation and maintenance requirements, monitoring and reporting requirements, policy for inspections and entry to the farms, general conditions and the penalty assessment policy. A Certificate of Coverage (CoC) is issued with each permit that is permittee-specific and designates the permitted number of animals and type of animal operation. All permitted animal operations are required to have a Certified Animal Waste Management Plan (CAWMP) that has been developed by a Certified Technical Specialist. The CAWMP identifies the fields to which the waste is applied, the crops to be grown and other operational details of the waste management system. Animal waste must be applied at no greater than agronomic rates – an amount that can be used productively by the crops planted.

North Carolina contains approximately 2,100 permitted swine farms and is the nation's second highest producer of swine. The CFRAFOMS was conducted primarily in Duplin County where there are 483 permitted animal farming facilities, which accounts for approximately 23% of the state's permitted swine facilities.

Methods

Surface Water Quality Monitoring Study Plan

The CFRAFOMS was designed to investigate potential water quality impacts in highly concentrated areas of AFOs. Ten (10) water quality monitoring stations and one reference/background station were included in this study (Figure 1). General information on the selected monitoring stations including their location, stream index number, and watershed characteristics can be found in Table 1. The station locations were selected to provide a picture of the surface water quality adjacent to animal feeding operations.

The Stocking Head Creek watershed has 22,353 acres of land mass and is located in the Cape Fear River basin. Seven of the eleven water quality monitoring stations are located in this watershed. Murphey's Creek monitoring site is located in Rockfish Creek watershed which has 30,981 acres. Muddy creek monitoring site is located in the Muddy Creek watershed with 30,718 acres. Sikes Mill Run monitoring site is located in Six Runs Creek watershed with 14,548 acres. The background monitoring site is located in Harrisons Creek watershed located in Pender county with 23,433 acres.

Water quality parameters most commonly analyzed to investigate water quality impacts from AFOs are nutrients and pathogens. These parameters along with a suite of other physical and chemical water quality parameters were monitored on a monthly basis between April 2018 and October 2019. The full list of parameters and the sample type are listed in Table 2.

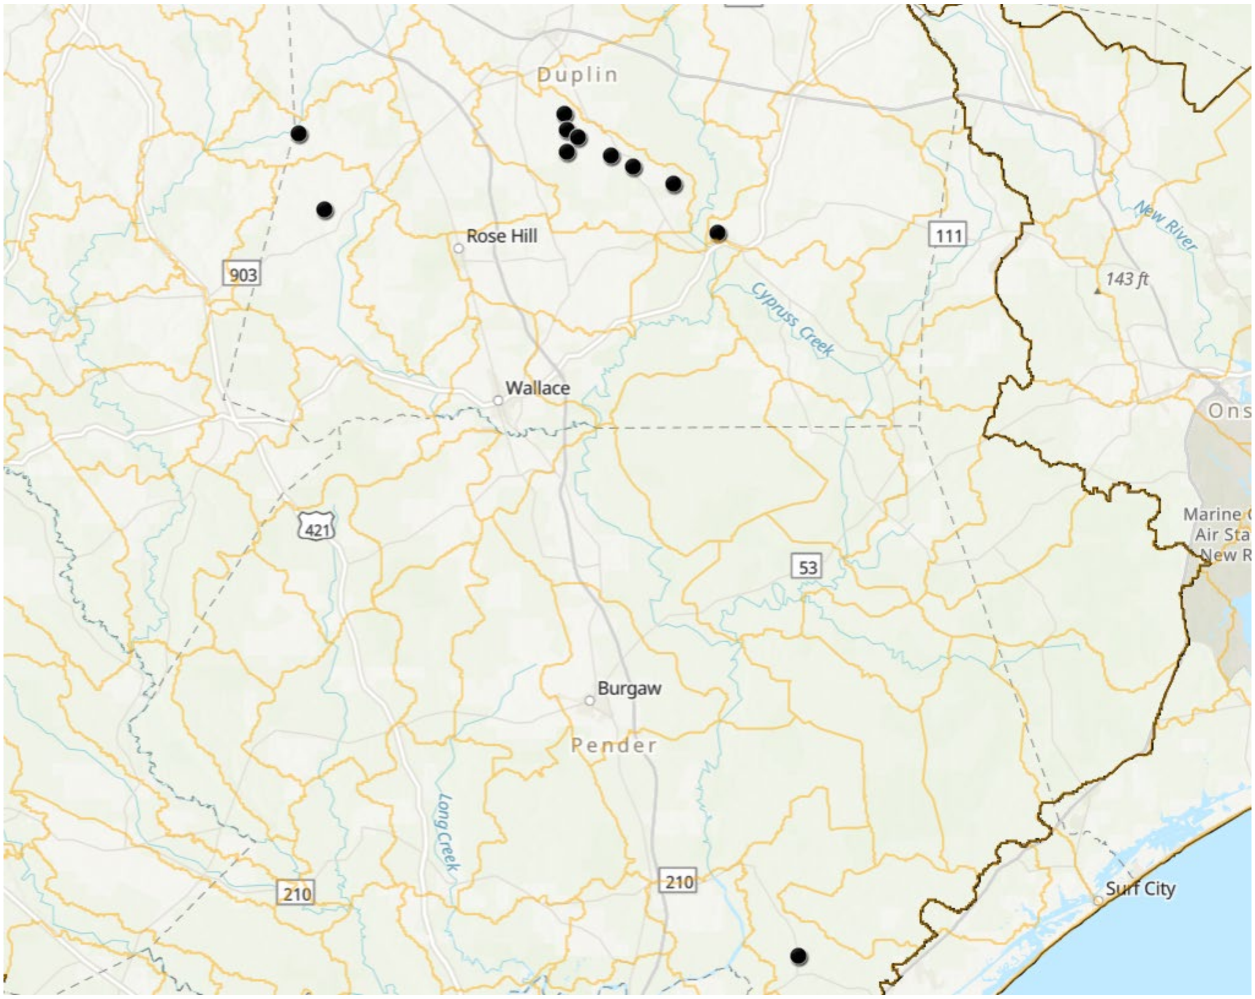

Figure 1. Map showing the watersheds and water quality monitoring sites.

Stream Name	Stream Index	Monitoring Location	Watershed Characteristics	County
Stocking Head Creek	18-74-24	Graham Dobson Road (SHC_GDR)	Several Crossroads throughout this high density CAFO watershed. This is a headwaters stream crossing.	Duplin
		Cool Spring Road (Unnamed Tributary) (TR_CSR)		
		S. Dobson Chapel Road (SHC_SDCR)		
		S. Dobson Chapel Road (Unnamed Tributary) (TR_SDCR)		
		Stocking Head Road (SHC_SHCR)		
		S NC Highway 50 (SHC_50)	Fish station at this crossroads.	
		Pasture Branch Road (SHC_PBR)	Benthic macroinvertebrate station at this crossroads.	
Murpheys Creek	18-74-29-0.5	Waycross Road (MC_WR)	High density CAFO watershed.	Duplin
Muddy Creek	18-74-25	Durwood Evan Road (MC_DER)	Medium density CAFO watershed. Impaired biological station at this location.	Duplin
Sikes Mill Run	18-68-2-10-4	Beasley Mill Road (SMR_BMR)	High density CAFO watershed with stream originating on hog farm.	Duplin
Harrisons Creek	18-74-49	Hwy 210 (HC_210)	Largely undeveloped watershed with some row crop and silviculture operations.	Pender

Table 1. Water quality monitoring locations with stream index number, watershed description and county name.

Parameter	Sample Type
Dissolved Oxygen (mg/L and percent saturation)	Surface
pH (SU)	Surface
Specific Conductance (µmhos/cm)	Surface
Temperature (°C)	Surface
Ammonia as N (NH_3) (mg/L)	Grab Sample
Nitrate+Nitrite (NO_3+NO_2) (mg/L)	Grab Sample
Total Kjeldahl Nitrogen (TKN) (mg/L)	Grab Sample
Total Phosporus (TP) (mg/L)	Grab Sample
Turbidity (mg/L)	Grab Sample
Fecal coliform (CFU/100 mL)	Grab Sample
Colored Dissolved Organic Matter (CDOM) (mg/L)	Grab sample

Table 2. Water quality analysis parameters and sampling type used for collecting and analyzing water samples.

Water samples were collected, stored, and transported from monitoring stations following approved monitoring standard operating procedures (SOPs) (AMS QAPP, 2017). Chemical analyses of all parameters except CDOM were conducted by the NC Water Sciences Section Chemistry Laboratory using EPA-approved methods (40CFR Part 136).

In April 2019, DWR began collecting samples for the stable isotope and excitation-emission matrix (EEM) fluorescence analysis. Samples were collected monthly for six months from all monitoring stations in accordance with the NC State University Osburn Biogeochemistry Laboratory (Osburn Lab) sampling protocol (CDOM Sampling SOP_DWR.pdf) and analyzed by the Osburn Lab.

NCDEQ also investigated any potential impacts that underground drain tiles located in fields receiving animal waste may have on water quality. Regional office field staff conducted intensive inspections on farms located in the study area to identify fields that had drain tiles (See Inspection Notes in Appendix 1).

Results

The mean and median concentrations for nutrient parameters and pathogens were calculated for the data between April 2018 and October 2019. The results are shown below in Figures 2-6 by parameter for each monitoring station.

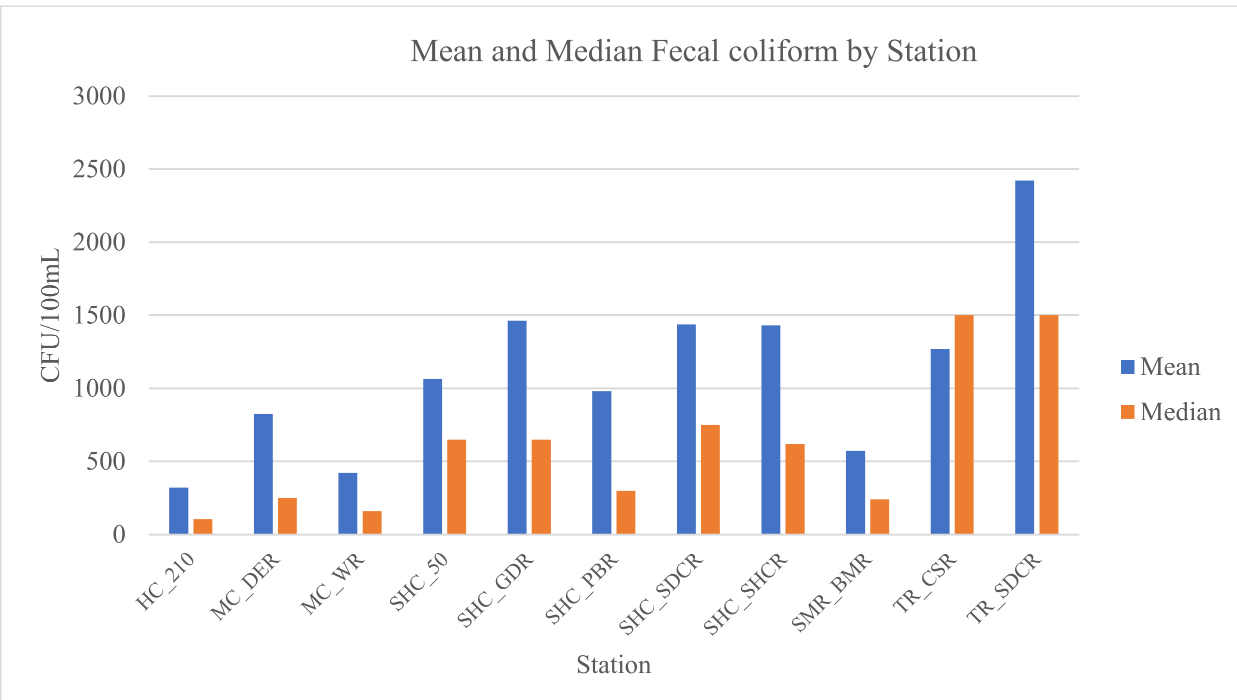

Figure 2. Mean and median concentrations for Fecal coliform (April 2018-October 2019).

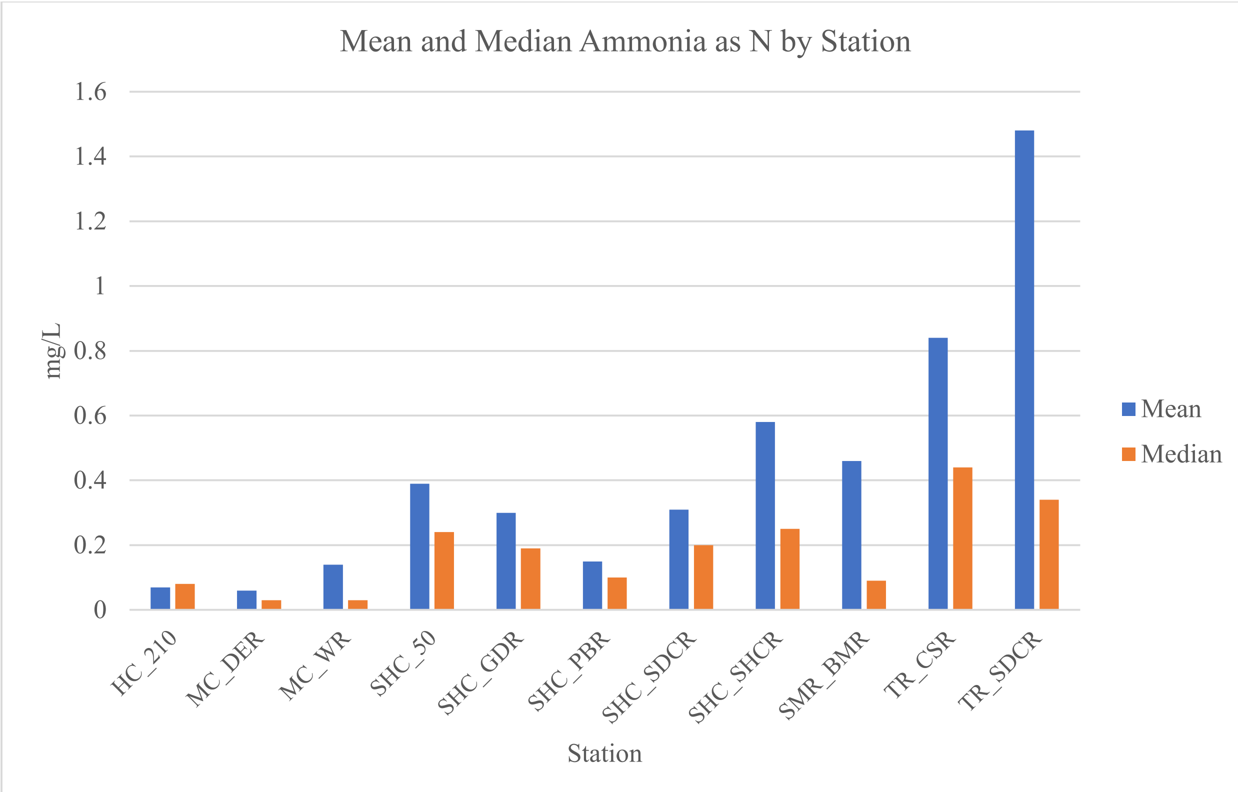

Figure 3. Mean and median concentrations for Ammonia as N (April 2018-October 2019).

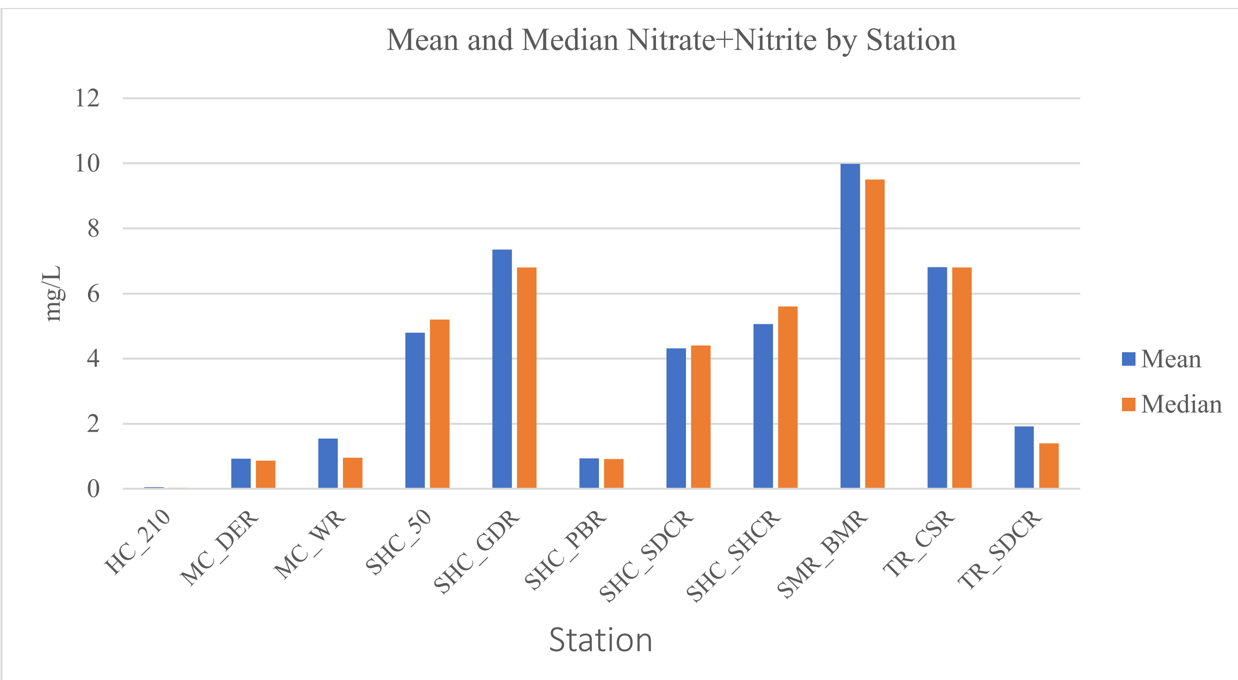

Figure 4. Mean and median concentrations for Nitrate+Nitrite (April 2018-October 2019).

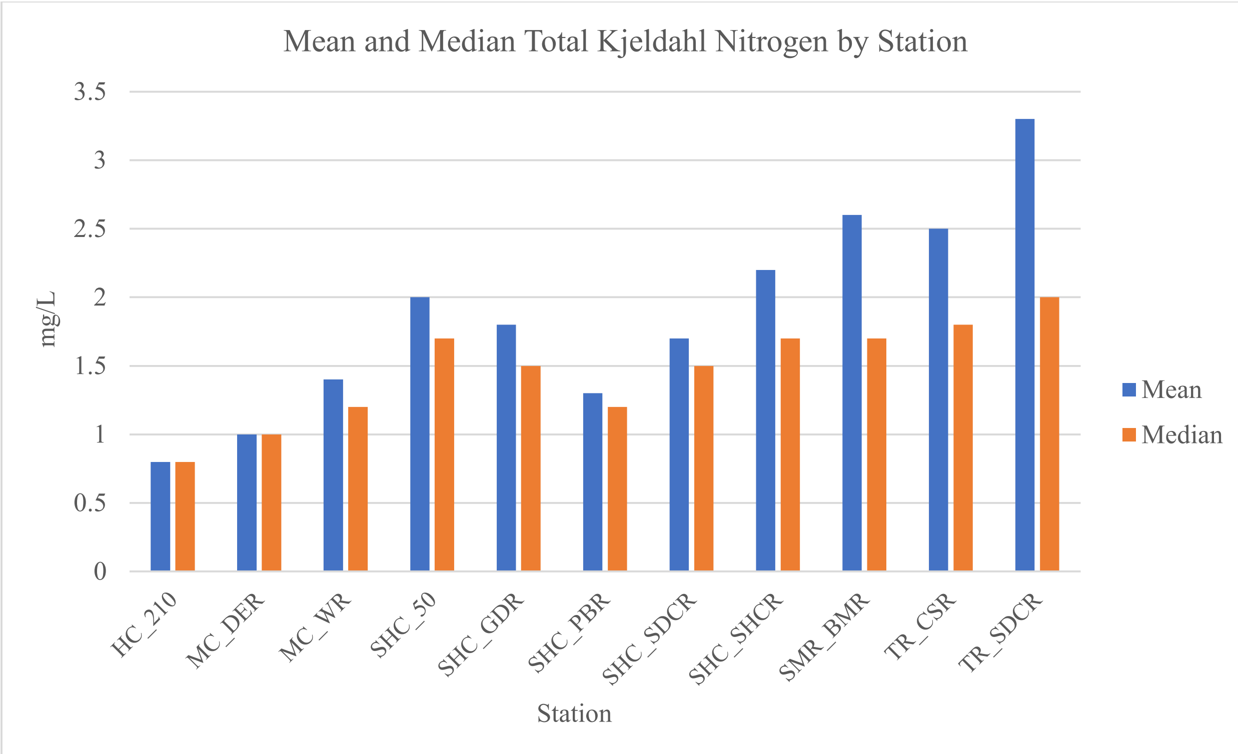

Figure 5. Mean and median concentrations for Total Kjeldahl Nitrogen (April 2018-October 2019).

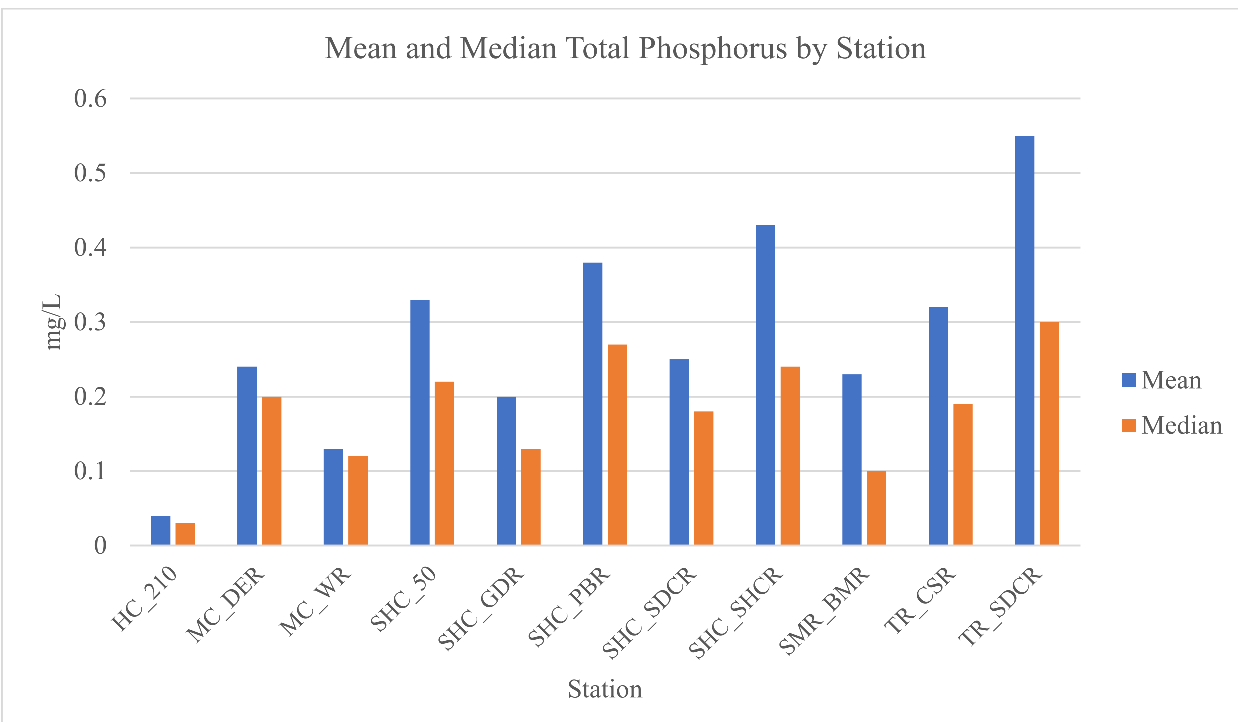

Figure 6. Mean and median concentrations for Total Phosphorus (April 2018-October 2019).

As shown in almost all cases in the tables above, the reference station (HC_210) had much lower mean and median concentrations by parameter than the test stations. To evaluate whether the parameter concentrations are significantly different in the test stations as compared to the reference stations, Kruskal-Wallis tests (2-sided) were conducted to compare the medians. The null hypothesis was that all medians are the same or not significantly different. Low p-values in the tables (highlighted in green) below indicate significant differences between the respective stations in the matrix.

Table 7. Kruskal-Wallis tests results for Total Phosphorus (p-value ≤0.05 indicates significant difference).

For all parameters, a majority of the test stations (six or more) were significantly different from the reference station. For NO_3+NO_2, TKN, and TP, nine of more of the test stations were significantly different than the reference station.

Discussion

Based on the results of this study to date, it appears that nutrient and pathogen concentrations are higher for the test stations in the concentrated AFO areas as compared to the reference station with no AFOs in the drainage area. The next step for this study is to determine the source of the nutrients and pathogens. Source identification for ubiquitous parameters such as nutrients and pathogens can be difficult. However, technological advances have made the identification of organic nitrogen and specific pathogens sources much more reliable. Two specific enhanced analytical techniques will be used to assist in source identification, excitation-emission matrix (EEM) fluorescence analysis and quantitative polymerase chain reaction (qPCR) analysis

EEM

NCDEQ has pursued enhanced analysis of surface water samples for the purpose of nutrient source identification. Analytical techniques such as stable isotope and EEM fluorescence analyses were used to identify organic nitrogen sources in ambient waters. Organic nitrogen sources such as wastewater effluent, fertilizers, and animal wastes have different ranges of isotope ratios. These ratio ranges can act as fingerprints for sources of the nitrogen. Excitation-emission matrix fluorescence analysis can also be used to identify the fluorescent properties of dissolved organic nitrogen (Osburn et al. 2016). Organic nitrogen exhibits different fluorescence signatures depending on the source of the nitrogen. These signatures are modeled in a parallel factor analysis to identify sources such as wastewater, animal waste, and septage and the relative nitrogen contributions of the sources (Ibid.).

NCDEQ contracted with North Carolina State University's Osburn Lab to conduct stable isotope and EEM fluorescence analyses (FLUORMOD) for samples collected as part of this study. Dr. Osburn's FLUORMOD analysis was designed to analyze a variety of organic nitrogen sources such as septage, poultry, swine, and wetlands/soil. Swine was of particular interest to this study. However, results from the preliminary analyses detected only minimal organic nitrogen from swine sources. Tables 8-11 show the results from the analyses. Samples collected in June were lost in transport, so only four sets of samples (March, April, May and July) were analyzed. Further discussion with Dr. Osburn revealed that the FLUORMOD analysis used at that time could have been misidentifying the organic nitrogen sources. FLUORMOD was developed using swine waste sampled directly from a lagoon. FLUORMOD would be likely to detect this fluorescence signature in ambient waters only in the event of a direct discharge from a swine lagoon to surface waters. Current regulatory requirements for inspection and management make direct discharges from lagoons to surface waters unlikely except in catastrophic events. The more likely path of a discharge to surface waters is during spray irrigation of waste onto sprayfields due to overspray, ponding and runoff, or infiltration into groundwater or underground drain tile. Chemical changes that occur in waste during spray irrigation, infiltration into soil, and residence time in surface waters can significantly change the fluorescence signature (Osburn personal communication). Therefore, it is unlikely that FLUORMOD as designed would detect contributions of organic nitrogen from swine through these pathways.

Dr. Osburn is currently revising his analytical model to detect the fluorescence signatures from swine waste applied to sprayfields. Once the revisions are completed, NCDEQ will begin collecting samples concurrently with nutrient and pathogen samples from all eleven stations for analysis using FLUORMOD in an attempt to identify organic nitrogen sources in these surface waters.

Quantitative Polymerase Chain Reaction (qPCR)

qPCR is a genetic identification analysis often used to identify bacterial markers (Kralik and Ricchi, 2017). This highly sensitive analysis can identify down to specific genus and species of bacteria. This is useful in pathogen source identification in surface waters where bacteria found only in specific animals (e.g., swine, poultry, cattle, humans) can be selected for analysis as identifying markers (Ibid). NCDEQ is establishing collaboration with researchers at North Carolina universities who conduct this analysis to participate in the CFRAFOMS. Samples for this analysis will be collected concurrently with nutrient and pathogen samples.

Once the FLUORMOD model has been revised and the qPCR collaborator has been identified, sample collection will begin again. The explicit purpose of this sampling will be to attempt source identification using the target parameters organic nitrogen and pathogens. It is anticipated that the source identification monitoring will provide insight to NCDEQ on nutrient and pathogen sources in the Cape Fear River basin in areas populated with high concentrations of animal waste facilities.

Appendix:1

The Department of Environmental Quality inspected 23 swine facilities as part of the Stocking Head Creek Watershed Study which could potentially impact surface water quality. During the inspections, NCDEQ looked for any unpermitted discharges coming from waste storage structures.

Notes from inspections conducted on the AFOs in the surrounding areas of water quality monitoring sites with corresponding subsurface drain tiles and average values for NH4-N and Fecal coliform.

Permit No.	Farm Name	Inspection Date	Notes	Nearest SHC Location	Average NH4-N (mg/L)	Average Fecal Coliform (CFU/100ml)	Subsurface Drains (Y/N)
AWS310466	Sands Farm	3/11/2019	DWR inspectors visited the farm on 3/11/2019. We rode and inspected the lagoons, fields and drainages. There are no subsurface drains on this farm and we did not see any areas of concern. This farm has no hogs or hog houses, and the representative on-site indicated that it has been approximately 2 years since they've land-applied wastewater. The facility is in the process of being converted to a truck wash.	MC_WR	0.19	436.46	No
AWS310445	Terry Miller Farm sites 1&2	3/14/2019	DWR inspected facility on 3/14/2019. Rode lagoon and viewed fields. No bad eroded areas. (Note: Farm was overtopped/inundated during Hurricane Florence)	SHC_PBR	0.16	1139.09	No
AWS310692	Liberty Farm	3/20/2019	DWR inspected facility on 3/20/2019. Lagoon and field was walked and some rode. No erosion or runoff issues. Subsurface drains are in field, currently waiting for a better map. Supposedly	SHC_SDCR	0.41	1727.27	Yes

			there are 2 laterals that go through the pivot pumping field and are run to the ditch on North side of the property. Farm didn't use correct Wa on some of the IRR2's and was missing calibration.				
AWS310386	**William Edward Brock Farm**	**3/20/2019**	**DWR inspected facility on 3/20/2019. Walked lagoons and fields on creekside of farm. No drain tiles in field that owner is aware. FB is noncompliant currently but POA is submitted. Discussed options and cost share "Pump and Haul". Instructed owner to communicate with DWR on FB. (Note: farm was inundated during hurricane Florence).**	**SHC_PBR**	**0.16**	**1139.09**	**No**
AWS310086	**ABS Family Farms, Inc.**	**3/26/2019**	**DWR on site 3/26/2019 to inspect farm for SHC study. Fields and records okay, fixing foundation cracks soon. Walked and rode fields looking for drains, found 1 in the ditch that leads to the pond, owner said there should be 2 more but could not find them.**	**SHC_SHCR**	**0.76**	**1979.09**	**Yes**
AWS310455	**Randy & Anna Harrell**	**3/26/2019**	**DWR inspected the facility on 3/26/2019 with a consultant. Numerous issues were discovered, including but not limited to, a lack of irrigation visible equipment (permitted for a solid set system), suspected equipment/pipe failure issues, suspected runoff from irrigation field, leaking from house and/or flush tank, multiple high and unreported FB events, no irrigation**	**SHC_50**	**0.49**	**1373.64**	**No**

			records for review, flooded irrigation field that is overgrown with trees/shrubs (has not been used), lack of suitable crop on the irrigation field that is used, etc. The consultant did not know if there were subsurface drains on the fields, and we did not locate any during the inspection. DWR will conduct a follow-up inspection with the farm owner or his son.				
AWS310035	**Waters Farm 1-5 M&M Rivenbark**	**3/11/2019**	**DWR inspectors visited the site on 3/11/2019. We rode and inspected the lagoons, fields, drainages and subsurface drains at the farms. We did not see any areas of concern other than one area in the center pivot field on the Waters 3,4,5 farm. There was a low spot where wastewater had the potential to pond and possibly runoff in the event of an over application event. DWR suggested that additional dirt be brought to address this area.**	**MC_WR**	**0.19**	**436.46**	**Yes**

AWS310160	**Carter and Sons Hog Farm 1&2**	**3/7/2019**	**David Powell inspected the farm on 3/7/2019. A pile of mulch was placed near a UT of SHC. Eroded areas from some fields had straw/hay around and in them to reduce erosion. Lagoons out of compliance currently with POA submitted. Amended POA coming to account for new lagoon levels. Summary of Findings: 1) Discharge to UT of SHC of <1000 gals leaving back of houses/piping, then running between lagoons and across small field to UT. Onsite observations show green grass in area of runoff and a drainage "swath", from stormwater mixed with nutrients from around lagoon and houses, have been doing this for a while 2) Mulch/hay bales in eroded areas. This can add nutrients into water of UT. Please replace soil in eroded areas and remove hay/mulch. Crop should be removed from fields irrigated on and disposed of properly. 3) Lagoon levels not in compliance; POA submitted and notification received 4) Fix leak at back of houses and eroded areas around farm. Replace soil, grass and reduce erosion. Replace also on dike walls and have markers reshot. Keep documentation. 5) Crop needs improvement. The fields are wet and are grazed. DWR**	**SHC_SDCR**	**0.41**	**1727.27**	**No**

			suggested having additional acreage for wet winters and additional pumping needs. Samples/pics taken. Sample 1 at 11:50 am; Sample 2 at 11:55 am; Sample 3 at 12:00; Sample 4 at 12:20 pm; Sample 5 at 1:40 pm; Sample at Envirochem at 3:05 pm. Suggest fixing stormwater runoff areas around lagoon/houses.				
AWS310321	**James E. King Farm**	**3/7/2019**	**DWR Michael Meilinger and Robb Marris visited farm on 3/7/2019 in response to SHC study, rode lagoons and walked fields, drain tiles in two fields that lead to SHC, marked on map. Some erosion from storm, fix spots and re-plant or re-seed field that was flooded from storm. Farm has cows and cow paths leading from the corrals and fields lead towards the ditches, told farmer to get grass cover and improve grass cover on dike wall. While riding the lagoon's saw signs of wild hogs rooting around the toe of the dike and in the edge of the woods next to the creek.**	**SHC_SHCR**		**1979.09**	**Yes**
AWS310451	**Otis Brown Farm**	**3/4/2019**	**DWR visited the farm as part of the SHC study. Rode roads along ditches and along field edges. Subsurface drains are known to be on the farm and marked on**	**SHC_SHCR**	**0.76**	**1979.09**	**Yes**

			the map. Water flowing out of the pipe into the ditch beside the road was a little dirty from all of the rain water. Farm and records look good, owner lost wheat crop after/during Hurricane in fields 1-4 has cover crop on fields now.				
AWS310254	**Bobby Brown Farm**	**3/4/2019**	**DWR visited farm in response to SHC study, farm had severe erosion after storm, fields have been fixed, farm has drain tiles and marked on map. Re-planting fescue where fields where flooded from hurricane Florence. Abstract

North Carolina is one of the leading US states in livestock and poultry production. In 1993, the on-farm inventory was approximately 4.4 million animal units, as defined by the U.S. Environmental Protection Agency. Current trends toward farm consolidation, specialization and intensification are sound from an economic and management perspective, but may fail to adequately address important environmental impacts.

A nutrient assessment was initiated to determine where clusters of livestock and poultry are located, to assess manure generation by county, to determine the recoverable manure nutrients which can be made available for plant growth, to determine the quantity of nutrients required for agronomic crops and forages in each county and to determine the balance in each county between plant available manure nutrients and agronomic crop needs.

Approximatelv 27 million tons of fresh manure containing 205,000 tons of nitrogen, 138,000 tons of phosphorus (P205), and 133,000 tons of potassium (K2O) were generated in 1993. About 57% of the total manure was considered collectable. After storage, treatment and field losses, about 19% of the fresh manure nitrogen, 37% of the phosphorus, and 29% of the potassium were considered plant available as fertilizer nutrients. Statewide, about 20% of the nitrogen and 66% of the phosphorus could be met with animal manure. Three counties had enough manure to exceed their nitrogen requirements while 18 counties had more than enough phosphorus.

Kevwords: Livestock, Manure, Nutrient, Distribution, Balance

Introduction and Objectives

North Carolina is one of the leading US states in livestock and poultry production. In 1993, approximately 4.4 million animal units, as defined by the U.S. Environmental Protection Agency, were counted as on-farm inventories. Current trends are toward production farm consolidation, specialization and intensification. These efforts, while being sound from an economic and management perspective, must also consider the full environmental impact which can ensue from the increased generation of unevenly distributed animal manure. Processing by-products and animal mortalities also cont.ibute to the nutrient load to be managed, however, this project only deals with production farm generated manure nutrients.

All animal by-products contain organics and nutrients. Manure organics can provide a fuel source, while the nutrients, if managed properly, can be used as a feed supplement or as a plant fertilizer. "Best Management Practices" (BMPs) for manure used as a feed or fertilizer include manure collection, treatment, storage, and nutrient/feed analysis. Additional BMPs are required when manure is used as a fertilizer. These practices include proper timing, rate, and application uniformity in relation to the nutrient needs of the growing plants. In addition, soil conservation practices to reduce the soil, manure, and nutrient movement off site are needed.

The nutrient assessment project was initiated to: 1) geographically depict where the livestock are located and identify "clustering effects", i.e., high densities of livestock production around support facilities such as feed mills, hatcheries, processing plants, etc.; 2) assess current generation of manure by county; 3) determine the amount of nutrients from manure which can be recovered and made available to agronomic crops; 4) determine the quantity of nutrients required for non-legume agronomic crops and forages in each county; and 5) calculate the percent of agronomic crop and forage nutrients which can be supplied by animal manure.

ObViously, to proceed with a nutrient assessment, many assumptions must be made regarding production methods, manure handling systems, application techniques, crops, and nutrient needs. Most assumptions have been made on a statewide basis, although it is recognized that they will change somewhat county by county. The information is presented to provide a methodology for an animal manure nutrient assessment and to get a first glance as to the carrying capacities of localized areas within the state.

Methods and Assumptions

Manure Characterization

Data on manure, litter, wastewater, and sludge quantities and characteristics are necessary, to assist in the planning, design, and operation of manure collection, storage, pretreatment, and utilization systems for livestock and poultry enterprises. Databases have been developed over the past 12 years containing summaries from a wide base of published and unpublished information on livestock manure production and characterization (Barker et al., 1995). These summaries represent typical domestic food animal and poultry species as well as different farm manure management systems within species. Fresh manure values represent "as voided" feces and urine. Farm manure management systems include the following:

1. paved lot manure scraped within two days either directly into a manure spreader for field spreading or into a short-term storage;
2. annual accumulations of poultry manure with wood shavings or peanut hulls as a litter base;
3. liquid slurry accumulating for 6-12 months from manure, excess water usage, and storage surface rainfall surplus;
4. surface liquid from an anaerob~c treatment lagoon; and
5. bottom sludge from an anaerobic treatment lagoon.

Actual values vary due to differences in animal diet, age, usage, productivity, management and location. Whenever site-specific data are available or actual sample analyses can be performed, such information should be considered in lieu of the mean summarized values.

Collectable Manure

All animals are not raised in confinement where their manure can be easily collected for reuse. Cattle and sheep spend most of their time on pasture. Some hog enterprises consist of dirt or pasture lots. A small percentage of turkeys are still finished on open range. While these unconfined animals still contribute manure nutrients to the pasture system, these nutrients are not addressed in this assessment.

Nutrients Remaining After Storage and Treatment Losses

During the time between manure voiding by the animal and transport to the field for spreading, much of the nutrients can be lost through drying or dilution, surface runoff, volatilization, or microbial digestion. Since different manure management systems either conserve or sacrifice varying amounts of nutrients, an estimate must be made of the percentage of farms using specific systems. Applying these percentages to the manure characteristics appropriate to the specific method gives the remaining nutrients after storage and treatment losses.

Plant Available Nutrients

Estimates of nutrient availability coefficients for various manure management systems and application methods are summarized in Table 1. The plant-available portion of the manure nitrogen was determined by combining a percentage of the ammonia (ammonium) -nitrogen using the appropriate ammonia volatilization value based on the application method with one-half of the organic nitrozen assumed to be plant available during the same year of application. Availability of all other nutrients were based on the application method.

Table 1. Manure Nutrient Plant Availability Coefficients

Crop Nutrient Requirements

Crop nutrient requirements were determined for all agronomic crops (barley, oats, wheat, corn (grain), corn silage, sorghum (grain), cotton, soybeans and burley tobacco; and forages (hay and pasture). Horticultural and silvicultural crops, most legumes and flue- cured tobacco were not included. Nitrogen recommendations for all crops were calculated by using suggested nitrogen fertilizer rates based on realistic yield expectations (Zublena et al., 1994). Crop and hay yields were based on averaging the highest 2 years of the last 5 years according to the 1993 North Carolina Agricultural Statistics (NCDA, 1989-94a) Grass pasture data was obtained from the 1992 Census of Agnculture (USDC, 1994). No nitrogen credit was given to soybeans since they are legumes. No nitrogen credit was given to flue-cured tobacco since its N needs are relatively low and it is very sensitive to N. Burley tobacco has a high nitrogen requirement and was included.

When calculating application rates for phosphorus, specific Soil Test Index values of 10, 40, 70 and 110 from "Crop Fertilization Bases on N.C. Soil Tests" (NCDA, 1987), were used in the computations. These values coincide with the Soil Test Index ranges of 0-25, 26-50, 51-100, and 100+, respectively.

Copper and zinc nutrient recommendations are based on a mineral soil classification. When representative soil samples fall within the range of 0-25 on the Soil Test Index, copper and zinc application rates of 2.2 kg/ha and 6.7 kg/ha were suggested, respectively (NCDA, 1987).

County Nutrient Balances

All county crop acreages were based on "Acres Harvested" from the North Carolina Agricultural Statistics (NCDA, 1994a). County soil test data was obtained from the North Carolina Soil Test Summary (NCDA, 1994b). Organic and inorganic sources of nutrients other than animal manure were not included in this assessment because individual county sources of information for those nutrients were not considered reliable. It would be important in doina a complete nutrient balance to consider all sources of nutrients as well as all crop needs (agronomic, horticultural, silvicultural) in a given watershed.

RESULTS AND DISCUSSION

Manure Characterization

Table 2 gives the mean values of livestock and poultry manure, litter, wastewater and sludge amounts and nutrient concentrations for several animal species and manure management methods. Fresh manure values are mostly taken from published literature sources and with few exceptions tend to be from the 1960s and 70s. Very little new research has been done recently on quantifying and characterizing fresh livestock manures. The remaining databases are more recent and represent measured parameter concentrations. Values were obtained primarily from state analytical laboratories, university research labs, and published literature sources. Primary nutrients have substantial numbers of samples averaged ranging to 1400 for some parameters. Secondary and micronutrients have smaller numbers of values. The databases for manure volumes are rather sparse and are highly dependent on production systems, manure storage and treatment, and climatic factors. Extreme values outside the range of three standard deviations from the mean of the raw data set were not included in the averages in Table 2. The complete databases provide the numbers of samples for each parameter plus the range of values, mean, and standard deviation.

Livestock and poultry on-farm inventories as of December 1993 were obtained from the *North Carolina Agricultural Statistics* (NCDA, 1994). Animal production in North Carolina produced approximately 27 million tons of fresh manure in 1993 (Table 3). These manures contained 205,000 tons of nitrogen, 138,000 tons of phosphorus (P205), 133,000 tons of potassium (K20), 1,700 tons of zinc, and 290 tons of copper.

Collectable Manure

In North Carolina most ruminants are on pasture, while most of the hogs and poultry are fed in confinement where the manure is collected. Table 4 lists the estimated percent of time that animals of various ages and usages are in confinement. From Table 3 approximately 57% of the total fresh livestock and poultry manure is considered collectable.

Nutrients Remaining After Storage and Treatment Losses

Table 4 gives estimates on the percent of farms using either a lot scrape manure collection method, a liquid manure slurry handling and storage method, or an anaerobic treatment lagoon. Using the appropriate manure characterization databases, approximately 35% of the nitrogen, 50% of the phosphorus, 40% of the potassium, 47% of the zinc, and 71% of the copper were available for land application after handling, storage and treatment losses (Table 3).

Plant Available Nutrients

All lot scraped manure, liquid manure slurry, and lagoon sludge were assumed to be soil incorporated within 48 hours of application. Dry poultry litter was assumed to be equally divided between surface broadcast and soil incorporation. All lagoon liquid was assumed to be irrigated without soil incorporation. From Table 4, a 50% mineralization rate for organic nitrogen was used for all manures. The appropriate plant nutrient availability coefficient corresponding to the application method was chosen from Table 1. Approximately 19% of the fresh manure nitrogen, 37% of the phosphorus, 29% of the potassium, 34% of the zinc, and 60% of the copper were determined to be plant available. This illustrates the transient nature of manure nutrients and how they can be affected by collection, handling, storage, treatment and application method.

Crop Nutrient Requirements

When considering on a state-wide basis the nutrient requirements of all non-legume agronomic crops and forages and the plant available nutrients from livestock and poultry manure, about 20% of the nitrogen, 66% of the phosphorus, 85% of the zinc, and 42% of the copper needs can be met with animal manures.

County Nutrient Balances

Figures 1 and 2 present geographically the nutrient distribution and balances by county for nitrogen and phosphorus, respectively. From Table 5, at the county level in 1993, 3 counties (3% of state) had enough animal manure to exceed the nitrogen requirements of all non-legume agronomic crops and forages, while 55 counties (55% of state) could only supply less than 10% of their nitrogen needs with animal manure. However, 18 counties (18% of state) could exceed their phosphorus needs with animal and poultry manure, while 29 counties could supply less than 10% of their needs.

Figure 1. Percent of non-legume agronomic crop and forage nitrogen needs supplied by recoverable plant available manure nutrients.

Figure 2. Percent of non-legume agronomic crop and forage phosphorus needs supplied by recoverable plant available manure nutrients.

Table 5. Summary of North Carolina County Livestock Manure Plant Available Nutrient Balances with Agronomic and Forage Crop Needs.

SUMMARY

Information derived from this livestock manure nutrient assessment project can be geographically depicted to serve as a tool for:

1. determining where the livestock are located and identifying "clustering effects";
2. evaluating the quantities of manure nutrients available for plant gro~vth and how they may supplement the inorganic nutrient sources in a given area;
3. assessing the potential for nutrient impairment of water resources; and

4. providing a decision-making guide for future county or area-wide growth and development.

Nutrient assessments can be used for layers in a geographic information system (GIS). Obviously, large volumes of data must be manipulated and computerization is a must.

This assessment is being used by the North Carolina Cooperative Extension Service to focus and network educational efforts on animal manure management where there is the greatest need. Discussions have been initiated with livestock and poultry integrators on the need to consider dispersing livestock operations to prevent nutrient "saturation" in localized areas. This excess nutrient load might be sources of water impairments if they exceed the crop nutrient needs of the area. The information is shared with county commissioners, planners, and commodity advisory boards.

Meetings have also been conducted with representatives of the inorganic fertilizer industry to explore opportunities for incorporating organic sources into existing fertilizer operations.

Characterization of atmospheric ammonia emissions from swine waste storage and treatment lagoons

Viney P. Aneja, J. P. Chauhan,[1] and J. T. Walker[2]

Department of Marine, Earth, and Atmospheric Sciences, North Carolina State University, Raleigh

Abstract. Fluxes of atmospheric ammonia-nitrogen (NH_3-N, where NH_3-N = (14/17)NH_3) from an anaerobic ~2.5 ha (1 ha = 10,000 m^2) commercial hog waste storage lagoon were measured during the summer of 1997 through the spring of 1998 in order to study the seasonal variability in emissions of NH_3-N and its relationship to lagoon physicochemical properties. Ammonia-nitrogen fluxes were measured during each season (summer, fall, winter, and spring) using a dynamic flow through chamber system. Measured lagoon physicochemical parameters included surface lagoon temperature (T_ℓ°C, ~15 cm below surface), lagoon pH, and Total Kjeldahl Nitrogen (TKN). The pH and TKN of the surface lagoon water ranged from 7 to 8 pH units, and 500 to 750 mg N L^{-1}, respectively. The largest fluxes were observed during the summer (August 1997) (mean NH_3-N flux = 4017 ± 987 μg N m^{-2} min^{-1}). Fluxes decreased through the fall (December 1997) months (844 ± 401 μg N m^{-2} min^{-1}) to a minimum flux during the winter (February 1998) months (305 ± 154 μg N m^{-2} min^{-1}). Emission rates increased during spring (May 1998) (1706 ± 552 μg N m^{-2} min^{-1}), but did not reach the magnitude of fluxes observed during the summer. Lagoon emissions in eastern North Carolina were estimated to constitute ~33% of total NH_3-N emissions from commercial hog operations in North Carolina based on current inventories for NH_3-N emissions published by the North Carolina Division of Air Quality, North Carolina Department of Environment and Natural Resources. The ammonia flux may be predicted by an observational model $\log_{10}$ (NH_3-N flux) = 0.048 T_ℓ + 2.1.

1. Introduction

1.1. Background

Atmospheric ammonia (NH_3) emissions have garnered increased interest in the past few years, due in part to the detrimental effects of excess nitrogen deposition to nutrient-sensitive ecosystems [*Aneja et al.*, 1998a; *Asman et al.*, 1998; *Nihlgard*, 1985; *van Breemen et al.*, 1982]. Moreover, NH_3 is the primary gaseous base found in the atmosphere, and it is therefore fundamental in determining the overall acidity of precipitation [*Warneck*, 1988], cloudwater [*Li and Aneja*, 1992], and atmospheric aerosols [*Lefer et al.*, 1999]. Ammonia emissions contribute substantially to atmospheric nitrogen loading, and may contribute about the same order of magnitude as emissions of NO in some parts of the world [*Asman et al.*, 1998; *Steingröver and Boxman*, 1996]. The impact of atmospheric NH_3 deposition may be substantial as reduced nitrogen species are thought to be more biologically active than oxidized nitrogen species in coastal and estuarine ecosystems [*Paerl*, 1997]. In the atmosphere, NH_3 can react with acidic species to form ammonium sulfate, ammonium nitrate, or ammonium chloride, or it may be deposited to the Earth's surface. The spatial scale of a particular NH_3 source's contribution to atmospheric nitrogen deposition will be governed in part by the gas-to-particle conversion rate of NH_3 to NH_4^+. Because of the short lifetime of NH_3 in the atmosphere (τ = 1–5 days or less) [*Warneck*, 1988], low source height, and relatively high dry deposition velocity [*Asman and van Jaarsveld*, 1992] it may deposit near its source. However, ammonium (NH_4^+) aerosols with atmospheric lifetimes of the order of τ = 1–15 days [*Aneja et al.*, 1998b] will deposit at larger distances downwind of sources.

There are several environmental consequences associated with atmospheric NH_3 and its deposition; including particulate matter formation, soil acidification, aquatic eutrophication, and, near strong sources, odor emanation. In Great Britain and the Netherlands, which have dense spatial distributions of animal operations, soil acidification is a major environmental problem [*Aben and Dekkers*, 1996; *van Breemen et al.*, 1982]. *van Breemen et al.* [1982] identified deposition of ammonium sulfate as the major cause of soil acidification in the Netherlands because the oxidation of NH_4^+ via nitrifying bacteria releases 2 H^+ ions into soil. *Nihlgard* [1985] implicates NH_4^+ in Europe's forest decline, as nitrogen "oversaturated" trees succumb to wind, drought, and parasitic damage. Coastal Plain river systems in North Carolina have been under the influence of nutrient loading for several years [*Aneja et al.*, 1998c; *Paerl*, 1997, 1995]. Estimates suggest that atmospheric deposition may contribute 35–60% of total nitrogen loading to North Carolina coastal waters [*Paerl*, 1995]. The increase in nutrient loading over the past several years is related to agricultural management, human population growth, and increasing animal production. In July 1995 the appearance of the dinoflagellate Pfiesteria and its association with several large fish kills

Turkeys (1995)	NH_3	16,486	5.0
Fertilizer application (1999)	NH_3	8,270	2.5
"Other" chickens (1995)	NH_3	6,476	2.0
NH_3 point sources (1995)	NH_3	1,665	0.5
Total		330,743	100.0

Adapted from *Aneja et al.* [1998b].

[a]Nitrogen calculated from NO_x emissions assumes 100% NO_2 though the actual proportion is closer to 95%. Thus $NO_x - N$ (tons) × (14/46) and $NH_3 - N$ (tons) = NH_3 (tons) × 14/17).

[b]NO_x emission taken from Division of Air Quality (DAQ) inventories developed for modeling purposes; NH_3 emissions based upon factors presented by *Battye et al.* [1994]; and animal production statistics from the NCDA.

[c]Two minor ammonia sources, together totaling <6000 t statewide, have been omitted. Factors for these, emissions from sewage treatment plants and emission associated with human breathing, are based upon vary limited data and are currently being reevaluated.

[d]Relative proportions of NO_x = 58%, NH_x = 42%.

have resulted in efforts to reduce nitrogen loading into the Neuse River Basin [*Burkholder and Glasgow*, 1997]. A successful reduction strategy requires an accurate nitrogen budget for affected ecosystems and reliable source apportionment of nitrogen inputs to such systems. From an atmospheric standpoint, accurate emission factors for NH_3 sources, as well as measurement-based estimates of wet atmospheric deposition and dry deposition to various surface types, are essential. This study will address NH_3 emissions from swine waste lagoons, as this source is believed to contribute a substantial fraction of total NH_3 emissions in North Carolina [*Aneja et al.*, 1998b].

1.2. Ammonia Emissions

Ammonia is an important contributor to the atmospheric nitrogen budget; however, its sources and their emission strengths have received scant attention in the United States. The major global sources of ammonia include the decay of domestic livestock waste, volatilization losses from fertilizers, emissions from soils, and biomass burning. However, the largest contributor of ammonia to the global budget is domestic animal waste [*Bouwman et al.*, 1997; *Dentener and Crutzen*, 1994; *Schlesinger and Hartley*, 1992; *Warneck*, 1988; *Buijsman et al.*, 1987]. A preliminary nitrogen emission inventory for North Carolina (Table 1) suggests that ammonia emissions are primarily associated with livestock farming. Table 1 also reveals that swine operations contribute ~20% toward North Carolina's nitrogen emissions inventory and comprise ~47% of total NH_3 emissions in the state.

North Carolina has witnessed intense growth in its hog industry over the last decade (Figure 1). More than 90% of the states hog population resides in the Coastal Plain region [*Walker et al.*, 2000; *Walker*, 1998] where there is greater potential to directly impact coastal estuaries (Figure 2). The six most highly populated counties in this region have an average hog population density of ~528 hogs km^{-2} [*North Carolina Department of Agriculture* (*NCDA*), 1998] (Table 2), whereas the average hog population density for the remainder of the Coastal Plain region is ~65 hogs km^{-2} [*Walker et al.*, 2000]. Ammonia emissions from these six Coastal Plain counties account for approximately 36% of total statewide NH_3 emissions, with emissions from swine operations accounting for 77% of total NH_3 emissions within this six county region [*Chauhan*, 1999]. Using source-receptor modeling, *Walker et al.* [2000] have shown that under certain meteorological conditions NH_3 emissions from this six county area enhance wet deposition of NH_4^+/NH_3 at National Atmospheric Deposition Program/National Trend Network (NADP/NTN) sites up to 80 km away. The precipitation samples were collected by wet-only collectors (AeroChem Metrics Model 301 Wet/Dry Collector [*NADP/NTN*, 1998]). This distance is sufficient to allow for deposition to nitrogen-sensitive coastal and estuarine ecosystems. This illustrates the importance of quantifying NH_3 emissions from swine operations and properly relating these emission estimates to those factors which control emission rates. This information is necessary as inputs to atmospheric transport and deposition models such as the Regional Acid Deposition Model (RADM) currently being modified to accurately address the atmospheric transport and deposition of NH_x (=NH_3 + NH_4^+). Such models will help policy makers assess the impact and magnitude of atmospheric nitrogen deposition on local and regional scales.

Emission factors used thus far for generating preliminary North Carolina ammonia emission inventories for various animal husbandry operations are largely based on European work [*Battye et al.*, 1994]. The European factors must be verified or refined for conditions in North Carolina. An initial step in this process is the development of swine factors since total emissions from swine are greater than other animal categories in North Carolina. There are four principal sources of NH_3 emissions on a current commercial hog operation: hog production houses, waste storage and treatment lagoons, land application of lagoon slurry to adjacent cropland, and subsequent reemission of NH_3 from the soil. Lagoon NH_3 emissions arise

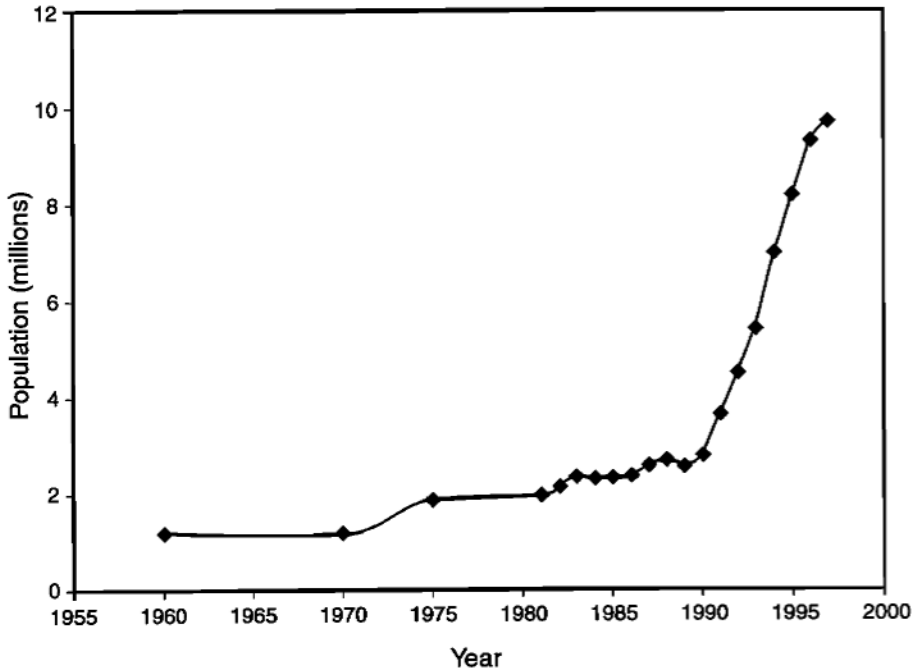

Figure 1. Trend in swine population in North Carolina, 1960–1997 (source of data: *NCDA* [1998]).

as urine and feces are flushed with water from the hog houses and discharged into the lagoon. Gas and liquid phase mass transfer processes are thought to be equally important in determining the overall desorption/absorption rate of ammonia [*Leuning et al.*, 1984]. As the slurry (~98% water [*Bicudo et al.*, 1999]) is stored in the lagoon, urea is hydrolyzed by the enzyme urease, present in feces, to produce NH_3 and carbon dioxide [*Aarnink et al.*, 1995; *Miller and Gardiner*, 1998].

The primary objective of this study was to measure the atmospheric flux of NH_3 from a swine waste storage and treatment lagoon during the four seasons at an intensively managed industrial hog operation in order to develop emission factors. The secondary objective was to parameterize the NH_3 flux process with respect to changes in lagoon physicochemical parameters (lagoon temperature, pH, and Total Kjeldahl Nitrogen (TKN)) for use in air quality models.

2. Methods and Materials

2.1. Sampling Site

Flux measurements were made at a farrow to finish commercial hog operation in Sampson County, North Carolina. The farm consisted of 13 hog production houses housing approximately 10,000 animals: 1212 sows and boars (average weight ~181 kg each), 7480 finishers (~61 kg each), and ~1410 suckling pigs (~11 kg each) (R. B. McCulloch, Division of Air Quality, North Carolina Department of Environment and Natural Resources, personal communication, 1998). The

waste from the hog sheds (urine and feces) was flushed out with recycled lagoon water and discharged into the lagoon from the top ("toploading"). The lagoon itself was an aboveground anaerobic system with sloping sides that reached a maximum depth of ~4 m at the center. The surface area of the lagoon was ~25,000 m^2 (~100 m × ~250 m).

2.2. Slurry Composition and Analysis

To determine the concentration of total nitrogen (aqueous ammonia, ammonium, and nitrates) in the slurry, lagoon water samples were taken once every day during the flux sampling periods and submitted to the Department of Soil Science, North Carolina State University for analysis. Samples were analyzed for Total Kjeldahl Nitrogen (TKN) using a digestion procedure, which converts all N in the lagoon sample to NH_4^+. The NH_4^+ concentration in the sample was determined by colorimetry.

2.3. Flux Measurements

Ammonia flux was measured using a dynamic chamber system [*Aneja et al.*, 1996a, b]. Summer measurements were made from August 1–15, 1997. The fall (December 1997) and winter (February 1998) intensives lasted intermittently for 6 and 10 days, respectively. Flux measurements were discontinued during precipitation events. In spring, ammonia flux measurements were made from May 16–27, 1998. Lagoon water temperature was monitored continuously with a temperature probe (Fascinating Electronics, Deer Island, Oregon) immersed ~15 cm below the lagoon water surface ≈48 cm from the chamber, and the lagoon pH was monitored continuously using a double junction submersible electrode (Cole Parmer, Vernon Hills, Illinois), also placed ≈48 cm from the chamber and adjacent to the temperature probe. Some measurements of temperature and pH were also recorded manually.

2.4. Chamber Design and Operation

The dynamic chamber used in this study is a fluorinated ethylene propylene (FEP) Teflon-lined (5 mil thick) open bottom cylinder (diameter ~27 cm, height ~42 cm, and volume ~25 L) inserted into a 1.22 m × 1.22 m floatable platform. When the platform and chamber were placed on the lagoon, the chamber penetrated the lagoon surface to a depth of ~4 cm forming a seal between the lagoon surface and the air within the chamber. The placement of the chamber on the lagoon surface was performed in a statistically random manner. Figure 3 shows a schematic of the floating dynamic chamber system. Compressed zero-grade air (National Welders, Raleigh, North Carolina) was pumped through the chamber at a constant flow rate of ~4.73, 4.14, 2.69, and 2.36 ℓ min^{-1} for the summer, fall, winter, and spring field measurement periods,

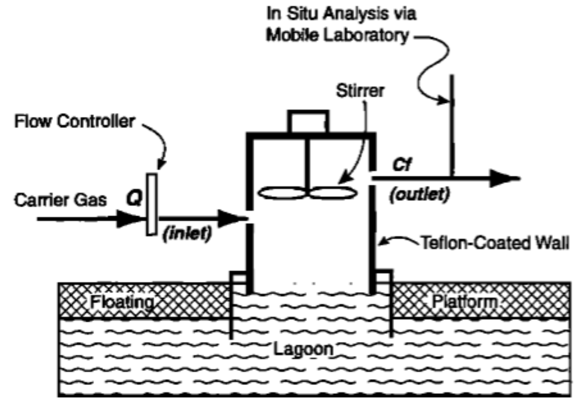

Figure 3. Schematic of a dynamic flow through chamber. The chamber fits on a floating platform which is placed on the surface of the waste treatment lagoon ~24 hours prior to start of measurements to minimize disturbances.

respectively. The air in the chamber was well mixed continuously by a motor-driven Teflon impeller (~20 cm diameter at ~50 rpm). The length of the Teflon tubing (0.64 cm OD) connecting the chamber and the ammonia analyzer was less than 10 m.

2.5. Flux Calculation

The mass balance for NH_3 in the chamber is given by

$$\frac{dC}{dt} = \left[\frac{Q[C]_o}{V} + \frac{JA_L}{V}\right] - \left[\frac{LA_c[C]}{V} + \frac{Q[C]_f}{V}\right] - R \quad (1)$$

where A_L is the lagoon surface area covered by the chamber, A_c is the inner surface area of the chamber, V is the volume of the chamber, Q is the flow rate of carrier gas through the chamber, J is the emission flux, $[C]$ is the NH_3 concentration in the chamber, $[C]_f$ is the NH_3 concentration at the outlet of the chamber, L is the loss term by the chamber wall per unit area assumed first order in $[C]$, and R is the chemical production rate in the chamber.

Because compressed zero air was used as the carrier gas, there is no inlet concentration of ammonia, $[C]_o = 0$, and for a well mixed chamber $[C]_f$ may be assumed to be equal to the NH_3 concentration everywhere in the chamber, $[C]$. Finally, at steady state the above equation reduces to

$$J = [C]_f\left[\frac{LA_c}{V} + \frac{Q}{V}\right]h \quad (2)$$

where h is the height of the chamber measured from the lagoon surface. The value of the total loss term L was obtained (0.079 m min^{-1} and 0.059 m min^{-1} during summer and winter seasons, respectively) by conducting the surface loss experiment as proposed by *Kaplan et al.* [1988] and *Aneja et al.* [1996b].

Once the chamber reached steady state conditions (~30 min of operation), the outgoing air was conducted through Teflon tubes to a Measurement Technologies 1000N stainless steel NH_3 converter which transformed the N_T (=NH_3 + R-NH_2 + NO + NO_2) constituents of the sampled air into nitric oxide (NO) at ~825°C [*Aneja et al.*, 1978]. The sample flow from the NH_3 converter was routed to an Advanced Pollution Instruments (API) Model 200 chemiluminescence-based NO monitor where the transformed N_T concentration in ppbv was de-

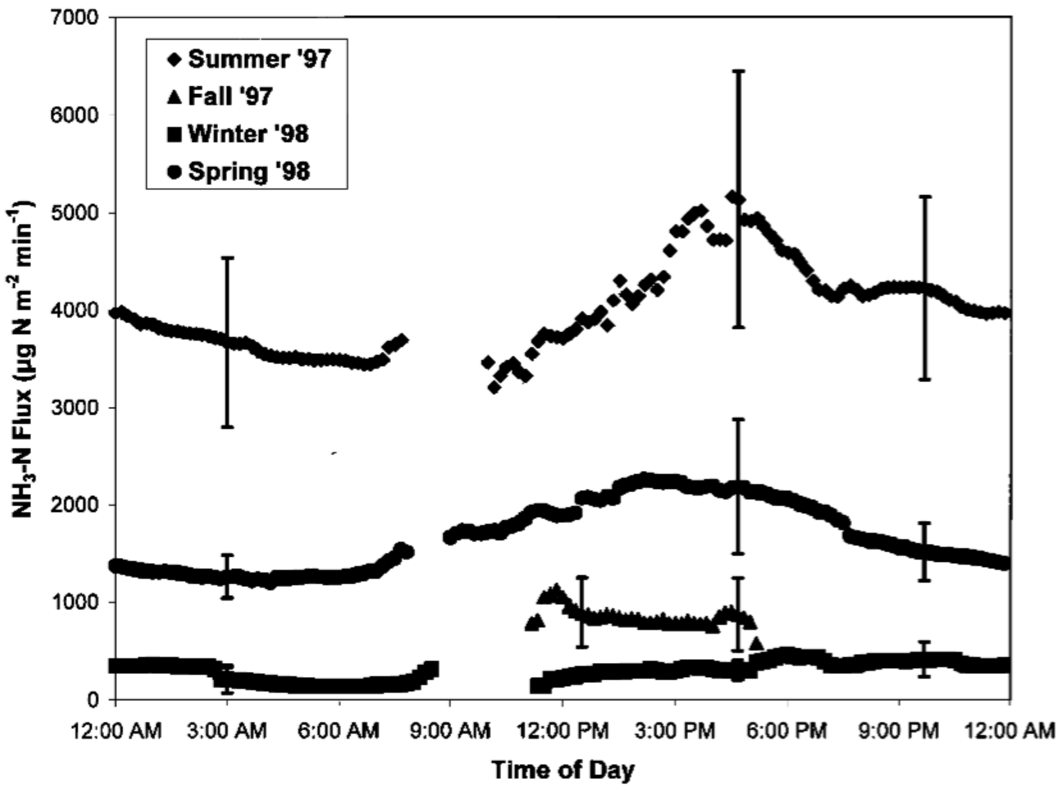

Figure 4. Daily trends of ammonia-N flux from the lagoon during the four seasons. $N = 12$ in summer, $n = 12$ in spring, $n = 6$ in fall, and $n = 4$ in winter except between 1100 and 1700 LT where $n = 8$. Vertical lines represent one standard deviation.

termined. Part of the flow from the chamber was bypassed directly to the API, which transformed to NO only the NO + NO_2 (=NO_x) portion of N_T via a molybdenum converter heated to ~350°C [*Aneja et al.*, 1996a, b; *Fehsenfeld et al.*, 1987]. The API then determined the NH_3 concentration in surface lagoon air by subtracting the NO_x signal from the N_T signal ($NH_3 = N_T - NO_x$). The API was calibrated following written protocols using a Thermo Environment Instruments Inc. Model 146 gas dilution/titration instrument with a calibration gas mixture of NO in N_2 (734 ppmv) and compressed zero-grade air. A multipoint calibration on the API analyzer was performed before each intensive, and the instrument was zeroed and spanned daily during each measurement intensive. The early morning data gaps (Figure 4) represent the time period during which the daily zero/span procedure was performed on the ammonia analyzer. The efficiency of the ammonia converter was checked regularly using a known ammonia concentration. Laboratory tests using a known concentration of NH_3 have shown no measurable conversion of NH_3 to NO at 350°C within a molybdenum converter. Instrumentation was housed in a temperature-controlled mobile laboratory (modified Ford Aerostar van).

3. Results and Discussion

The ammonia-water system has been studied in the past because of its industrial importance and as a means for studying the absorption/desorption mechanism [*Whitman and Davis*, 1924; *Godfrey*, 1973; *Levenspiel and Godfrey*, 1974; *Ibusuki and Aneja*, 1984; *Leuning et al.*, 1984]. All these previous studies indicate that generally both the gas and liquid phase resistance are equally important in determining the overall desorption/absorption rate.

The measurements described for determining ammonia flux at the lagoon-atmosphere interface are made with the dynamic chamber system with continuous impeller stirring (the carrier gas flow rate through the chamber and stirrer speed may be changed). Utilizing the power law profile which is frequently used in air pollution applications [*Arya*, 1999], we are able to estimate what wind velocities are at a height of 0.1 m (the height of the impeller above water-air interface) when 10 m wind heights are known. The power law profile is given by

$$\frac{V}{V_r} = \left(\frac{Z}{Z_r}\right)^m \tag{3}$$

where V_r is the wind velocity at a reference height Z_r and m is taken to be 0.1 for water surfaces [*Arya*, 1988].

Throughout the measurement period during this study, mean wind velocities were between 1 and 4 m/s at a height of 10 m. Through the power law profile above, this equates to wind speeds between 0.6 and 2.4 m/s at a height of 10 cm similar to wind speeds inside the chamber (measured with a hot wire anemometer between ~1 and 2.5 m/s) for our design configuration.

The dynamic chamber system with continuous impeller stirring meets the necessary criteria for performance as a Continuously Stirred Tank Reactor (CSTR). For performance as a CSTR, the chamber needs to be "ideally" mixed [*Aneja*, 1976]. In ideal mixing, the composition of any elemental volume within the chamber is the same as that of any other volume.

Table 3. Summary Table of Average Daily NH_3-N Fluxes by Season

	Mean[a]	Maximum	Minimum
Summer 1997	4017 (987)[b]	8526	2358
Fall 1997[c]	844 (401)	1913	369
Winter 1998[d]	305 (154)	695	90
Spring 1998	1706 (552)	3594	851

NH_3-N flux = (14/17) NH_3 flux.
[a]Units of daily flux are $\mu g\ N\ m^{-2}\ min^{-1}$.
[b]Numbers in parentheses are one standard deviation.
[c]All values were measured from 1100 to 1700 LT.
[d]Measurements were made on February 1, 2, 8, 15, 18, 20, 21, 22, 23, 25, and 26, 1998 (1100–1700 LT), with February 21, 22, and 25 being diurnal variations.

Tracer experiments (Residence Time Distribution) were used to test the flow and mixing characteristics of the system. The results of these mixing studies showed that the dynamic chamber behaved as a "perfect" mixer with negligible stagnancy or channeling.

3.1. Seasonal Fluxes

Table 3 summarizes the average fluxes for each season. Using seasonal averages, the percent of total yearly flux attributable to summer months is ~60%. The change in the daily flux pattern for each season can be seen in Figure 4 together with one standard deviation (±1 s.d.). Each data point in this figure represents an average of the flux measured at a particular time over the entire measurement period. In general, $n = 12$ (where n is the number of flux values that made up the average) for the summer and spring seasons, $n = 4$ for the winter season except between 1100 and 1700 LT where $n = 8$ and $n = 6$ for the fall season. The morning data gaps (Figure 4) represent the time period during which the daily zero/span procedure was performed on the ammonia analyzer. The analyzer was also multipoint-calibrated regularly during the same time period. The reasons for the slight flux increase during morning hours, prior to the daily zero/span procedure, is not known. However, ammonia desorption from the inner surfaces caused by morning temperature increase may be a possibility [*Williams et al.*, 1992; *Adema et al.*, 1990].

3.2. Lagoon Temperature and Ammonia Flux

The pronounced summer maximum flux suggests that temperature is an important factor regulating the loss of NH_3 from the waste lagoon to the atmosphere. In this study the relationship between lagoon temperature and NH_3 flux is examined over a relatively wide range of temperatures (~4°C to ~40°C). Table 4 lists average lagoon surface temperatures measured during each season. We observed an exponential ($r^2 = 0.78$) relationship between NH_3 flux and lagoon water temperature measured over the year as illustrated in Figure 5. Each point in this figure represents an hourly averaged NH_3 flux ($n = 6$, where n is the number of flux values in an hourly average) plotted against the corresponding hourly temperature measurement. Reasons for the exponential relationship are that the liquid phase mass transfer coefficients of NH_3 in water are exponential functions of temperature in the range 5°C to 30°C [*Ibusuki and Aneja*, 1984], and the dependence of Henry's law on temperature [*Dasgupta and Dong*, 1986; *Bates and Pinching*, 1950]. Thus the transfer of NH_3 across the liquid-gas interface follows an exponential model; and the flux increases exponentially with surface lagoon temperature. The ammonia flux from the waste storage and treatment lagoon in North Carolina may be predicted by the observational model

$$\log_{10}(NH_3 - N\ \text{flux}) = 0.048\ T_\ell + 2.1$$

where NH_3 − N flux ($\mu g\ N\ m^{-2}\ min^{-1}$); T_ℓ lagoon surface temperature (°C).

The reason for the high NH_3 flux during summer is a combination of chemical and physical processes occurring within the lagoon. First, the decomposing waste sludge at the bottom of the lagoon acts as a source of NH_3, and the rate of decomposition increases with temperature. As NH_3 from the surface of the lagoon is volatilized, NH_3 formed from the decomposition of sludge at the bottom of lagoon diffuses upward and replenishes the volatized NH_3 in the upper layers of the lagoon. Since this lagoon is not physically mixed by forced means, ammonia's principle mode of transport is through diffusion and mass transfer processes [*Muck and Steenhuis*, 1982]. As illustrated by *Ibusuki and Aneja* [1984], higher temperatures increase the transfer rate of NH_3 across the liquid-gas interface. Thus summer temperatures coupled with a readily avail-

Table 4. Sampling Periods for NH_3-N Flux Measurements and the Mean, Standard Deviation, and Range of Lagoon Surface (i.e., 15 cm Depth) Parameters Measured During the N-NH_3 Flux Experiments

Season	Sample Dates	Lagoon Temperature[a]	Lagoon pH	TKN[b]
Summer	Aug. 1–15, 1997	30 (3.3)[c]	7.5 (0.18)	648.1 (27.7)
		25.3–39.1	7.1–7.8	587–695
Fall	Dec. 1–17, 1997[d]	11.6 (2.2)[e]	8.0 (0.06)	663.3 (33.7)
		8.4–15.3	7.9–8.1	599–715
Winter	Feb. 1–26, 1998[f]	12.1 (2.1)[e]	7.8 (0.13)	641.7 (39.0)
		8.8–15.1	7.66–8.02	580–727
Spring	May 16–27, 1998	24.7 (3.2)	7.7 (0.06)	603.3 (48.2)
		20.4–35.9	7.64–7.81	540–720

[a]Units of lagoon temperature are degrees Celsius.
[b]Units of TKN nitrogen are mg N L^{-1}.
[c]Numbers in parentheses are one standard deviation.
[d]Flux measurements were made on December 1, 3, 5, 7, 15, and 17, 1997 (from 1100 to 1700 LT).
[e]All values of lagoon temperature and pH were measured from 1100 to 1700 LT manually.
[f]Measurements were made on February 1, 2, 8, 15, 18, 20, 21, 22, 23, 25, and 26, 1998 (from 1100 to 1700 LT), with February 21, 22, and 25 representing diurnal variations.

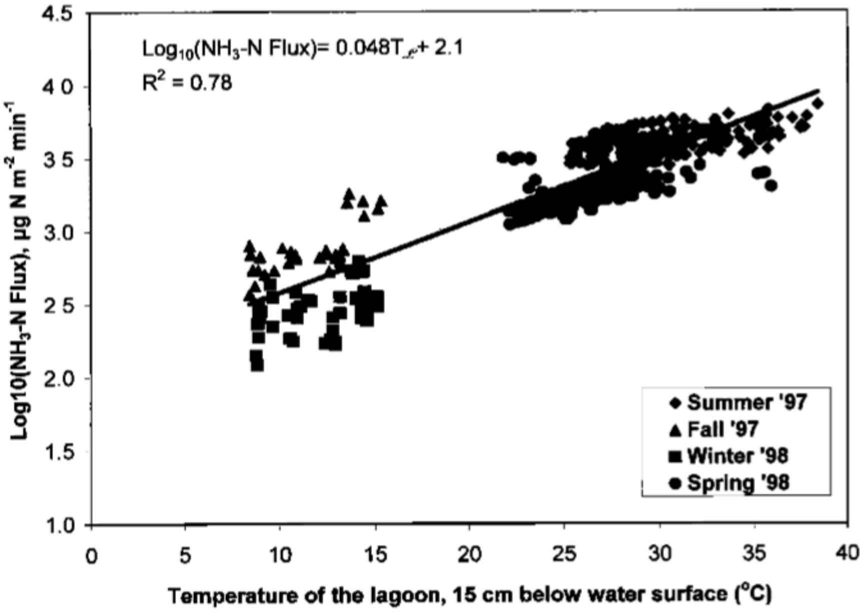

Figure 5. Log of hourly averaged ammonia-nitrogen flux from the lagoon surface plotted against lagoon aqueous phase surface temperature.

able source of NH_3 results in summer fluxes (4017 ± 987 μg N m^{-2} min^{-1}) which are about an order of magnitude greater than those observed during the winter (305 ± 154 μg N m^{-2} min^{-1}) season.

Temperature (lagoon surface water and/or ambient) is a controller of NH_3 emissions in the boundary layer, and therefore NH_3 mixing ratios in the lower troposphere. *Langford et al.* [1992] have suggested that the "typical" seasonal and diel cycles of boundary layer NH_3 levels are, in general, a function of air temperature, with higher NH_3 mixing ratios associated with warmer temperatures. These seasonal NH_3 concentrations should therefore be manifest in ammonium ion concentration [NH_4^+] in precipitation. Multiple regression analysis of monthly volume-weighted ammonium concentration in precipitation at the National Atmospheric Deposition Program (NADP) site located in close proximity to the flux study, NC35 (located in Sampson County, latitude 35°01′33″ N and longitude 78°16′21″W [*NADP/NTN*, 1998]), during the period 1982–1996 reveals a statistically significant ($p < 0.01$, $r^2 = 0.29$) positive correlation between mean monthly surface temperature and log of ammonium concentration (Figure 6). The present study has shown that volatilization of NH_3 from swine waste lagoons has a positively correlated exponential relationship with lagoon surface water temperature. At sites such as NC35, which are likely influenced by multiple nearby swine facilities, this may also contribute to the temperature dependence of ambient NH_3 concentrations and subsequent NH_4^+ concentrations in precipitation. *Walker* [1998] has shown a statistically significant seasonal cycle for [NH_4^+] in precipitation, which maximizes during summer months, at NADP sites across North Carolina.

3.3. Lagoon pH and Ammonia Flux

The highest pH values were observed in the fall and winter seasons and ranged from 7.7 to 8.1 (Table 4). *Koelliker and Minor* [1973] have also observed pH values up to 8 in the fall and winter at a Missouri hog lagoon. The relative stability of lagoon pH throughout the year is due to the high buffer capacity of the slurry [*Olesen and Sommer*, 1993]. The pH of the lagoon is maintained by the bicarbonate ion, formed as a product of the hydrolysis of urea and microbial conversion of organic matter (equation (4)), which neutralizes the H^+ ion released into solution by NH_4^+(aq) as NH_3(aq) volatilizes (equation (5)) [*Sommer et al.*, 1991; *Fordham and Schwerdman*, 1997]:

$$CO_2(aq) + H_2O(aq) \leftrightarrow CO_3^-(aq) + 2H^+(aq) \quad (4)$$

$$NH_4^+(aq) \leftrightarrow H^+(aq) + NH_3(aq). \quad (5)$$

Several published modeling studies [*Dewes*, 1996; *Muck and Steenhuis*, 1982; *Vlek and Stumpe*, 1978; *Sommer et al.*, 1991] report a positive relationship between lagoon NH_3 flux and pH. In lagoon slurry, NH_3 will be in solution with NH_4^+ according to the following equilibrium [*Warneck*, 1988]:

$$NH_3(aq) + H_2O(aq) \leftrightarrow NH_4^+(aq) + OH^-(aq). \quad (6)$$

The direction of the equilibrium in (6) depends on the pH. As the pH increases ([OH^-] increases), the equilibrium shifts toward the left increasing the concentration of NH_3(aq) and hence the potential for volatilization. Thus the proportion of the total NH_3 concentration that is ionized at any time is a function of lagoon pH. Equation (7) provides the theoretical relationship between the aqueous ammonia fraction, $F = NH_3/(NH_3 + NH_4^+)$, and pH of the lagoon [*Loehr*, 1984]:

$$F = \frac{1}{1 + 10^{(pK_a - \mathrm{pH})}} \quad (7)$$

where pK_a is the negative logarithm of the ionization constant for (6). The relationship between flux and the pH over the range observed in this study (7.1 to 8.1) follows the theoretical prediction given by (7).

3.4. TKN and Ammonia Flux

A plot of the average daily flux over the entire year against TKN nitrogen for lagoon samples collected on the same day as

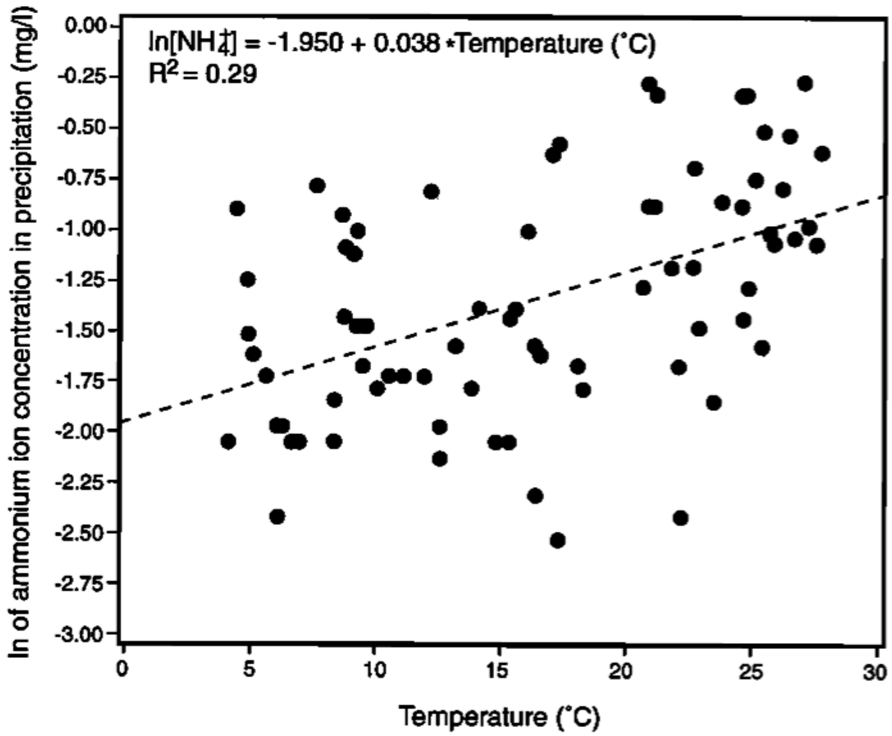

Figure 6. Natural log of monthly volume-weighted ammonium (NH_4^+) ion concentration in precipitation versus mean monthly atmospheric ambient temperature for the NADP/NTN site NC35, located in Sampson County during the period 1983–1996 (solid circles) and the corresponding regression line (dashed line).

the flux measurement is shown in Figure 7. We observed that the TKN levels remain relatively constant, varying between ~500 and ~750 mg N L^{-1} (Table 4). This stability is because the lagoon on which our measurements were taken is part of a steady state commercial operation at which animal weight and feed distributions are about the same throughout the year. Thus the fresh waste input into the lagoon has a relatively constant nitrogen content which keeps lagoon TKN levels steady throughout the year. Across different seasons the lagoon experiences various rates of evaporation and receives varying amounts of precipitation; however, these factors are likely to cause relatively minor fluctuations in the nitrogen concentration of the lagoon.

3.5. Scaling Ammonia Emissions Utilizing Remotely Sensed Data

Using the Geographic Information System (GIS) spot satellite image of North Carolina for the period 1995–1996, a statistically random sample of 50 lagoons was obtained for lagoon surface area in eastern North Carolina (http://www.lib.ncsu.edu/stacks/gis). The 50 lagoons sampled for surface area, measured with the help of ARCVIEW 3.0, was 54 ha (i.e., ~1 ha/lagoon). The number of lagoons in eastern North Carolina is ~2500 lagoons [*NCDA*, 1998]. The seasonal average lagoon ammonia emission from this study is ~1718 ± 523 μg N m^{-2} min^{-1}; and the total ammonia emissions from swine operations is ~68,540 t N yr^{-1} [*Aneja et al.*, 1998b, c] (Table 1). From the emissions obtained in this study, it is therefore estimated that lagoon ammonia emissions in eastern North Carolina comprise approximately 33% of total swine NH_3 emissions in North Carolina.

4. Conclusions

The data presented in this paper add to the growing knowledge of NH_3 flux from animal agricultural practice. The summer intensive conducted during August 1–15, 1997, presented us with typical summer temperatures observed in North Carolina and gave the highest flux estimates of the year. Using the dynamic chamber system, the average flux in the summer of 1997 was 4017 ± 987 μg N m^{-2} min^{-1}. The averages during the spring, fall, and winter seasons were 1706 ± 552, 844 ± 401, and 305 ± 154 μg N m^{-2} min^{-1}, respectively. We found that the NH_3 flux displays a diurnal variation which is highly correlated with lagoon surface water temperature and reaches a maximum between 1500 and 1800 LT. Ammonia flux is found to vary exponentially with lagoon surface water temperature. The pH and TKN levels in the lagoon remained relatively constant at an average value of ~7.5 pH, and ~650 mg N L^{-1}, respectively.

The emission factors obtained by this research and other similar measurements on swine agriculture are summarized in Table 5. In general, there is reasonable agreement between researchers making NH_3 flux measurements from swine agriculture. The emissions factors listed represent emissions values from varying locations around the globe. The scatter in the emission factors may be explained by differences in meteorology, management practices, animal feeds, and experimental error. Using remotely sensed lagoon surface area data, we have also estimated that lagoon ammonia emissions in eastern North Carolina comprise approximately 33% of total swine NH_3 emissions in North Carolina.

It is reasonable to assume that animal agriculture will be a

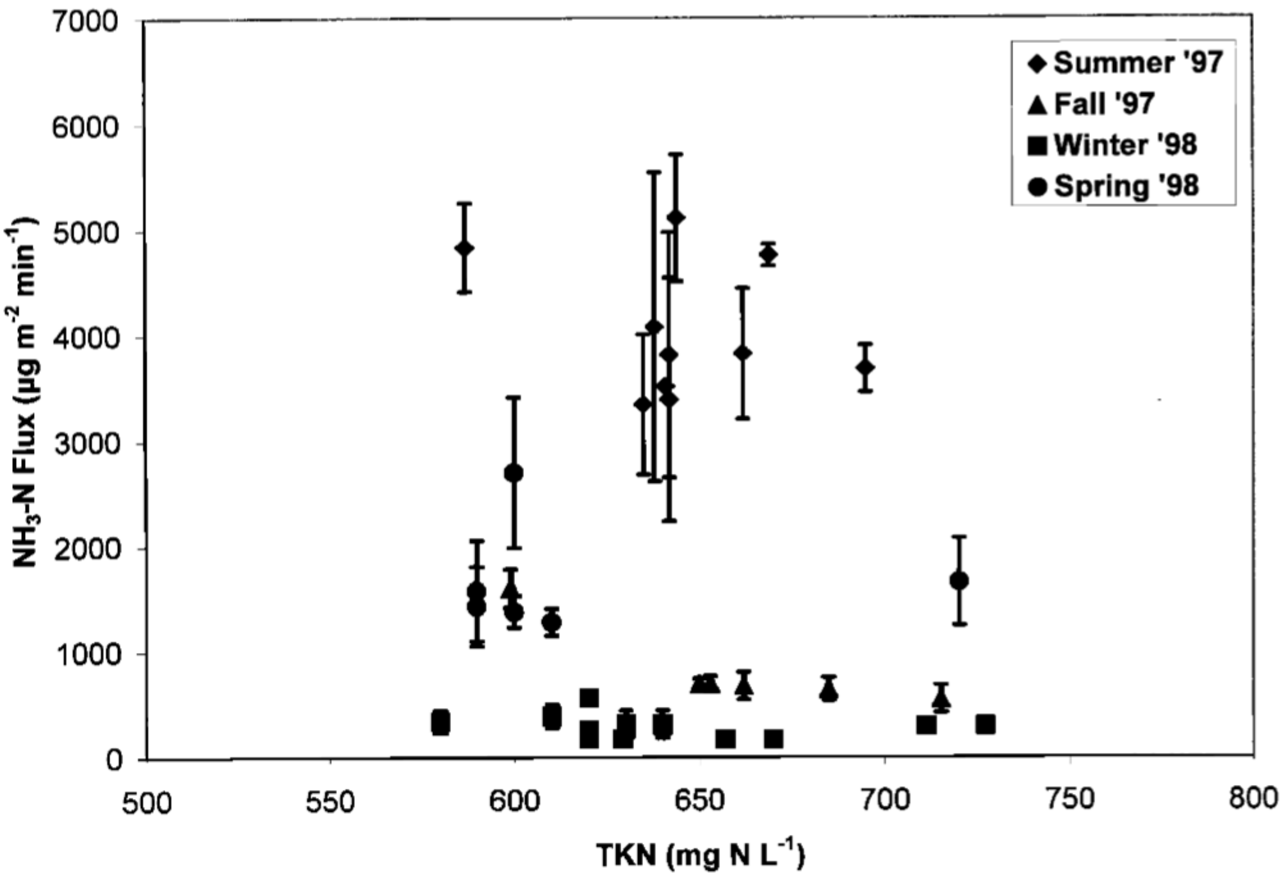

Figure 7. Average daily ammonia-N flux from the lagoon surface versus Total Kjeldahl Nitrogen (TKN) sampled from lagoon collected on the same day as the flux measurements. TKN measurement includes ammonia, ammonium, and nitrates in the aqueous phase.

continued source of significant atmospheric NH_3 emissions in eastern North Carolina. Moreover, *Walker et al.* [2000] have demonstrated that increasing trends in ammonium concentration in precipitation in eastern North Carolina are directly correlated to the ever-expanding hog population in this region. Atmospheric deposition of NH_x will undoubtedly continue to impact nearby ecosystems with the potential of enhancing eutrophication and soil acidification. Furthermore, enhanced NH_3 emissions will enhance particulate matter formation in the region, which reduces visibility [*Barthelmie and Pryor*, 1998] and also causes health problems for workers in livestock agriculture [*Reynolds and Wolf*, 1988; *Michaels*, 1999]. Another concern associated with NH_3 emission is its potentially harmful odor. To address these concerns and outline possible control strategies, further research is required in modeling the fate of NH_x with regional deposition models.

Abstract

Program OPEN (Odor, Pathogens, and Emissions of Nitrogen) was an integrated study of the emissions of ammonia (NH_3), odor and odorants, and pathogens from potential environmentally superior technologies (ESTs) for swine facilities in eastern North Carolina. This paper, as part of program OPEN, focuses on quantifying emissions of NH_3 from water-holding structures at two of the best ESTs and compares them with the projected emissions from two conventional lagoon and spray technologies (LSTs). The evaluated ESTs are: (1) Super Soils at Goshen Ridge; and (2) Environmental Technologies at Red Hill. The water-holding structures for these two ESTs contained no conventional anaerobic lagoon. A dynamic flow-through chamber was used to measure NH_3 fluxes from the water-holding structures at both the ESTs and at the conventional LST farms. In order to compare the emissions from the water-holding structures at the ESTs with those from the lagoons at the conventional sites under similar conditions, a statistical-observational model for lagoon NH_3 emissions was used. A mass-balance approach was used to quantify the emissions. All emissions were normalized by nitrogen-excretion rates. The percentage reductions relative to the conventional lagoons were calculated for the two ESTs. Results showed substantial reductions in NH_3 emissions at both ESTs. Super Soils had reductions of 94.7% for the warm season and 99.0% for the cool season. Environmental Technologies had slightly larger reductions of 99.4% and 99.98% for the cool and warm season, respectively. As a result of such large reductions in ammonia emissions, both technologies meet the criteria to be classified as ESTs for ammonia emissions.

Keywords: Ammonia emissions; Ammonia flux; Water-holding structures; Environmentally superior technologies (ESTs); Lagoon and spray technologies (LSTs)

1. Introduction

Atmospheric ammonia (NH_3) is a very important alkaline constituent, and has a significant influence

doi:10.1016/j.atmosenv.2007.08.037

on a variety of environmental processes (Aneja et al., 2006a, b). Ammonia reacts with a variety of acidic atmospheric species, such as sulfuric acid (H_2SO_4), nitric acid (HNO_3), and hydrochloric acid (HCl), to form ammonium aerosols, namely, ammonium bisulfate (NH_4HSO_4), ammonium sulfate ($(NH_4)_2SO_4$), ammonium nitrate (NH_4NO_3), and ammonium chloride (NH_4Cl).

Ammonia and ammonium are removed from the atmosphere through both wet and dry deposition processes. Wet deposition occurs by either below cloud scavenging (washout) or by rainout (in-cloud processes). Atmospheric NH_3 and its deposition lead to a variety of environmental consequences such as fine particulate matter formation, soil acidification and aquatic eutrophication.

Ammonia is emitted by a large variety of sources such as soils and agricultural crops, synthetic fertilizers, animal waste, biomass burning, fossil-fuel combustion, and human excreta (Oliver et al., 1996; Bouwman et al., 1997). Domestic animal waste is the leading source of global atmospheric ammonia. Studies suggest that it contributes between 20 and 35 Tg of nitrogen per year (Bouwman et al., 1997; Warneck, 2000). In North Carolina, swine waste is the dominant source accounting for 47% of all ammonia emissions, and it is estimated that about 75 000 tons of nitrogen per year are released by hog waste (Aneja et al., 1998). These emissions are related to a rapid increase in hog population, from approximately 3 million in 1992 to 10 million in 1997, when a moratorium was placed. The increase in hog population has been concentrated in the coastal plain region of North Carolina, which contains about 85% of the current pig population (Aneja et al., 2000). The lagoon and spray technology (LST) is the system currently employed to manage hog waste in North Carolina. It consists of an anaerobic lagoon to store and biologically treat the hog waste, which is then sprayed on nearby crops as a source of nutrients.

Due, in part, to the environmental problems associated with ammonia/ammonium emissions from LST farms, a moratorium in 1997 was placed on the construction of swine facilities and the expansion of existing swine facilities until September 2007.

In order to develop sustainable solutions to this problem, an agreement between the North Carolina Attorney General and several commercial hog farming companies was reached to develop potential environmentally superior technologies (ESTs) for hog facilities (Williams, 2001). Program OPEN (Odor, Pathogens, and Emissions of Nitrogen) was an integrated study of the emissions of ammonia, odor and odorants, and pathogens from potential ESTs for hog facilities. Its objectives were to evaluate 16 potential ESTs at swine facilities to determine if they would be able to substantially reduce atmospheric emissions of NH_3, pathogens, and odor from their observed or estimated emissions from the conventional LST used at selected conventional farms in different (warm and cool) seasons or observation periods. Previous papers present the results for the conventional LST farms (Aneja et al., 2007a), and the evaluation of six potential ESTs, that would need improvements/modifications to qualify as ESTs (Aneja et al., 2007b). This paper focuses on characterizing and quantifying emissions of NH_3 from water-holding structures at two ESTs that met the specified performance standards (Williams, 2004) for ammonia emissions reduction, and therefore qualified as ESTs. This evaluation was achieved by comparing them with projected emissions from two conventional (also called, baseline) LST farms. The evaluated ESTs are: (1) Super Soils at Goshen Ridge; and, (2) Environmental Technologies at Red Hill. The water-holding structures for both of these ESTs contain no conventional anaerobic lagoon. Therefore, these might be considered to be most effective for reducing ammonia.

2. Methodology

2.1. Approach to evaluate ammonia emissions at EST farms

Ammonia flux measurements were conducted during 2-week periods representing different seasons (characterized here as warm and cool) at two EST sites in eastern North Carolina and also at two conventional farms (Stokes Farm and Moore Farm), which are also referred to as "baseline" sites for comparison with EST sites (for locations see Fig. 1). Measurements at the different sites were made at different times of the year. Therefore, to compare the EST and LST sites, the different environmental conditions at each site need to be taken into account. This is achieved by the development of a statistical-observational model (Aneja et al., 2007a).

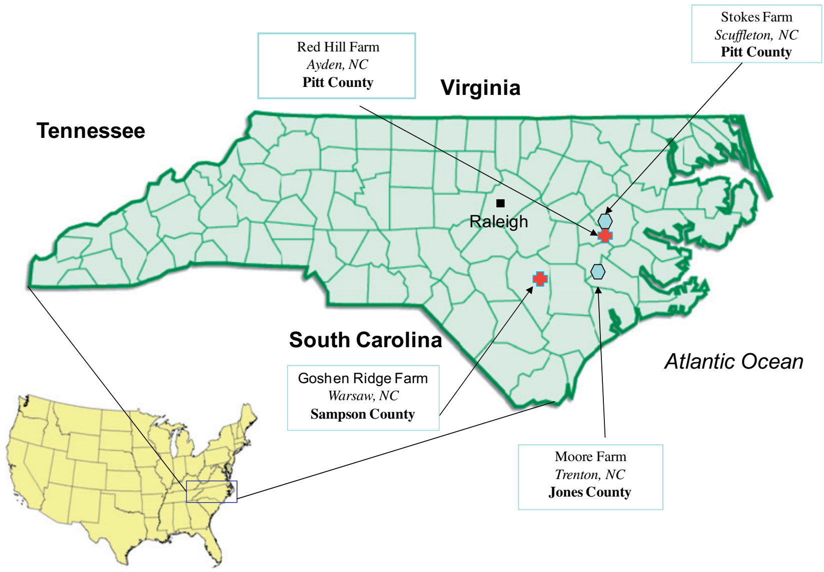

Fig. 1. Map of North Carolina indicating the location of the environmentally superior technologies (ESTs), and lagoon and spray technologies (LSTs). Blue hexagon indicates an LST farm, red cross an EST farm.

2.1.1. Statistical-observational model for lagoon NH_3 flux based on conventional farm measurements

Aneja et al. (2007a) developed a model based on flux measurement data from two conventional farms. For more information on the development of the model, the reader is referred to Aneja et al. (2007a). In this paper the model development is only briefly summarized.

The relationships between NH_3 flux, lagoon temperature, pH and a range of environmental parameters were examined over a relatively wide range of lagoon temperatures (~2–~35 °C) and lagoon–air temperature differences. These were observed during the warm and cool seasons at both conventional farms. The statistical–observational model was developed using multiple regression analysis on flux measurement data from two conventional farms. It is given as

$$\mathrm{Log}_{10}\, F = 3.8655 + 0.04491(T_1) - 0.05946(D). \quad (1)$$

Here, F denotes the average NH_3-N emission from the conventional lagoon in $\mu g\, min^{-1}(1000\, kg\, lw)^{-1}$, T_1 is the lagoon temperature in °C, and D is a hot-air variable that is equal to zero if lagoon is warmer than air, but is equal to $\Delta T = T_a - T_1$ when $T_a > T_1$, and T_a is air temperature in °C at 2 m height. This statistical–observational model was used to estimate the projected NH_3-N flux from lagoons at the LST baseline farms to compare with the measured NH_3-N flux from water-holding structures at an EST site, for the average values of T_1 and D observed at the latter.

2.1.2. Estimation of % reduction in ammonia emissions at EST sites

Both the measured EST emissions and the model estimated LST emissions were normalized by the nitrogen excretion rate (E) for the farm, and are called $\%E$, where $\%E$ represents the loss of ammonia from a source, as a percentage of N-excretion rate. Nitrogen excretion was based on a mass balance approach. Nitrogen excretion rate (E) in unit of $kg\, N\, week^{-1}\, (1000\, kg\, lw)^{-1}$ was determined using the following equation:

$$E = \frac{F_c \times N_f \times (1 - e_r)}{\bar{w}} \times 1000, \quad (2)$$

where F_c is the feed consumed ($kg\, pig^{-1}\, week^{-1}$), N_f is the fraction of nitrogen content in feed, e_r is the feed efficiency rate (ratio of average gain of nitrogen-to-nitrogen intake) (PigCHAMP, 1999), and $\bar{w}$ is the average live animal weight ($kg\, pig^{-1}$). Nitrogen excretion at each farm was calculated in term of the same units as NH_3-N emissions estimated from the water-holding structure of the EST farm and are shown in Table 1.

A potential EST was evaluated by comparison of $\%E$ value from the EST ($\%E_{EST}$) farm to $\%E$ value from a baseline conventional farm ($\%E_{CONV}$), and percent reduction of NH_3-N can

be estimated as

$$\%\text{reduction} = \frac{(\%E_{\text{CONV}} - \%E_{\text{EST}})}{\%E_{\text{CONV}}} \times 100. \qquad (3)$$

An algorithmic flow diagram is shown in Fig. 2, which summarizes the evaluation of NH_3 emissions from water-holding structures at EST farms.

2.2. Sampling sites

2.2.1. LST sites

Stokes Farm (35.43°N, 77.48°W, 17 m MSL) is located in Pitt County, North Carolina. Measurement campaigns were conducted during 9–20 September 2002 and 6–17 January 2003, respectively. Four naturally ventilated finishing barns housed 4392 animals with an average weight of 104 kg in the fall season and 3727 animals with an average weight of 88 kg in the winter season. The waste (urine and feces) from the hog houses was flushed periodically (4 times a day) with recycled lagoon water and discharged into a storage lagoon from a single effluent pipe. The storage and treatment lagoon was an anaerobic system with 15 170 m^2 of lagoon surface area.

Sampling at Moore Brothers Farm (35.14°N, 77.47°W, 13 m MSL) located near Kinston in Jones County, NC, was conducted during 30 September–11 October 2002 and 27 January–7 February 2003. The farm has eight fully slatted finishing houses (pit recharge) with tunnel ventilation system. The eight finishing barns housed 7611 animals with an average weight of 52 kg in the fall season and 5784 animals with an average weight of 67 kg in the winter season. Pit recharge houses are typically flushed once a week. Waste from all the hog barns was flushed out with recycled lagoon water and discharged into a storage and treatment lagoon from eight effluent pipes, one for each hog barn. The lagoon was an anaerobic system with 17 150 m^2 of surface area.

2.2.2. EST sites

The two EST sites were Goshen Ridge Farm and Red Hill Farm. A brief description of each of the potential ESTs that have been evaluated is provided here. Williams (2006) provides comprehensive detailed information including site plans, design schematics, economics, and projected operational characteristics associated with the technology.

2.2.2.1. Goshen Ridge Farm (solids separation/nitrification–denitrification/soluble phosphorus removal/solids processing system (Super Soils)). Goshen Ridge Farm is located near Beautancus, NC in Duplin County. The NH_3 measurements were conducted during 21 April–2 May 2003 for the warm season and 23 February–1 March 2004 for the cool season. A schematic layout of the EST at Goshen Ridge Farm, including the various sampling points, is given in Fig. 3.

The treatment system employed at Goshen Ridge Farm, known as Super Soils, treats the liquid portion of the waste. The liquid treatment begins with separation of the solid and liquid portions of the waste stream. Solids separation is accomplished using polyacryalmide, a flocculating agent.

The liquid portion of the waste stream flows between tanks in a circulating loop undergoing denitrification as a result of anaerobic activity in one tank, and nitrification through the use of concentrated nitrifying bacteria in the second tank under aerobic conditions. Nitrogen is removed from the waste stream during this stage of the process. The liquid then flows to a settling tank, where phosphorus is removed through the addition of

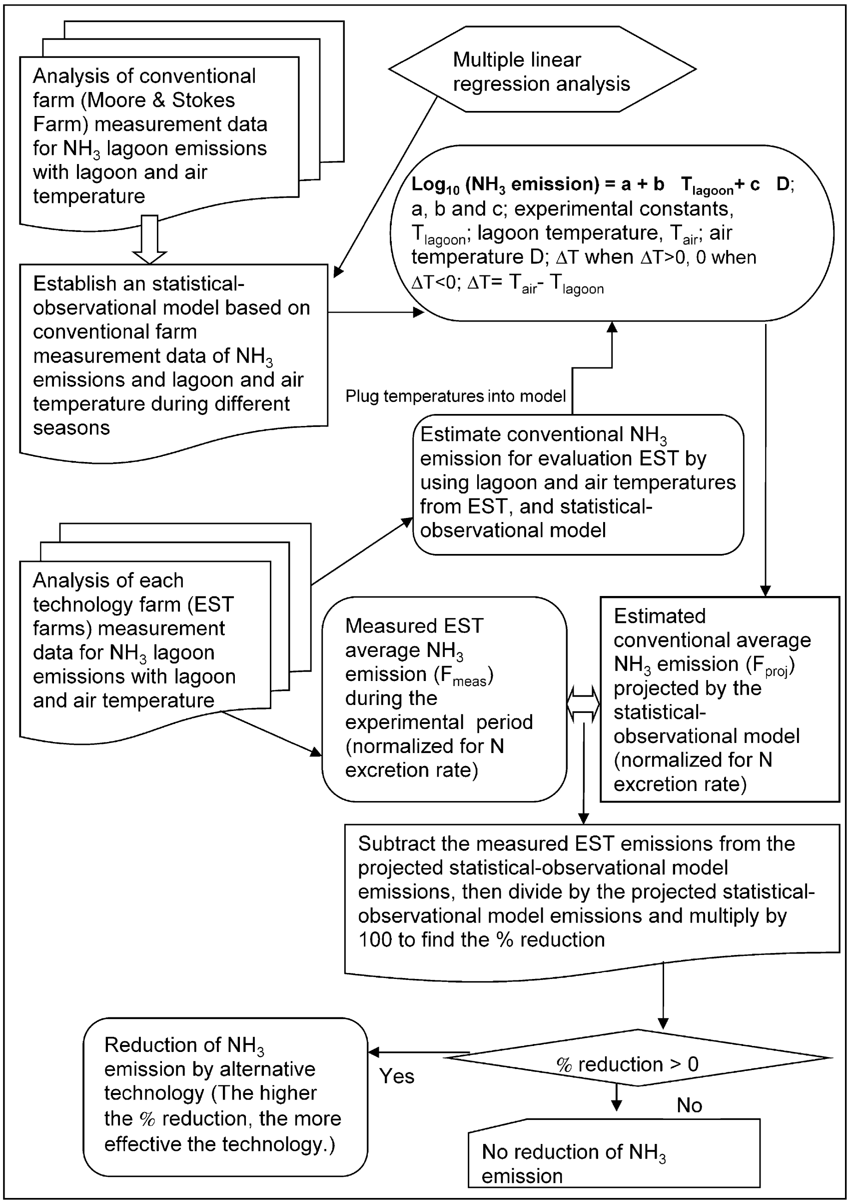

Fig. 2. Algorithm flow chart for evaluation of EST ammonia emissions from water-holding structures.

calcium hydroxide and a dewatering bag system. Calcium phosphate, which has value as a fertilizer, precipitates out during this process, providing a value-added product. During phosphorus removal, the pH of the liquid is raised to 10.5 using lime, which precipitates the soluble P and disinfects the effluent. Roughly 80% of the liquid is recycled through the hog houses, while 20% is used to irrigate crop fields.

At Goshen Ridge Farm, six naturally ventilated houses were treated by the potential EST. For the warm season evaluation period there were 3519 pigs with an average weight of 93.4 kg. For the cool season evaluations, there were 3138 pigs with an average weight of 99.8 kg for the February to March sampling period. For the warm evaluation period, NH_3 fluxes and emissions were measured from the homogenization tank, the 1st denitrification tank, the nitrification tank, the 2nd denitrification tank, and the storage tank. For the cool period evaluation, measurements were repeated in all the water-holding structures except the 2nd denitrification tank.

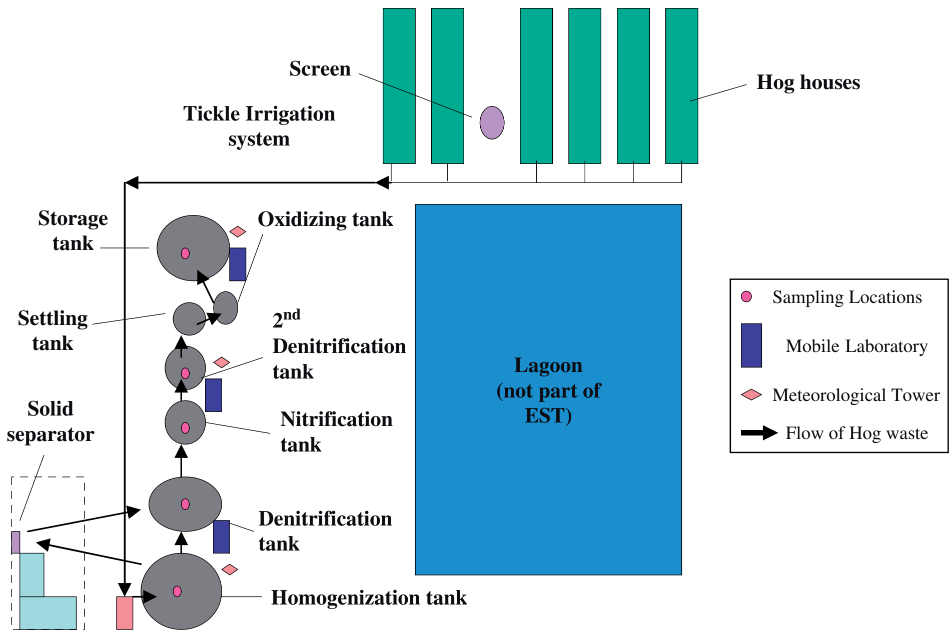

Fig. 3. A schematic layout of the potential EST at Goshen Ridge farm.

2.2.2.2. Red Hill Farm ('closed loop' swine waste treatment system). Red Hill Farm is located near Ayden, NC, in Pitt County. Field campaigns were conducted from 21 March–8 April 2005 for the cool season, and 18 July–5 August 2005 for the warm season. A schematic layout of the EST at Red Hill Farm is given in Fig. 4.

The EST at Red Hill farm was provided by 'Environmental Technologies'. This EST is described as a "closed-loop" system, and its primary objective is to treat the liquid fraction of the waste in such a way that it can be used both for flushing the hog barns and for hog drinking water. This could eliminate the need for the traditional hog waste lagoon. A flush system is used for removing the manure from the barns, which, prior to installation of the treatment system, flushed the waste into a lagoon. The first step in the closed loop process is collection of the waste in an "equalization" or buffering tank. The waste in the tank is continuously pumped to an inclined separator, where the solids are collected and further treated. The liquid collected from the separator is injected with a polymer flocculant and sanitizer/disinfectant and pumped into a settling tank, where flocculated solids collect at the bottom over a period of approximately four hours.

Most of the liquid fraction from the settling tank is returned to the hog barns for re-use as flush water. When the flush tanks are full, however, excess water is pumped to a tertiary treatment system. This system provides filtration and aeration and is housed in a septic tank. The treated water is blended with well water to achieve a dissolved-solids content that is consistent with human drinking water standards for use as hog drinking water. Solids from the settling tanks are combined with the solids from the inclined separator for further treatment.

At this EST farm there are three naturally ventilated hog houses in total. During the cool season evaluation period there were 2390 pigs with an average weight of 69.0 kg. For the warm season evaluation there were 3113 pigs with an average weight of 66.5 kg. During both experimental periods, measurements were conducted at the water tank and at both settling tanks.

2.3. Sampling technique and instrumentation

A dynamic flow-through chamber system was used to measure ammonia fluxes from water-holding structures at the potential ESTs and conventional farms. Various environmental measurements were also made simultaneously. Aneja et al. (2007a) gives a detailed description of the sampling techniques/scheme as well as the

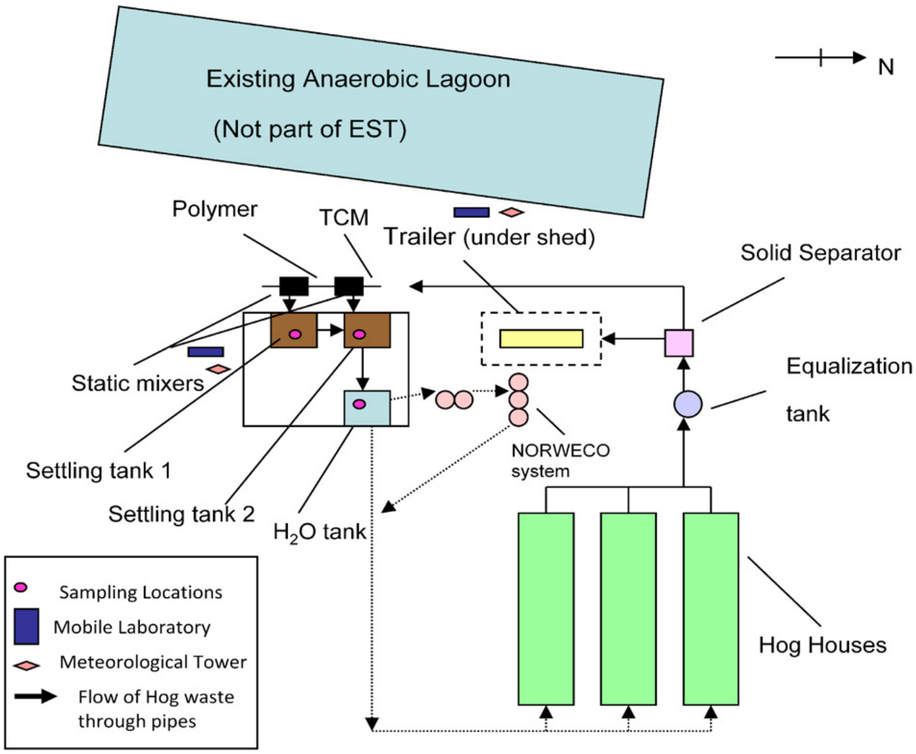

Fig. 4. A schematic layout of the potential EST at Red Hill farm.

instrumentation and environmental measurements used at each experimental site.

3. Results and discussion

3.1. NH_3 fluxes and emissions from water-holding structures

Water-holding structure emissions from two EST farms (Goshen Ridge and Red Hill) were calculated from measurements of NH_3 flux from EST farms, water-holding structure surface areas, and farm production data (number of pigs, feed consumed, and average pig weight) during experimental periods representing both cool and warm seasons. Emissions at the EST farms were normalized to steady-state live animal weight (lw) in the units of kg N week^{-1}(1000 kg lw)$^{-1}$. Average fluxes and total estimated emissions for the water-holding structures are given in Table 2.

At Goshen Ridge farm, ammonia flux measurements for the 1st experimental period were conducted from the homogenization tank, the denitrification tank, the nitrification tank, the 2nd denitrification tank and the storage tank. Their water-holding structure surface areas were 91.6, 67.9, 28.3, 28.3, and 91.6 m^2, respectively.

For the 2nd experimental period, measurements were conducted for all of the same water-holding structures, except the 2nd denitrification tank.

During the 1st sampling period, the highest flux was measured at the denitrification tank, with a 15 min average flux of 5838.1 μg NH_3-N m^{-2} min^{-1}, and a maximum hourly average flux of 6242.1 μg NH_3-N m^{-2} min^{-1}. It should be noted, though, that the concentrations in the flux chamber were beyond the upper limit of detection of the ammonia analyzer; therefore flux values from this tank are highly uncertain. The homogenization tank had the 2nd highest flux with an average 15 min flux of 3092.3 μg NH_3-N m^{-2} min^{-1}, with a maximum hourly flux of 6885.6 μg NH_3-N m^{-2} min^{-1}. Although the homogenization tank has the larger surface area, the higher flux from the 1st denitrification tank results in this tank having the larger emissions.

The other water-holding structures were found to have much lower fluxes and emissions relative to the denitrification and homogenization tanks. The nitrification tank, 2nd denitrification tank and the

storage tank had 15 min average fluxes of 213.7, 543.1, and 33.6 $\mu g\ NH_3$-$N\ m^{-2}\ min^{-1}$, respectively. Correspondingly, the emissions followed the same pattern as the fluxes.

For all of the water-holding structures, the flux and emissions were lower in the 2nd evaluation period. For this evaluation, the average 15 min flux for the homogenization tank was the highest at 881.1 $\mu g\ NH_3$-$N\ m^{-2}\ min^{-1}$, with a maximum hourly average flux of 2059.5 $\mu g\ NH_3$-$N\ m^{-2}\ min^{-1}$. The most significant decrease in flux and emissions was from the denitrification tank, with an average 15 min flux of 33.5 $\mu g\ NH_3$-$N\ m^{-2}\ min^{-1}$. The storage tank had the lowest average flux, 13.7 $\mu g\ NH_3$-$N\ m^{-2}\ min^{-1}$. The emissions though were higher than the emissions for the nitrification tank due to the storage tanks' larger surface area.

At Red Hill Farm, fluxes were measured from three water-holding structures, the two settling tanks and the treated water storage tank all of which had an area of 5.8 m^2. Average fluxes during the March–April sampling period for settling tanks 1 and 2 were 2073.9 and 5492.8 $\mu g\ NH_3$-$N\ m^{-2}\ min^{-1}$, respectively. The treated water storage tank had the lowest flux value, with a flux of 80.4 $\mu g\ NH_3$-$N\ m^{-2}\ min^{-1}$. For the July–August 2005 measurement period, the pattern of flux values was repeated. The fluxes were 996.9, 1223.3, and 43.3 $\mu g\ NH_3$-$N\ m^{-2}\ min^{-1}$, for settling tanks 1, 2, and treated water storage tank, respectively. The

emissions from individual water-holding structures follow the same pattern as the fluxes.

3.2. Evaluation of ammonia emissions from water-holding structures

In order to evaluate the percentage reduction of NH_3 emissions for the water-holding structures, measured or estimated EST emissions were compared with projected emissions at the conventional LST farms. The estimated emissions from the LST farms were adjusted to the environmental conditions, i.e. air and lagoon temperature, which have been determined to be statistically correlated with ammonia emissions. For Environmental Technologies, lagoon temperature measurements were made at a lagoon on the farm that was not part of the EST. At Super Soils, no measurements were made at a lagoon. Therefore, in order to make a fair and logical comparison, lagoon data was used from an earlier reported EST with similar air temperatures. For the 1st evaluation at Super Soils (April–May 2003), the Barham farm (April 2002) lagoon (waste water-holding pond component) temperatures were used (Aneja et al., 2007b). For the 2nd evaluation (February–March 2004) at Super Soils, Barham farm (November 2002) lagoon temperatures were used.

Table 3 shows the summary of the water-holding structure NH_3 emissions measured from EST farms, projected emissions from the water-holding structures at the conventional (LST) farms, and % reduction values for their evaluation of potential N reduction.

For both farms there is substantial reduction in NH_3 emissions from water-holding structures. The Super Soils technology employed at Goshen Ridge farm had reductions of 94.7% and 99.0% for the warm and cool season, respectively. The Environmental Technologies closed loop system had slightly larger reductions, with a reduction of 99.4% in the cool season, and 99.98% in the warm season.

4. Conclusions

Two potential ESTs with no conventional anaerobic lagoon component were evaluated to determine if they would substantially reduce atmospheric emissions of ammonia at the hog facilities and meet the performance standards as compared with estimated or projected emissions from the conventional LST used at two selected hog farms in two different (warm and cool) measurement periods. Both farms showed substantial reductions in NH_3 emissions from their water-holding structures. The Environmental Technologies closed loop system had the largest reductions, with reduction of 99.4% and 99.98% for the cool and warm season, respectively. Super Soils technology had a reduction of 94.7% in the cool season, and 99.0% in the warm season. This study did not address the potential reductions in odor and pathogens that were evaluated by other scientists in the OPEN project (Williams, 2006).

Under the conditions reported herein these two potential ESTs meet the criteria established for ammonia emissions as described for ESTs (Williams, 2004).

Acknowledgments

Financial support provided by the North Carolina State University Animal and Poultry Waste Management Center (APWMC) is greatly appreciated. We sincerely acknowledge the help and support provided by Ms. Lynn Worley-Davis. We thank the technology PIs, farm owners, Cavanaugh & Associates, and Mr. Bundy Lane, C. Stokes, and P. Moore for their cooperation.

We also thank the various people who assisted in fieldwork including, Hilawe Semunegus, Wesley Stephens, and Srinath Krishan.

We acknowledge the discussions and gracious help provided by Dr. John Fountain, Dr. Richard Patty, Dr. Ray Fornes, and Dr. Johnny Wynne of North Carolina State University. We thank Mark Barnes, Guillermo Rameriz, and Rachael Huie. ABSTRACT

To examine the consequences of increased spatial aggregation of livestock production facilities, we estimated the annual production of nitrogen in livestock waste in North Carolina, USA, and analyzed the potential distribution of atmospheric nitrogen deposition from confined animal feeding operations ("CAFO") lagoons. North Carolina is a national center for industrial livestock production. Livestock is increasingly being raised in CAFOs, where waste is frequently held, essentially untreated, in open-air lagoons. Reduced nitrogen in lagoons is volatilized as ammonia (NH_3), transported atmospherically, and deposited to other ecosystems. The Albemarle-Pamlico Sound, NC, is representative of nitrogen-sensitive coastal waters, and is a major component of the second largest estuarine complex in the U.S. We used GIS to model the area of water in the Sound within deposition range of CAFOs. We also evaluated the number of lagoons within deposition range of each 1 km^2 grid cell of the state. We considered multiple scenarios of atmospheric transport by varying distance and directionality.

Modeled nitrogen deposition rates were particularly elevated for the Coastal Plain. This pattern matches empirical data, suggesting that observed regional patterns of reduced nitrogen deposition can be largely explained by two factors: limited atmospheric transport distance, and spatial aggregation of CAFOs. Under our medium-distance scenario, a small portion (roughly 22%) of livestock production facilities contributes disproportionately to atmospheric deposition of nitrogen to the Albemarle-Pamlico Sound. Furthermore, we estimated that between 14–37% of the state receives 50% of the state's atmospheric nitrogen deposition from CAFO lagoons. The estimated total emission from livestock is 134,000 t NH_3 yr^{-1}, 73% of which originates from the Coastal Plain. Stronger waste management and emission standards for CAFOs, particularly those on the Coastal Plain nearest to sensitive water bodies, may help mitigate negative impacts on aquatic ecosystems.

1. Introduction

Agricultural waste is an inevitable byproduct of raising livestock. Historically, farmers have managed this problem by using nutrient-rich livestock wastes as a crop fertilizer. Yet, as small independent farms are increasingly converted to large-scale, industrialized, confined animal feeding operations ("CAFOs"), livestock waste management and disposal becomes more challenging. Here, we address the regional consequences of industrialized livestock production in North Carolina, where

the number of animals produced has greatly increased while the number of farms is declining (Furuseth, 1997).

North Carolina is one of the leading states in livestock production. Here, we use the term "livestock" to include swine, cattle, and poultry. The state ranks second in the nation in both swine and turkey production, accounting for approximately one-sixth of the U.S. total (North Carolina Department of Agriculture and Consumer Services [NCDA & CS], 2007). Currently, the retention of liquid waste in large anaerobic storage reservoirs ("lagoons") is the most widespread and least costly treatment method for livestock waste (Barker, 1996). In North Carolina there are over 2500 CAFO lagoons, 85% of which are located in the Coastal Plain (NC Division of Environment and Natural Resources, Division of Water Quality [NCDENR DWQ], 2002a; also see Fig. 1). Unlike the municipal treatment of human waste, these waste management facilities employ few wastewater treatment processes. Recent studies report that CAFOs in the Coastal Plain of North Carolina are major sources of nitrogen to the region's nutrient-sensitive estuarine and coastal water (Cahoon et al., 1999; Walker et al., 2000; Whitall and Paerl, 2001; Mallin and Cahoon, 2003).

Nitrogen limitation is widespread worldwide, and occurs commonly in terrestrial, freshwater, and marine systems (Elser et al., 2007). Excessive nutrient loading to nitrogen limited waters can create eutrophic conditions, which are linked to noxious phytoplankton blooms and hypoxia (Paerl and Whitall, 1999; Paerl, 2002), changes in fish and benthic macroinvertebrate communities (Burkholder and Glasgow 1997, Glasgow and Burkholder, 2000; Alderman et al., 2005), and outbreaks of harmful aquatic organisms (e.g. Burkholder et al., 1992).

Atmospheric transport is a major pathway by which nitrogen is delivered to riverine, estuarine and coastal ecosystems (Walker et al., 2000; Whitall et al., 2004). Ammonia (NH_3) volatilizes from lagoons and terrestrial systems to which the waste is applied (Barker et al., 2006; Shaffer and Walls, 2005). In the atmosphere, it is transformed to other forms of reduced nitrogen, transported via air movement and atmospheric patterns, and deposited to other ecosystems through both wet and dry deposition. Approximately 80% of NH_3 emissions in the U.S. are generated by livestock waste (Battye et al., 1994).

Atmospheric deposition of nitrogen emissions now accounts for up to 40% of new nitrogen inputs to coastal ecosystems (Paerl et al., 2002). In North Carolina, direct deposition of reduced N is likely to have a large impact on the large estuarine complex including the Albemarle and Pamlico Sounds (Fig. 1), collectively called the Albemarle-Pamlico Sound. Together with its

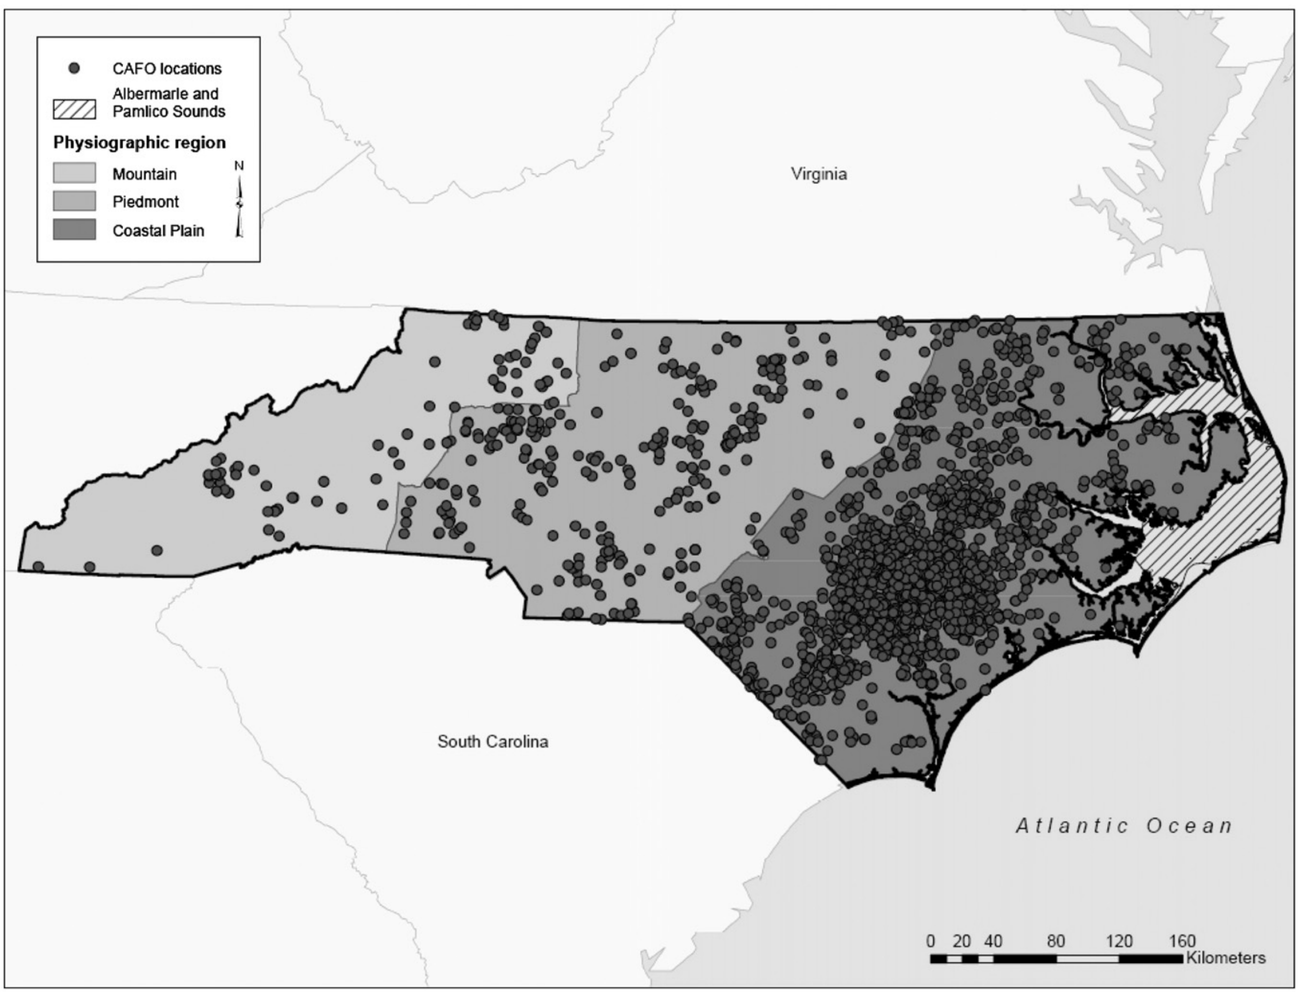

Fig. 1 – Map showing the statewide distribution and aggregation of CAFOs in North Carolina, the physiographic regions of the state, and the Albemarle-Pamlico Sound.

subestuaries, the Sound is the second largest estuarine system in the U.S. It is chronically N-limited, and direct deposition to open water can bypass the mesohaline zone of the estuary, where biological uptake removes much of the N from riverine inputs (Paerl et al., 2002).

National Atmospheric Deposition Program (NADP) data indicate that wet deposition of NH_4^+ has increased in the past decade in southeastern North Carolina, and rates are particularly high in portions of the state's Piedmont and Coastal Plain (NADP, 2006; see Fig. 2). The spatial aggregation of CAFOs in the state's Coastal Plain suggests that nitrogen loading from these operations may be greatest in this region. While CAFO lagoons are considered to be the largest contributors to NH_3 emissions (EPA, 2003), the observed NADP rates (Whitall and Paerl, 2001; Walker et al., 2004) have not been directly linked to CAFO nitrogen emissions.

To better understand the sources of nitrogen deposition, we address two questions. First, how much nitrogen do North Carolina livestock produce in manure, and how much is emitted as NH_3? Second, what is the potential spatial distribution of atmospheric nitrogen deposition from CAFO lagoons? Although management decisions are often made on a statewide basis, few studies have made such assessments at spatial scales larger than single watersheds (but see Paerl et al., 2002; Mallin and Cahoon, 2003; Walker et al., 2004). For this reason, and because North Carolina makes a significant contribution to national livestock production (NCDA & CS, 2007), we seek to address these two questions at the state level.

2. Methods

2.1. *Nitrogen production and ammonia emissions from livestock manure*

We calculated total annual nitrogen production and ammonia (NH_3) emission rates (in units of metric tons (t) NH_3 yr^{-1}) for three categories of livestock: swine (breeders and growers), poultry (broilers, other chickens and turkeys), and cattle (beef and dairy). We estimated total statewide annual nitrogen

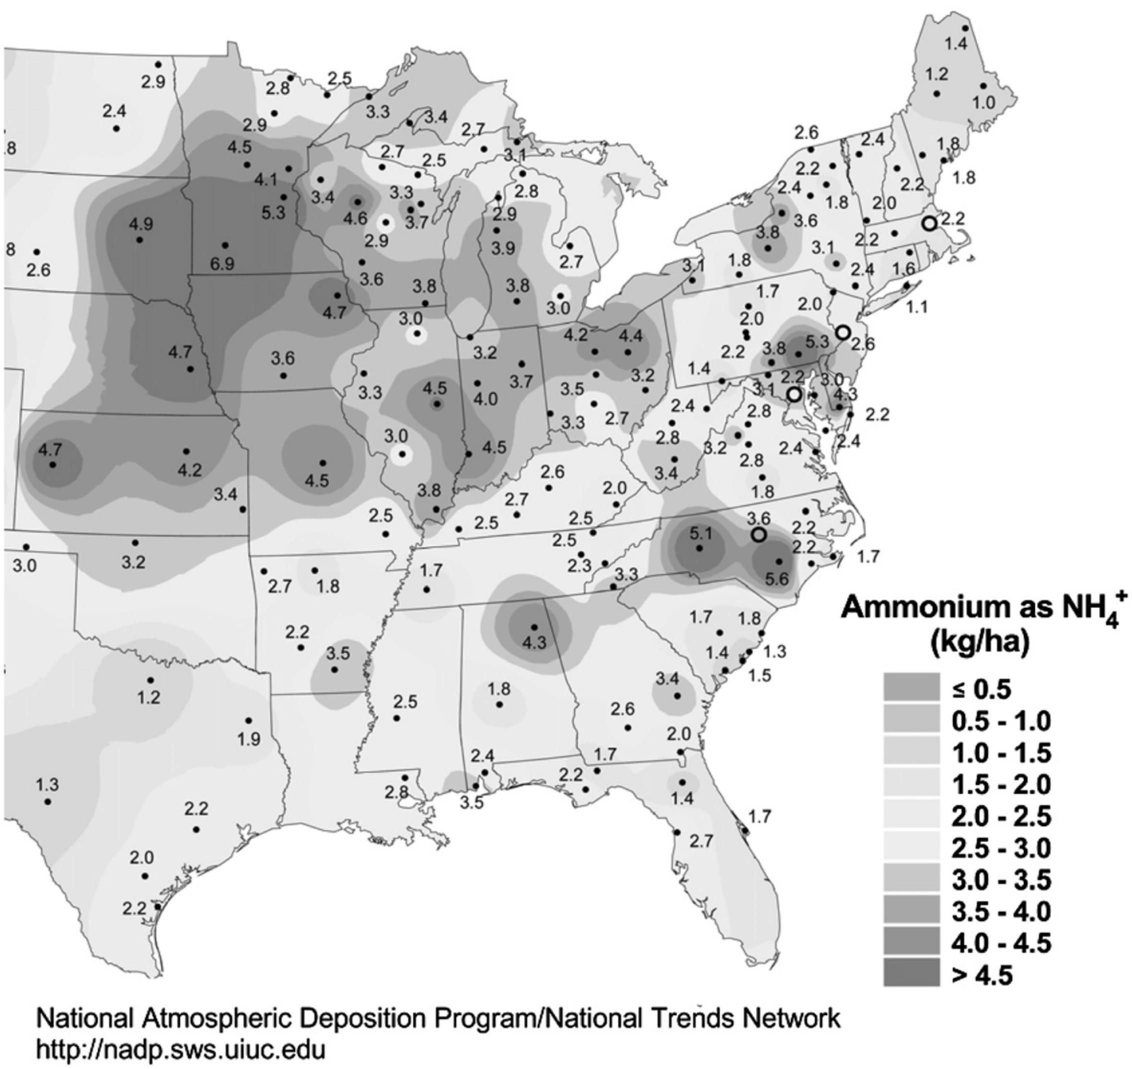

Fig. 2 – Map showing 2005 ammonium atmospheric deposition rate (kg NH_4^+ ha^{-1} yr^{-1}), reproduced from the National Atmospheric Deposition Program (2006).

production for the Mountains, Piedmont, and Coastal Plain physiographic provinces of North Carolina (Fig. 1) following Kellogg et al. (2006). In order to determine nutrient content of manure, we first calculated total manure production. Using 2006 county census of agriculture data, we divided census head counts by the number of animals per animal unit (AU), which represents 1000 lb of live animal weight and serves as a common unit for aggregating over different types of livestock (Kellogg et al., 2006). These standard animal unit conversions are based on the average live weight associated with each livestock category. We then multiplied this value by the mass of "as excreted" manure produced annually per AU to provide an estimate of the total mass of manure produced by all livestock categories. From this value, we determined total nitrogen production in t N yr^{-1} by multiplying metric tons of manure produced by published values for the mass of elemental nitrogen per metric ton of manure (Kellogg et al., 2006).

NH_3 emission rates for all livestock categories were estimated using the Carnegie Mellon University Ammonia Model Version 3.6 (Strader et al., 2004). Source activity data used in the model are from the 2002 Census of Agriculture and emission factors for diary cattle, beef cattle, swine, and poultry are from the EPA National Emission Inventory (2004). The emission factors used in the model are an improvement upon other existing emission inventories (Asman, 1992; Battye et al., 1994; Bouwman and Van Der Hoek, 1997; Doorn et al., 2002), which do not account for seasonal changes in emissions or type of animal production practices used. In addition, most other emission inventories, excluding Doorn et al. (2002), are from European studies and therefore may not be applicable to the U.S. (EPA, 2004).

2.2. Atmospheric transport of nitrogen from livestock waste lagoons

To examine the potential spatial distribution of atmospheric nitrogen in the form of reduced N inputs to North Carolina's aquatic ecosystems from CAFO lagoons, we used a geographic information systems (GIS)-based approach. All spatial analyses were performed using ArcGIS Desktop 9.2 software (Environmental Systems Research Institute, 1999–2006). We analyzed short-, medium-, and long-distance nitrogen transport scenarios by assuming the transport radius from each lagoon to be 80 km, 160 km, or 400 km for the three scenarios, respectively. These distances were derived from studies quantifying nitrogen atmospheric transport distances. We modeled an 80 km radius for our short-distance scenario based on Walker et al. (2000), who showed that wet deposition of reduced N can occur at sites up to 80 km away from NH_3 emissions sources in the North Carolina Coastal Plain. We modeled a 400 km radius for our long-distance scenario based on airshed modeling studies (Dennis and Mather, 2001; Paerl et al., 2002) that have estimated the normalized range of influence of ammonia sources, in the prevailing direction of transport, to be 300–450 km. For our intermediate-distance scenario, we modeled a 160 km transport radius based on the airshed modeling studies (Dennis and Mather, 2001; Paerl et al., 2002), but adjusted the distance to account for more restricted transport in directions other than the prevailing one, and for the fact that deposition rates are higher closer to the source.

For each of the three distance scenarios, we used GIS to perform two analyses based on the locations of CAFOs statewide and the number of lagoons used by each CAFO (NCDENR DWQ, 2002a). Our first analysis examined variation in potential atmospheric nitrogen deposition inputs from NC CAFO lagoons to the state as a whole, and to the Albemarle-Pamlico Sound specifically. To calculate potential deposition, we converted a polygon shapefile of North Carolina to a raster with 1 km×1 km grid cells. For each of the distance scenarios described above, we assumed that some of the emitted ammonia would subsequently be deposited in all directions within the given radius from the livestock operation (isotropic transport and deposition). Therefore, for each 1 km^2 grid cell in the state, we summed the number of CAFO lagoons within the given transport radius (i.e. 80, 160, or 400 km) in any direction.

However, because the prevailing direction of air mass transport in North Carolina is generally from the southwest for 10 months of the year (Brook et al., 1995; State Climate Office of North Carolina, 2007), we assumed that transport and subsequent deposition of reduced N from a given CAFO lagoon would be higher to the northeast of the lagoon. We therefore performed a separate calculation to sum only the number of CAFO lagoons to the southwest of a given grid cell (within the 90-degree arc between south and west): the lagoons that would contribute to deposition of reduced N assuming air mass transport was strictly to the northeast. For each distance scenario, we assumed that 50% of transport and deposition is isotropic; that is, it occurs evenly in all directions. The other 50% is deposited in the 90-degree arc between north and east from each CAFO. Combining these two assumptions in our model gave 62.5% of transport toward the northeast, and the other 37.5% of transport in all other directions combined. We then accounted for the area over which deposition of reduced N may occur under each scenario by dividing the weighted count by the deposition area (area=π r^2, where r is 80, 160, or 400 km under the three scenarios, respectively). We report this predicted weighted count of lagoons within transport range as relative deposition intensity.

We performed the same analysis for 1 km^2 grid cells in the Albemarle-Pamlico Sound. We used digital data showing salinity zones for coastal water (NOAA, 1999) and only included polygons corresponding to the portion of the Albemarle-Pamlico Sound that falls in the mixing zone (5–25 parts per thousand salinity). We converted these polygons to a 1 km^2 grid and performed the same analysis as above. While the area analyzed includes the mesohaline zone (5–18 ppt salinity) where much riverine N is biologically filtered, the majority of the area analyzed is open sound, which is predicted be highly sensitive to direct atmospheric deposition of nitrogen (Paerl et al., 2002).

To test how sensitive our results were to the assumption that 50% of transport and deposition is anisotropic, we constructed a scenario in which 70% of transport and deposition occurs only between north and east, and the other 30% is isotropic from each CAFO. Under this assumption, 77.5% of transport and deposition occurs toward the northeast, and 22.5% occurs in all other directions combined.

Additionally, we examined variation among CAFOs in their potential direct deposition of reduced N to the Albemarle-Pamlico Sound. We calculated the surface area of the Sound that fell within each assumed deposition radius (80-, 160-, and 400-km) of each CAFO in the state. We did this analysis twice.

First, for each distance scenario, we summed the area of the Albemarle-Pamlico Sound that fell within the given transport radius, assuming transport and deposition of reduced N from each CAFO is isotropic. Then, we summed the area of the Albemarle-Pamlico Sound that falls within the transport radius only to the northeast of each CAFO (within the 90-degree arc between north and east).

3. Results

3.1. *Nitrogen production and ammonia emissions from livestock waste*

We calculated total nitrogen production and NH_3 emissions for each physiographic region across the state of North Carolina for cattle, swine, and poultry (Table 1). An examination of 2006 county livestock census data for North Carolina shows that there were 860,000 cattle, 9,500,000 swine and 805,701,000 poultry, including broiler chickens, other chickens, and turkeys (NCDA & CS, 2007). This census data highlights the disparity among population sizes of livestock — they are orders of magnitude apart. In addition, the nitrogen content of manure for all categories of poultry (12.17, 12.22, and 13.77 kg N t^{-1} manure for broiler chickens, other chickens, and turkeys, respectively) was at least two times higher than that of swine and cattle manure (breeder pig manure had the next highest nitrogen content, with 6.01 kg N t^{-1} manure). The estimated total nitrogen production from livestock in North Carolina was 494,000 t, approximately 75.0% of which was produced by poultry, followed by swine, then cattle.

The estimated total NH_3 emission from livestock in North Carolina was 134,000 t NH_3 yr^{-1} (Table 2). Swine contribute 78,000 t NH_3 yr^{-1} or 58% of emissions, followed by poultry (50,700 t NH_3 yr^{-1}; 38% of total) and cattle (5000 t NH_3 yr^{-1}; 4% of total), respectively. With respect to total statewide emissions, approximately 72% were generated in the Coastal Plain region for all livestock categories; over half (55%) of total emissions were generated by swine alone. Poultry accounted for 38% of emissions, with nearly equal amounts generated in the Piedmont and Coastal Plain regions.

Table 2 – Estimated regional annual NH_3 emissions (metric tons yr^{-1}) by animal category

Category	Mountains	Piedmont	Coastal plain
Cattle	1400	2900	710
Swine	995	3570	73,500
Poultry	6820	21,000	22,900
Total	9215	27,470	97,110

3.2. *Atmospheric transport of nitrogen from livestock waste lagoons*

Livestock operations in North Carolina are, on average, located 155 km from the nearest portion of the Albemarle-Pamlico Sound. Therefore, in our 160 km and 400 km dispersal scenarios, a majority of CAFOs are within transport distance to the Sound. To examine variation among CAFOs in their potential direct deposition of reduced N to the Albemarle-Pamlico Sound, we ranked each CAFO based on the area of the Sound within the modeled transport distance. In most scenarios, a relatively small percentage of CAFOs contributed disproportionately large atmospheric reduced N inputs to the Sound. Under the 160 km scenario, 70% of CAFOs were within transport distance to the Albemarle-Pamlico Sound, regardless of whether transport was assumed to be isotropic (Fig. 3a) or strictly toward the northeast (Fig. 3b). Furthermore, 22% of CAFOs were in deposition range of one-third or more of the Albemarle-Pamlico Sound when isotropic deposition was assumed (Fig. 3a), and 10% were in deposition range of one-third or more of the Sound when deposition toward the northeast only was assumed (Fig. 3b). In the 80 km scenario,

*M = Mountain; P = Piedmont; CP = Coastal Plain. Nitrogen content values are from Kellogg et al., 2006.

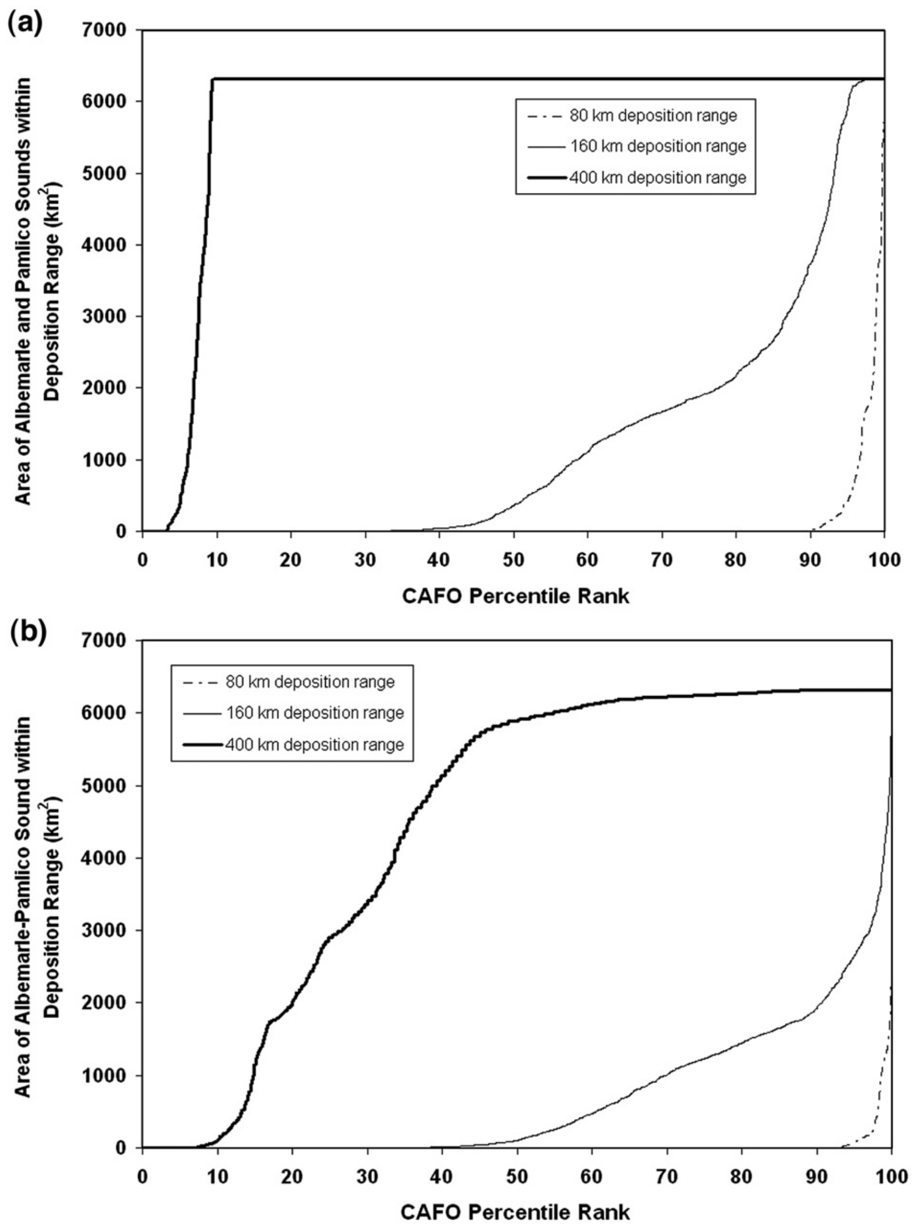

Fig. 3 – Area of the Albemarle-Pamlico Sound within atmospheric nitrogen deposition range of North Carolina CAFOs, for modeled transport distances of 80, 160, and 400 km, assuming (a) isotropic (omnidirectional) transport and deposition from each CAFO, and (b) anisotropic transport strictly toward the northeast of each CAFO.

only the 12% or 9% of CAFOs were within dispersal distance of the Albemarle-Pamlico Sound when isotropic or northeast transport and deposition are assumed, respectively (Fig. 3). Under the assumptions of 400 km transport distance and transport only toward the northeast, 55% of CAFOs were within deposition range of 93% of the Sound (Fig. 3b). In contrast to these five scenarios, under the assumptions of 400 km transport distance and isotropic transport, 90% of CAFOs were within deposition range of the entire Albemarle-Pamlico Sound (Fig. 3a).

We analyzed the spatial distribution of modeled relative deposition intensity both across the state of North Carolina, and within the Albemarle-Pamlico Sound specifically. For the 160 km transport scenario, portions of the Piedmont and Coastal Plain were contained within deposition range of up to 3356 lagoons (Fig. 4a). In addition, portions of the Albemarle-Pamlico Sound were within transport distance of 2645 lagoons. The 80 km scenario produced a qualitatively similar pattern with high relative deposition intensity on the Coastal Plain of North Carolina. Under this scenario (Fig. 4c), portions of the state were within the dispersal distance of up to 2494 lagoons. However, only 320 lagoons are within deposition range of the Albemarle-Pamlico Sound under this scenario (Fig. 4b). Under the short- and medium-distance scenarios, the areas of the state that received the bulk of the loading fall in several major watersheds, including the Tar-Pamlico, Neuse, and Cape Fear watersheds. Under our long-distance scenario, portions of North Carolina were contained within the airshed

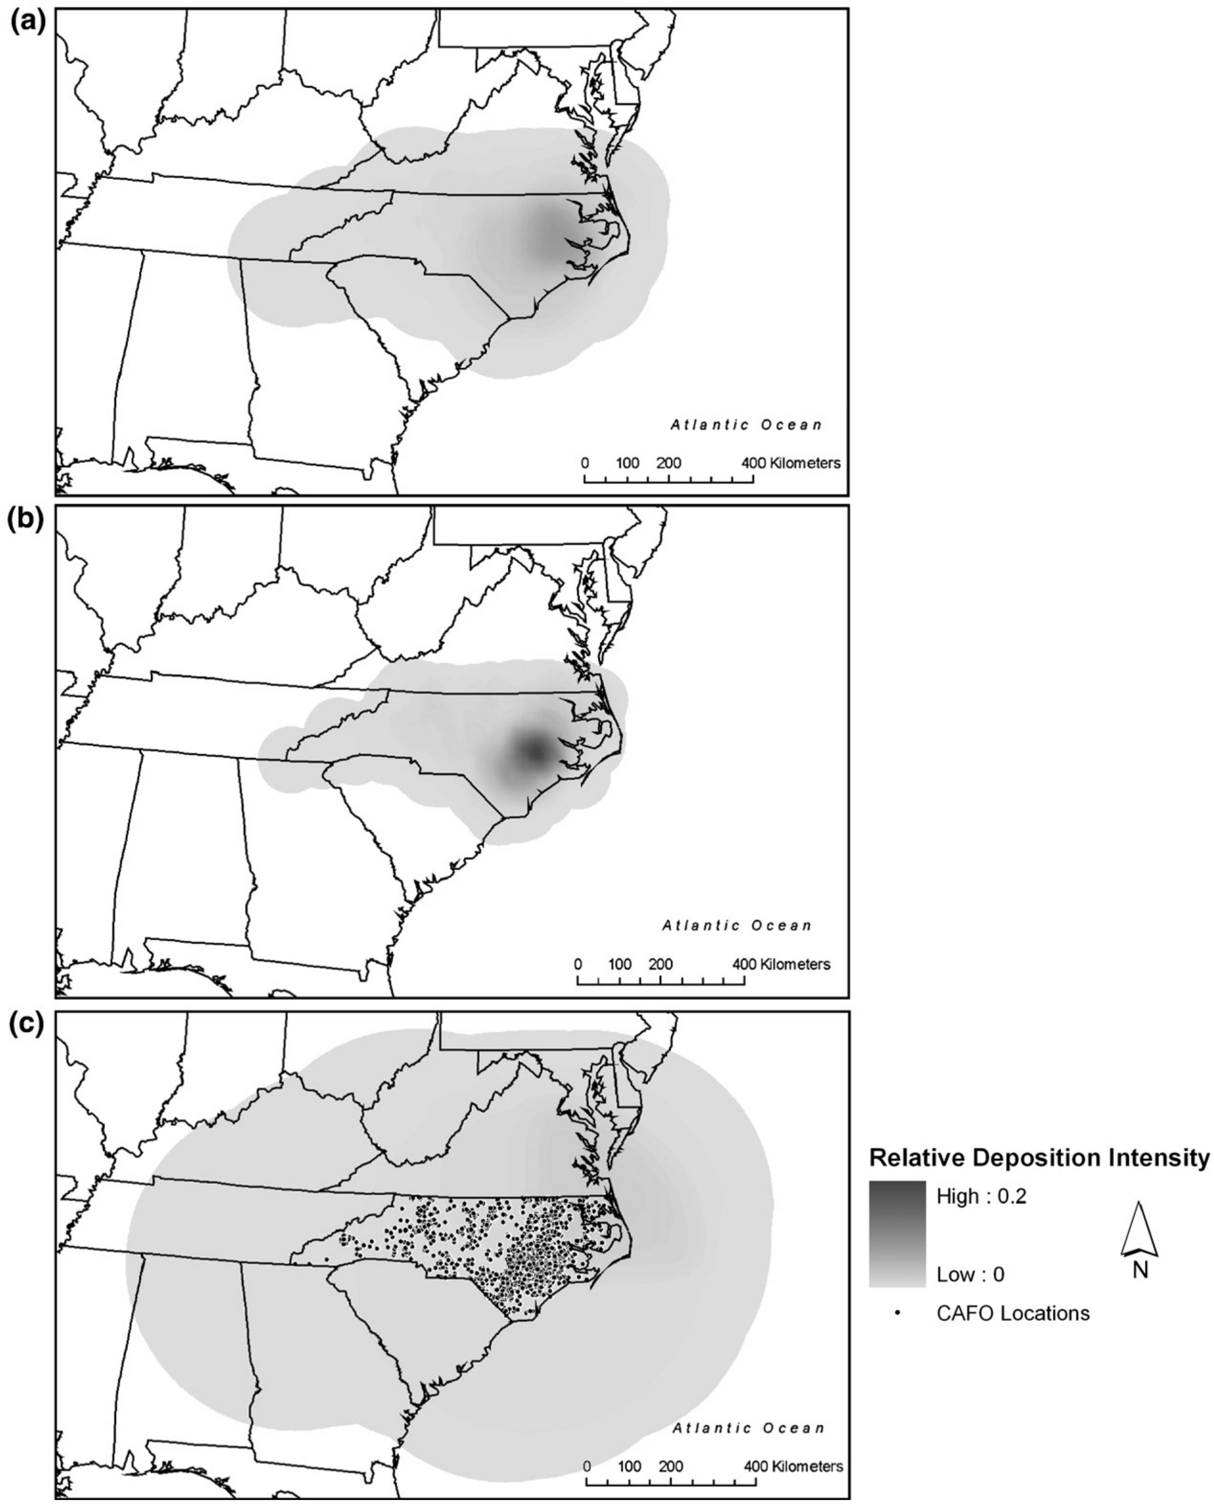

Fig. 4 – Relative deposition intensity for modeled transport distances of: (a) 160 km, (b) 80 km, (c) 400 km. Locations of CAFOs are shown in (c), but are not displayed for (a) and (b) because they would obscure the relative deposition intensity pattern shown on these maps. Atmospheric transport was assumed to be 50% isotropic, and 50% strictly to the northeast of CAFO lagoons.

of up to 3763 lagoons. Finally, we note that the maximum relative deposition intensity varied by an order of magnitude between the short- and long-distance transport scenarios. This is because the same quantity of ammonia emissions from the source is diluted over a larger deposition area as the deposition range is increased.

To further quantify the spatial concentration of reduced N deposition, we ranked each square kilometer of the state based on the number of CAFO lagoons within the modeled transport distance. Overall, we estimated that between 14% and 37% of the state potentially received 50% of atmospheric nitrogen deposition from CAFO lagoons (Fig. 5a). Therefore, a

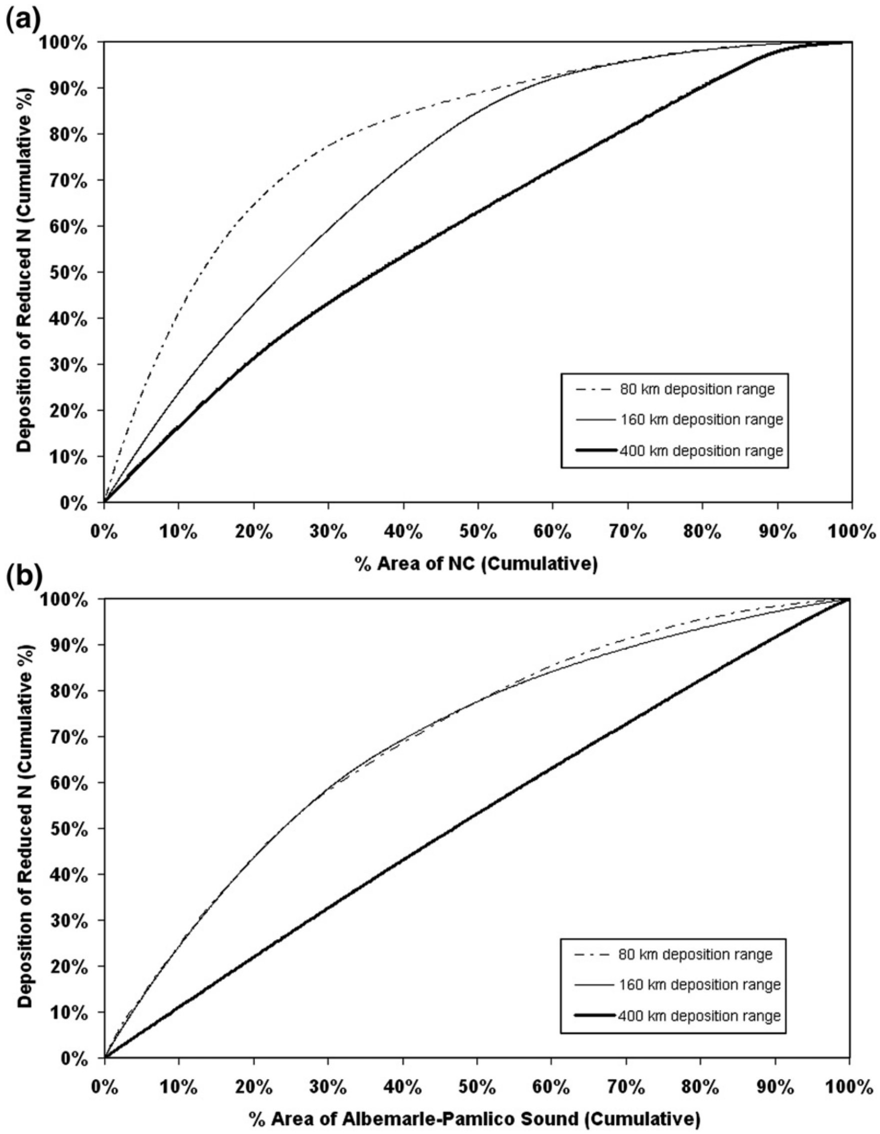

Fig. 5 – The cumulative spatial distribution of atmospheric reduced nitrogen deposition from CAFO lagoons, for modeled transport distances of 80, 160, and 400 km: (a) to North Carolina, and (b) to the Albemarle-Pamlico Sound from CAFO lagoons. Atmospheric transport was assumed to be 50% isotropic, and 50% strictly to the northeast of CAFO lagoons. Percentages are based on the total received by the state and the Sound, respectively.

small portion of the state potentially receives the bulk of the deposition. Under the 160 km scenario, 31% of reduced N may travel outside state boundaries, while in the 80 km scenario, only 10% of reduced N may travel outside state boundaries. However, assuming a 400 km transport distance, up to 77% of the total reduced N originating from CAFO lagoons may travel outside state boundaries. We also ranked each square kilometer of the Albemarle-Pamlico Sound based on the number of CAFO lagoons within transport distance. Between 24% and 47% of the Sound receives 50% of the atmospheric nitrogen deposition from CAFO lagoons (Fig. 5b).

When we modified our assumption of 50% anisotropic and 50% isotropic transport and deposition to 70/30% anisotropic/isotropic, we obtained similar results. Between 12% and 28% of the state potentially receives 50% of atmospheric N deposition from CAFO lagoons, and between 21% and 45% of the Albemarle-Pamlico Sound receives 50% of the deposition. Furthermore, between 10% and 78% of reduced N may travel outside state boundaries under the 80 km and 400 km scenarios, respectively, which is close to the range of values under the 50/50% assumption. Therefore, our results are not very sensitive to the assumption of 50/50% anisotropic/isotropic deposition and transport from CAFO lagoons.

Overall, the eastern portion of North Carolina had the highest number of waste lagoons within atmospheric transport distance regardless of the distance scenario assumed. This is not surprising considering the concentration of CAFOs in this region of the state. However, our results highlight the large number of lagoons within the deposition range of sensitive coastal systems, the concentration of the bulk of nitrogen inputs in a small fraction of the state, and the qualitative robustness of these patterns to variation in atmospheric nitrogen transport distance.

4. Discussion

Industrialized farming and CAFOs have replaced traditional farming practices by increasing livestock populations per farm, which also increases the amount and concentration of animal waste. Our results emphasize (a) the amount of nitrogen produced and emitted by livestock manure in industrialized farms in North Carolina, and (b) the significance of the spatial aggregation of CAFOs in the eastern portion of the state for patterns of atmospheric nitrogen deposition.

Much of the livestock feed originates from out-of-state sources (Cahoon et al., 1999). Thus, most of the nitrogen deposition from CAFOs originates from outside the state and represents a net input to the state's nutrient budget. Poultry contributes the largest percentage of total nitrogen production and is second only to swine in NH_3 emissions across the state of North Carolina. This resulted from both the size of the poultry population in North Carolina and the high nitrogen content in poultry manure. Poultry have significantly lower NH_3 emission rates than cattle and swine (Battye et al., 1994; Doorn et al., 2002), emphasizing the importance of livestock population size on NH_3 emissions. We examined the roles of livestock type and population size; however, NH_3 emissions are also influenced by farm facilities, waste management practices, and meteorological conditions (Battye et al., 1994).

Our results vary from other published figures. Mallin and Cahoon (2003) showed that swine were the top nitrogen producers on the Coastal Plain. However, our analysis also includes the state's Piedmont and Mountain physiographic regions (Table 2). Although swine may contribute the bulk of nitrogen when only CAFOs in the NC Coastal Plain are considered, our analysis includes the state's Piedmont, in which the bulk of poultry are produced. With the exception of poultry, our estimates are comparable with Mallin and Cahoon (2003) for the Coastal Plain region. The disparity for poultry appeared to result from our use of updated census data and animal waste nitrogen production rates.

Our analysis suggests that the aggregation of CAFOs on the Coastal Plain of North Carolina causes the majority of the reduced N deposition to be received by a small portion of the state's area, where aquatic systems are most abundant. In particular, the Albemarle-Pamlico Sound, which is vulnerable to direct deposition of reduced N, is located within transport range of the majority of CAFOs under our medium- and long-distance scenarios. These patterns highlight the relative magnitude of impacts from the aggregation of CAFOs, and underscore the importance of understanding transport distance and fate of NH_3 emitted from CAFOs.

We analyzed multiple scenarios regarding the atmospheric transport of reduced nitrogen originating from CAFOs, including short, medium, and long-distance transport, and varying degrees of isotropic vs. directional transport. Which of these scenarios is most realistic? Like all models, they are all caricatures of reality. Regional-scale atmospheric transport of nitrogen is complex (Walker et al., 2000; Dennis and Mather, 2001; Paerl et al., 2002) beyond what could be simultaneously applied to thousands of individually modeled sources. Deposition rates are higher closer to the source, declining with distance. Transport occurs via air mass movement, and thus is directional at a given time, but when averaged over a year occurs in all directions to some degree. Nonetheless, examining the consequences of different model assumptions begins to provide insight into these more complex processes. For example, while we assumed a constant deposition rate within the modeled transport distance, varying that distance allows some assessment of how deposition varies with distance from a source CAFO. Specifically, areas within the 80 km transport distance can be assumed to receive higher rates of deposition than those within the 160 km transport distance, which would receive higher rates than for the 400 km distance.

The analyses presented here are not intended to represent a detailed model of nitrogen deposition from CAFOs in North Carolina; rather, they are meant to explore the potential effects of a broad range of nitrogen transport scenarios from CAFOs. Our model examines general spatial patterns of potential transport of reduced N for all CAFOs throughout North Carolina, based on a few simple assumptions. First, we assume that all CAFOs and lagoons are equivalent, except in location. For discussion of variation among farms and lagoons, see Battye et al. (1994) and Aneja et al. (2001). Second, we assume that atmospheric reduced N occurs evenly over all landscapes and water types. In fact, the rate of deposition depends on water salinity and landcover type (Paerl et al., 2002). Airshed modeling (Dennis and Mather, 2001) and source-receptor modeling (Walker et al., 2000) have been able to examine in greater detail the transport distance of reduced N to and from a limited number of sites.

Nonetheless, the results of our GIS model agree qualitatively with NH_4^+ deposition maps developed by the NADP. NADP isopleth maps show a high amount of NH_4^+ wet deposition in southeastern North Carolina (NADP, 2006; see Fig. 2), corresponding to the area that is within transport distance of a high number of CAFO lagoons under our 80 km and 160 km transport scenarios (Fig. 4a,b). Our simplified model omitted many relevant factors. Thus, its ability to capture observed patterns of deposition suggests that observed regional patterns of reduced N deposition can be largely explained by the factors that it did include: limited atmospheric transport distance, and spatial aggregation of CAFOs.

We focused on one particular transport pathway in our analysis: atmospheric deposition of reduced N from North Carolina CAFO lagoons to the Albemarle-Pamlico Sound. This coastal system provides ecological goods and services to humans. In particular, it and its upstream estuaries provide a nursery for 80% of the fisheries on the mid-Atlantic U.S. coast (Copeland and Gray 1991). We did not directly consider other pathways such as surface runoff or groundwater transport from CAFO lagoons, riverine transport of nitrogen deposited to terrestrial ecosystems (Paerl et al., 2002), or other sources such as industrial wastewater effluent or agricultural and residential applications of synthetic fertilizers. However, due to the Sound's location downstream of the biological nitrogen sink in the mesohaline zone, direct deposition is likely to have a high impact on ecosystems there (Paerl et al., 2002).

Our analysis of the potential spatial distribution of CAFO reduced N deposition throughout North Carolina indicates that the highest deposition rates are in the eastern part of the state in the Neuse and Tar-Pamlico River watersheds, which are part of the Albemarle-Pamlico Estuarine System. These rivers are considered nutrient-sensitive waters by the State of

North Carolina (NCDENR DWQ, 2002b, 2004). In particular, the Neuse River is subject to the Neuse Basin Nutrient Sensitive Waters Management Strategy, which calls for a 30% reduction in total nitrogen entering the Neuse River Basin (NCDENR, 1997). Furthermore, the Neuse Estuary showed a 500% increase in NH^{+} concentration over the period 1993–2004 (Burkholder et al., 2006). Over the same period, the estuary showed a significant decrease in bottom water dissolved oxygen (Burkholder et al., 2006), a phenomenon that can result from nutrient loading to streams (Mallin et al., 2004).

Although we have focused on the Albemarle-Pamlico Sound, our results also have implications for freshwater systems. According to our analysis, heavy deposition of reduced N occurs in and near the Northeast Cape Fear River. This is a blackwater river that has shown increases in NH_4^+ at monitoring stations (Mallin and Cahoon 2003; Burkholder et al., 2006). Experiments in blackwater rivers indicate that because algal production in these systems is N-limited, N additions can increase biochemical oxygen demand, leading to lower dissolved oxygen in these freshwater systems as well (Mallin et al., 2004).

We suggest that these previous findings in both estuarine and freshwater systems are a direct result of the spatial distribution of transport and deposition of reduced N from CAFOs we modeled here. Thus, the increase in direct atmospheric deposition to freshwater, estuarine, and coastal systems can result in significant ecosystem impacts. Overall, our analysis emphasizes the magnitude and spatial distribution of NH_3 production and deposition from CAFOs, a significant source of atmospheric reduced N in North Carolina.

Acknowledgements

The authors would like to gratefully acknowledge Michael Aitken, JoAnn Burkholder, Larry Cahoon, Kim Colson, Evan Hammer, Hans Paerl, Gary Phillips, and Mansoureh Tajik for their helpful comments and guidance. This manuscript resulted from an interdisciplinary, project-based course at the University of North Carolina-Chapel Hill. C. Mitchell was the instructor and J. Costanza, A. Goewert, and S. Marcinko were students. Elizabeth Selig was also a member of the course, and helped with GIS analysis. Other members of the course contributed ideas to a project that eventually led to this paper, which would not have been possible without them. They are: Andrew George, Neville Handel, Erich Hester, Rachael Hyde, Jessica Long, Natasha McCurley, and Mary O'Connor.

Received 5 March 2002; revised 15 July 2002; accepted 13 November 2002; published 28 February 2003.

[1] Temporal and spatial variations in ammonia (NH_3) emissions and ammonium (NH_4^+) concentrations associated with aerosols and volume-weighted NH_4^+ concentration in precipitation are investigated over the period 1990–1998 in the southeast United States (Alabama, Florida, Georgia, Kentucky, North Carolina, South Carolina, Mississippi, and Tennessee). These variations were analyzed using an NH_3 emissions inventory developed for the southeast United States and ambient NH_4^+ data from the various Clean Air Status and Trends Network (CASTNet) and the National Atmospheric Deposition Program/National Trends Network (NADP/NTN). Results show that natural log-transformed annual NH_4^+ concentration associated with aerosols increases with natural log-transformed annual NH_3 emission density within the same county ($R^2 = 0.86$, $p < 0.0001$, $N = 12$). Natural log-transformed annual volume-weighted average NH_4^+ concentration in precipitation shows only a very weak positive correlation with natural log-transformed annual NH_3 emission densities within the corresponding county ($R^2 = 0.12$, $p = 0.04$, $N = 29$). Analysis of NH_4^+ concentration associated with aerosols at CASTNet sites revealed that temperature, precipitation amount, and relative humidity are the most statistically significant ($p < 0.05$) parameters in predicting the weekly concentrations of NH_4^+ during the period 1990–1998. Wind speed and wind direction were also statistically significant ($p < 0.05$) at several CASTNet sites, but the results were less consistent. Investigation into wet NH_4^+ concentration in precipitation consistently yielded temperature as a statistically significant ($p < 0.05$) parameter at individual sites. Trends over the period 1990–1998 revealed a slight decrease in NH_4^+ concentration at CASTNet site SPD, Claiborne County, Tennessee (2.14–1.88 $\mu g\ m^{-3}$), while positive trends in NH_4^+ concentration in precipitation were evident at NADP sites NC35, Sampson County, North Carolina (0.2–0.48 mg L^{-1}) and KY35, Rowan County, Kentucky (0.2–0.35 mg L^{-1}) over the period 1990–1998. *INDEX TERMS:* 0315 Atmospheric Composition and Structure: Biosphere/atmosphere interactions; 0322 Atmospheric Composition and Structure: Constituent sources and sinks; 0330 Atmospheric Composition and Structure: Geochemical cycles; 0365 Atmospheric Composition and Structure: Troposphere—composition and chemistry; *KEYWORDS:* ammonia, ammonium, aerosols, agriculture, southeast United States, statistical model

1. Introduction

[2] Ammonia (NH_3) plays an important role in the atmosphere, neutralizing acids formed by the oxidation of such compounds as sulfur dioxide (SO_2) and nitrogen oxides ($NO_x = NO + NO_2$) [*Aneja et al.*, 2000; *RIVM*, 1995; *Nihlgard*, 1985; *Asman et al.*, 1982]. These reactions result in ammonium (NH_4^+)-containing aerosols, which may be of concern in particulate matter (PM_{fine}) nonattainment areas. At the Earth's surface, NH_x (= $NH_3 + NH_4^+$) at low concentrations can be a valuable source of nutrient input; however, high concentrations can lead to acidification of soils, forest decline, and eutrophication of waterways [*Asman*, 1994; *Aneja et al.*, 1998]. Therefore, the spatial distribution of NH_3 emissions and parameters which control

0148-0227/03/2002JD002271

the fate of this specie are important in determining areas of excess nitrogen input, and will aid in the development of models to predict the transport and deposition of atmospheric NH_x.

[3] Globally, approximately 54 (22–83) Tg N-NH_3 (1 Tg $=10^{12}$ g) are emitted each year [*Bouwman et al.*, 1997; *Schlesinger and Hartley*, 1992; *Warneck*, 1988]. The largest fraction (~41%) is from domestic animal excreta, at approximately 22 Tg N-NH_3 yr^{-1}. In the United States, domestic animal waste is also the largest contributor to atmospheric NH_3 emissions, responsible for approximately 80% nationwide [*Battye et al.*, 1994]. Combined with fertilizer application to farmland, animal husbandry and agricultural practices account for ~90% of the total NH_3 emitted in the United States each year [*Battye et al.*, 1994]. Approximately 32% of the southeast United States (Alabama, Florida, Georgia, Kentucky, North Carolina, South Carolina, Mississippi, and Tennessee) is used for farming practices and agriculture and while the southeast accounts for only 12% of the total area of the continental United States, it holds 18% of the total farmland [*USDA*, 1999].

[4] Analysis of the fate of NH_3 emissions in the United States is complicated by a lack of data on gaseous NH_3 in the ambient atmosphere. NH_3 monitoring data for the United States are rare, and data on long-term ambient trends are generally not available for gaseous NH_3. However, acid deposition monitoring networks provide considerable data on NH_4^+ ion concentrations in particulate matter. The Clean Air Status and Trends Network (CASTNet) measures concentrations of particulate NH_4^+, sulfate (SO_4^{2-}), and nitrate (NO_3^-). These data can provide some insights into the fate of gaseous NH_3 emissions. Therefore the objective of this study is to investigate concentrations of NH_4^+ associated with aerosols and in precipitation and NH_3 emissions in the southeast United States over the period 1990–1998, with the intent of defining relationships between NH_4^+ concentrations, local meteorology and NH_3 emissions.

2. Methods

2.1. Data Selection

[5] To estimate NH_3 emissions, agricultural data was obtained from the 1997 Census of Agriculture [*USDA*, 1999]. The census provided a complete data set for cattle and horses (i.e., an exact number was provided for each county in each state). However, the data for poultry, swine, and sheep was incomplete. In this case, the total number of animals was based on the average farm inventory. When the statewide population was less than 5000 for a particular animal, the estimate for that animal was considered negligible and therefore excluded from the final estimates. In the case of fertilizer, data was obtained from the Association of American Plant Food Control Officials, Inc. and is based on sales made by fertilizer registrants in each state.

[6] Data on NH_4^+ concentration associated with aerosols was obtained from the Clean Air Status and Trends Monitoring Network [*CASTNet*, 1998]. CASTNet was designed to be a rural monitoring network collecting data to establish site-specific measurements of total deposition and is considered the nation's primary source for estimates of dry acidic deposition and rural ozone (O_3) concentrations [*CASTNet*, 1998]. The network consists of 51 monitoring sites located across the United States, most of which have been operational since 1987. Continuous measurements of meteorological data including temperature, relative humidity, solar insolation, precipitation, wind speed, and wind direction are taken at each site and atmospheric concentrations of NH_4^+ are obtained from weekly filter pack measurements [*Holland et al.*, 1999].

[7] The CASTNet monitoring network [*USEPA*, 1998] measures weekly average ambient concentrations of particulate NH_4^+ [*Lawrence et al.*, 2000; *Sickles et al.*, 1999; and *Clarke et al.*, 1997]. The network also measures concentrations of particulate SO_4^{2-}, NO_3^-, base cations, O_3, SO_2, and nitric acid (HNO_3). NH_4^+ in the particulate, which is collected on a Teflon filter, is measured on a weekly basis by colorimetry. The CASTNet network was not designed to measure NH_3 gas. Ten CASTNet sites chosen for this study were selected based on location and availability of data. All of the sites, excluding CKT (located in Morgan County, KY), have more than 290 weekly NH_4^+ measurements from 1990 to 1998 making them suitable for long-term trend analysis. For more information regarding CASTNet data analysis and validation procedures, see the studies of *Clarke et al.* [1997] and of *USEPA* [1998].

[8] Data on NH_4^+ concentration associated with precipitation were obtained from the National Atmospheric Deposition Program/National Trends Network (NADP/NTN) [*NADP/NTN*, 1999]. NADP/NTN began monitoring in 1978 and currently operates over 200 sites nationwide. The purpose of the network is to collect data on the chemistry and amount of precipitation for monitoring spatial and temporal long-term trends. The precipitation at each station is collected weekly from AeroChem Metrics wet–dry deposition samplers according to strict clean-handling procedures. The precipitation sample is then sent to the Central Analytical Laboratory in Illinois, where it is analyzed for hydrogen (acidity as pH), SO_4^{2-}, NO_3^-, NH_4^+, chloride, and base cations (such as calcium, magnesium, potassium, and sodium) (NADP/NTN). Data validation procedures used at the laboratory are described by *Bowersox* [1984].

[9] It should be noted that both positive and negative biases in NH_4^+ concentration in precipitation have been measured. A positive bias may result from the deposition of NH_3 gas to the open precipitation collector [*Jensen and Asman*, 1995]. This bias will, on average, be greatest in agricultural areas and will likely be positively correlated with ambient temperature. A negative bias, as large as 40% in some cases, has been shown to result from postcollection incorporation of NH_4^+ into microbial biomass [*Ramundo and Seastedt*, 1990; *Lamb and Comrie*, 1993]. This bias is also expected to be larger under warm temperatures. Unfortunately, it is not possible to quantify the net result of these biases. While this source of error may reduce the amplitude of season cycles, due to a net reduction of summer values at most sites, it should not greatly effect the magnitude of long-term trends. At agricultural sites, the competing biases may result in a relatively small net error.

[10] In order to assess the temporal variability in NH_4^+ concentrations associated with aerosols and precipitation across the southeast United States over the period 1990–1998, 10 CASTNet sites and 10 corresponding NADP sites were chosen based on location (distance between CASTNet and NADP sites) and availability of weekly data. For this

time series analysis, an additional NADP site was included (NC35, Sampson County, North Carolina) based on its location within an agricultural region, though this site does not have a corresponding CASTNet site. Table 1 summarizes the CASTNet and NADP sites used in the weekly and monthly analyses of NH_4^+ concentrations associated with aerosols and precipitation. To assess the influence of NH_3 emissions on wet and dry NH_4^+ concentrations, the remaining NADP and CASTNet sites located in the southeast United States which were active during 1997 were added to the analysis. Table 2 lists the CASTNet and NADP sites used in the analysis of NH_3 emissions and NH_4^+ concentrations in this study.

2.2. Data Analysis

[11] In this study, regression analysis, specifically the method of ordinary least squares, was used to identify relationships between dependent and independent variables. This method assumes that the regression errors have constant variance, are uncorrelated with each other in time, and have a normal distribution. Analyses were performed using SAS statistical analysis software.

2.3. Estimating Annual NH_3 Emissions

[12] The first goal of this study is to resolve the spatial variability of NH_3 emissions from agricultural sources in the southeast United States. To develop this regional emissions inventory, emission estimates from all major agricultural sources in the southeast United States were calculated using data from 1997. The sources considered in this inventory include dairy and beef cattle, poultry, swine, horses, and sheep, as well as fertilizer application. County totals are obtained for each source, and NH_3 emission estimates are performed at the county level. For the purpose of this study, NH_3 emissions are assumed to be uniform across the county. This provides a general spatial distribution of estimated NH_3 emissions across the eight-state region. County-level NH_3 emission estimates for each source type are based on the following equation:

$$\begin{aligned} &\mathit{Emission\ rate}\left(kg\ NH_3\ yr^{-1}\right)\\ &\quad = \mathit{Activity\ Data}(\mathit{animal\ population})\\ &\quad \times \mathit{Emission\ Factor}\left(kg\ NH_3\ animal^{-1}\ yr^{-1}\right) \end{aligned}$$

The activity data is simply the number of animals present in each county, and is obtained from the 1997 U.S. Census of Agriculture [*USDA*, 1999]. The emission factors are based on experimental measurements of average emissions per animal (kg NH_3 animal^{-1} yr^{-1}) and mass balance calculations. Most of the experimental emission factors are obtained from Europe, where animal practices may vary significantly from the United States. Furthermore, the NH_3 emissions are sensitive to changes in animal diet, atmo-

spheric temperature and humidity, waste-handling practices, and many other parameters [*Asman*, 1992]. Because of the many uncertainties, it may be difficult to obtain an accurate NH_3 emission estimate. Table 3 is a summary of documented emission factors that were considered in developing the emission inventory for this study. The large variation in estimates illustrates the difficulty in developing precise estimates.

[13] Emission factors were selected for each livestock group including beef and dairy cattle, hogs and pigs, chickens, broilers, turkeys, horses, and sheep. An earlier study and literature review by *Battye et al.* [1994] refined European emission factors based on United States agricultural practices. Their results have been used as a guide to obtain the emission factors employed in this study. The U.S. Census of Agriculture has provided estimates for both beef and dairy cattle; therefore, a unique emission factor was determined for each. *Battye et al.* [1994] recommend 15.19 kg NH_3 animal^{-1} yr^{-1} for beef cattle or "young cattle for fattening." This estimate includes total emissions resulting from animal housing, grazing, manure storage, and land spreading. The recommendation by *Battye et al.* [1994] is based on research and literature reviewed by *Asman* [1992]. Considering these estimates to be somewhat out of date, an average of more recent estimates by *Bouwman et al.* [1997], *Misselbrook et al.* [2000], and *Van Der Hoek* [1998] is used here resulting in an emission factor of 10.2 kg NH_3 animal^{-1} yr^{-1}. A similar approach is used for dairy cattle, taking the average of emission factors given by *Misselbrook et al.* [2000] and *Van Der Hoek* [1998] to obtain 28.04 kg NH_3 animal^{-1} yr^{-1}.

[14] Hogs and pigs are not divided into weight or class categories in the 1997 Census of Agriculture; however, *Van Der Hoek* [1998] suggests that 3 classes can be determined based on the total population of hogs. One can assume that approximately 50% are fattening hogs, 10% are sows, and the remaining 40% are young sows and piglets. Two unique emission factors, 6.39 and 16.43 kg NH_3 animal^{-1} yr^{-1}, are derived for fattening hogs and sows respectively. The factor 16.43 for sows includes a correction for young sows and piglets that account for 40% of the population. Therefore, to estimate total NH_3 emissions from a general hog population, 50% of the population was multiplied by 6.39 and 10% of the population by 16.43. This equates to an average emission factor of 4.84 kg NH_3 per hog, which has proved to be a satisfactory estimate based on recent studies at a commercial hog farm by *McCulloch* [1999]. His study estimated total NH_3 emissions from hog facilities to be in the range 3.4–6.9 kg NH_3 animal^{-1} yr^{-1} [*McCulloch*, 1999]. *Battye et al.* [1994] proposed emission factors for sheep, broilers, and laying hens older than 20 weeks based on the study of *Asman* [1992]. These estimates have been refined based on new experimental data, and the updated values are employed in this study [*Van Der Hoek*, 1998].

[15] For the remaining animal groups (pullets 13–20 weeks, pullets less than 30 weeks, and turkeys) and fertilizer application, the emission factors proposed by *Battye et al.* [1994] are used. Table 4 lists the estimated emission factors for various nitrogen fertilizers, based on total U.S. consumption in 1993. A summary of emission factors and corresponding 1997 emissions estimates for all domestic livestock and fertilizer application in the southeast are given in Table 5. Based on the emission factors and agricultural census data, both the relative

contribution from each source category (Figure 1) and the spatial distribution of NH_3 emissions were determined (Figure 2).

2.4. Influence of NH_3 Emissions on Atmospheric NH_4^+ Concentrations

[16] Exploratory regression analysis is used to determine relationships between county-scale NH_3 emissions and within-county observed annual average concentrations of NH_4^+ associated with aerosols and annual volume-weighted average concentration of NH_4^+ in precipitation (Table 2). This analysis is performed for the year 1997 to correspond with the NH_3 emission inventory described above.

2.5. Weekly NH_4^+ Concentration Analysis

[17] A statistical analysis is performed to investigate and model trends in NH_4^+ concentration associated with aerosols and precipitation based on correlation with meteorological parameters such as surface temperature, relative humidity, wind speed, and wind direction. Measurements of NH_4^+ concentration in aerosols from 10 CASTNet sites across the southeast United States and NH_4^+ concentration in precipitation from 10 neighboring NADP sites were analyzed for the period January 1990 to December 1998. Due to the proximity of each CASTNet and NADP site (Table 1), the same meteorological data were used for both analyses.

[18] To investigate the relationship between ambient and wet NH_4^+ concentration and meteorology, a multiple linear regression model of the following type was employed at all sites [*Walker et al.*, 2000a; *Holland et al.*, 1999; *Buishand et al.*, 1988; *Dana and Easter*, 1987]:

$$\log(C_t) = a_0 + [a\cos(2\pi t/52) + b\sin(2\pi t/52)] + ct + d_n x_n + e_i \quad (1)$$

where $\log(C_t)$ refers to the natural log-transformed weekly concentration of ambient NH_4^+ (μg m^{-3}) or wet NH_4^+ in precipitation (mg L^{-1}) at time t weeks from 1 January 1990. Raw data were transformed to help achieve the condition of normality in regression residuals. The second term in model (1) contains sine and cosine functions, which are commonly used to model seasonal cycles in data [*Lynch et al.*, 1995; *Holland et al.*, 1999]. In model (1), the amplitude (A) of the cycle is determined as:

$$A = \sqrt{a^2 + b^2} \quad (2)$$

and the phase angle (ϕ) is determined as:

$$\hat{\phi} = \arctan(b/a) \quad \text{if } a \geq 0$$
$$\hat{\phi} = \arctan(b/a) + \pi \quad \text{if } a < 0. \quad (3)$$

The regression routine calculates p-values for coefficients a and b under the null hypothesis that no cycle is present at frequency $2\pi t/52$ (a = 0 and b = 0). If the p-value for either of the regression coefficients is less than the specified alpha level, the null hypothesis may be rejected. Meteorological parameters (temperature, precipitation amount, relative humidity, wind speed, and wind direction) included in the model are represented by $x_n = x_1, x_2, x_3, x_4$, and x_5. Finally, a_o represents the intercept of the regression line, while the residual (e_i) represents the error in the point prediction of $\log(C_t)$. Only parameters with regression coefficient p-values < 0.1 were considered statistically significant.

2.6. Monthly Mean NH_4^+ Concentration Analysis

[19] Monthly averaged concentrations of NH_4^+ associated with aerosols and monthly volume-weighted average concentrations of NH_4^+ associated with precipitation were also investigated at each CASTNet and NADP site for the period January 1990 to December 1998 (Table 1). For this exercise, two models were applied to all sites in an attempt to better understand the interactions between overall trend, seasonality, and temperature dependence [*Holland et al.*, 1999]. Other meteorological parameters were excluded from this model because monthly averages would perform poorly as predictive parameters. The selected models are:

$$\log(C_t) = a_0 + a\cos(2\pi t/12) + b\sin(2\pi t/12) + ct + e_i \quad (4)$$

$$\log(C_t) = a_0 + bT_t + ct + e_i \quad (5)$$

Model (4) accounts for seasonal variability of C_t at each site, while model (5) accounts for the dependence of C_t on air temperature. Parameters in model (5) are defined as in model (1). In model (5), T represents monthly average temperature while the remaining terms are defined as in model (1). The use of both temperature and seasonality in

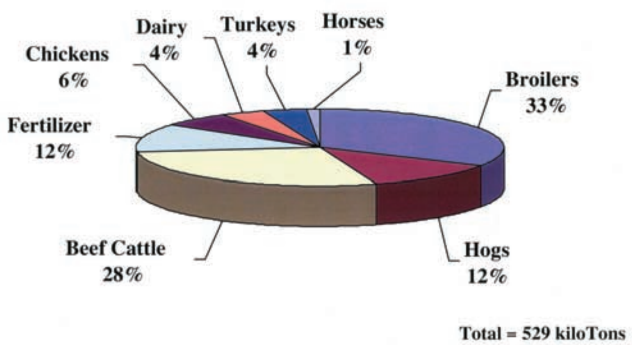

Figure 1. Relative contribution of NH_3 emissions in the southeast United States Source: Nelson, 2000.

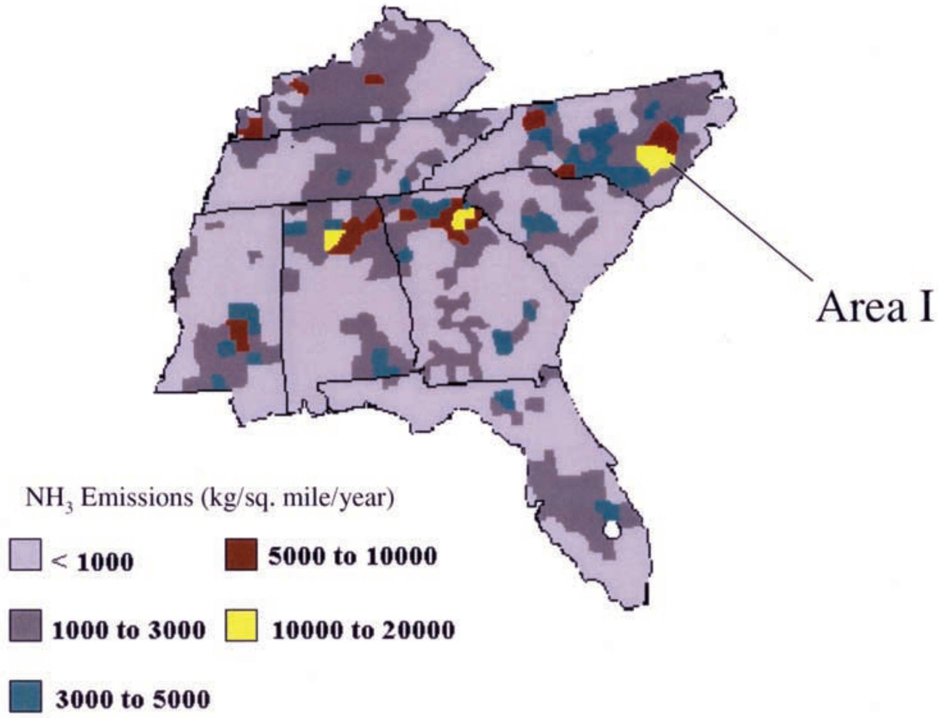

Figure 2. Spatial distribution of NH_3 emissions.

the same model can actually degrade the quality of the model because the two parameters are so highly correlated. Where a trend in NH_4^+ concentration was detected at a particular site, regression models were employed to test for trends in temperature and precipitation volume. This was necessary to determine if the trend in NH_4^+ concentration may have been caused by temporal changes in precipitation volume or temperature.

3. Results

3.1. Spatial Distribution of NH_4^+ Concentrations

[20] Linear regression analysis was performed to investigate the relationship between annual county-scale agricultural NH_3 emission density (Figure 2) and observed annual average NH_4^+ concentrations in aerosols and precipitation within that county during 1997. To improve the normality of regression residuals, NH_4^+ concentrations in aerosols and precipitation, along with emissions, were first natural log-transformed. Regression analyses were performed on transformed variables. Results show that natural log-transformed annual NH_4^+ concentrations associated with aerosols increase with natural log-transformed county annual NH_3 emission density ($R^2 = 0.86$, $p < 0.0001$, $N = 12$) (Figure 3a). The untransformed data show a clear logarithmic increase in NH_4^+ concentrations in aerosols with increasing emissions. This relationship suggests that local NH_3 emissions strongly influence ambient NH_4^+ concentrations, but that there exists a level above which NH_3 emission is no longer the primary source of variability in ambient NH_4^+ concentration. This can be explained by the fact that NH_4^+ aerosol formation is limited by the availability of acid gases in the presence of excess NH_3. Thus, counties with high NH_3 emission densities likely represent areas within which NH_4^+ aerosol formation is no longer NH_3 limited. A similar regression analysis shows that natural log-transformed annual volume-weighted average NH_4^+ concentration in precipitation shows only a very weak positive correlation with natural log-transformed annual NH_3 emission densities within the corresponding county ($R^2 = 0.12$, $p = 0.04$, $N = 28$) (Figure 3b). Perhaps the primary reason for this much weaker relationship is that the incorporation of NH_4^+ into rainfall takes place on a spatial scale greater than the area of individual counties. In most cases, the majority of NH_4^+ observed in rainfall at a particular location originates from relatively distant sources, and the local signal may result from the relatively inefficient process of below-cloud scavenging of NH_3 and NH_4^+ [*Shimshock and De Pena*, 1989]. In general, agricultural NH_3 sources are shown to influence local concentrations of NH_4^+ in aerosols and precipitation both in the United States and Europe [*Marquardt et al.*, 1996; *Erisman et al.*, 1998; *Asman et al.*, 1998; *Aneja et al.*, 2000; *Walker et al.*, 2000a; *Sutton et al.*, 2001a, 2001b].

3.2. Analysis of Weekly NH_4^+ Concentration Associated With Aerosols

[21] Table 6 summarizes the results from model (1) applied to the weekly ambient concentration data at each CASTNet site (Table 1). The R^2 values range from 0.18 at SUM (Liberty County, Florida) to 0.73 at PNF (Avery County, North Carolina). The poor performance of the model at site SUM may be attributed to its location, a Florida site with very little seasonal variability and strong coastal influence.

[22] Precipitation amount was the most significant parameter at 7 out of 10 sites, having a negative regression coefficient ranging from -0.0045 to -0.005. This inverse relationship has also been reported in other studies [*Prado-*

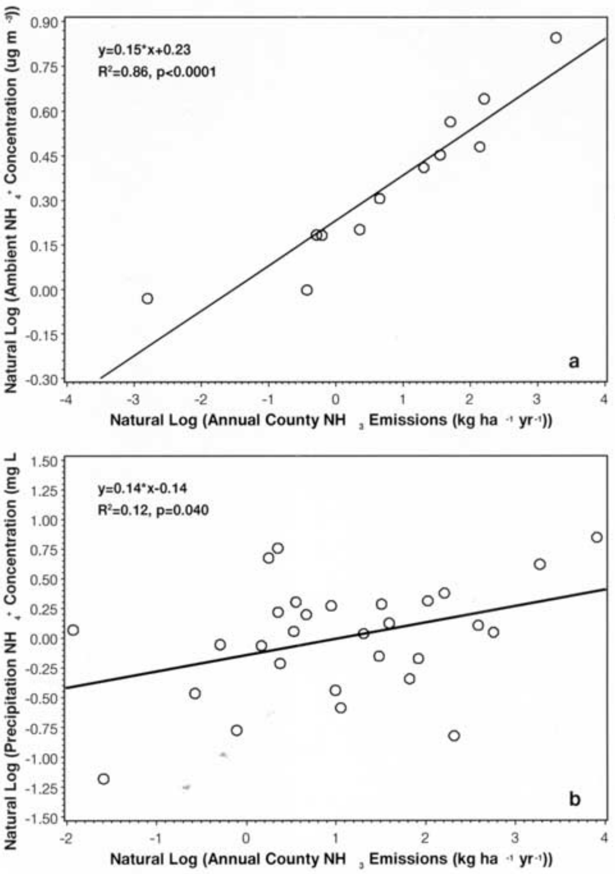

Figure 3. Natural log-transformed annual average ambient NH_4^+ concentrations ($\mu g\ m^{-3}$) versus natural log-transformed annual county NH_3 emission density (kg NH_3 ha^{-1} yr^{-1}) (a) and natural log-transformed annual volume-weighted average NH_4^+ concentration in precipitation (mg L^{-1}) versus natural log-transformed annual county NH_3 emission density (kg NH_3 ha^{-1} yr^{-1}) (b).

Fiedler, 1990; *Walker et al.*, 2000a]. Relative humidity is found to be a significant ($p < 0.05$) parameter at 6 sites. The positive regression coefficient (0.001–0.005) suggests that higher relative humidity leads to increased concentrations of NH_4^+ associated with aerosols. Therefore, increased water vapor in the atmosphere near sources of NH_3, lead to higher concentrations of NH_4^+ [*Andersen et al.*, 1999; *Asman*, 1994; *Warneck*, 1988; *McMurry et al.*, 1983]. Moreover, at high relative humidity (>62%) ammonium nitrate is less likely to dissociate into HNO_3 and NH_3 [*Stelson and Seinfeld*, 1982]. Wind speed is a significant parameter in the model at 6 sites and is negatively correlated to NH_4^+ concentrations. Low wind speeds often coincide with stable conditions and limited dispersion whereas lower concentrations are often characterized by higher wind speeds and increased mixing throughout the boundary layer [*Arya*, 1999]. Temperature is also a significant model predictor at half of the sites. Finally, wind direction is significant at 6 CASTNet sites. From the regression coefficients, however, it is difficult to interpret the effect wind direction has at any particular site and is better illustrated by showing NH_4^+ concentration associated with aerosols relative to wind direction for CASTNet site CND located in Montgomery County, North Carolina (Figure 4) [*Yamamoto et al.*, 1995]. From this plot, it is clear that higher concentrations of NH_4^+ associated with aerosols occur when the wind is from the E and SE. Indeed, Area I, previously defined as an area of elevated NH_3 emissions, is located to the E/SE of site CND (see Figure 2).

[23] The model with the best fit (R^2 = 0.73) was for CASTNet site PNF located in Avery County, North Carolina. A plot of measured and predicted concentrations at site PNF, for the period January 1990 to December 1998, shows that the model follows the general seasonal trends of the ambient NH_4^+ concentration but fails to predict the peaks (Figure 5). Temperature was found to be the most statistically significant parameter in this model ($p < 0.05$), and an analysis of temperature and NH_4^+ over the 9-year period

revealed that the concentration of NH_4^+ peaks during the summer when temperatures are warm. This relationship is to be expected based on the fact that atmospheric NH_4^+ is primarily a product of NH_3 reacting with acids formed in the atmosphere, such as H_2SO_4, HNO_3, and HCl and the formation of these acids depends on the availability of hydroxyl radical (OH) and O_3 in the atmosphere, which peak during the summer months [*Seinfeld*, 1986]. Furthermore, biogenic NH_3 emissions from soils and animal waste storage and treatment lagoons [*Aneja et al.*, 2000] are in part driven by temperature, where a 10°C increase in temperature approximately doubles the rate of ammonification [*Addiscott*, 1983].

3.3. Analysis of Monthly Mean NH_4^+ Concentration Associated With Aerosols

[24] Monthly mean concentrations of NH_4^+ associated with aerosols were modeled to test for the general trend and seasonal trends over the period 1990–1998. Models (4) and (5) were applied to each selected CASTNet site and the highest R^2 value [$R^2 = 0.86$, model (4)] was again found at site PNF. The results for all CASTNet sites (Table 1) selected are summarized in Table 7.

[25] The models of monthly NH_4^+ concentrations perform much better than those of weekly concentrations with R^2 values ranging from 0.14 to 0.86 for seasonality model (4) and 0.07–0.81 for temperature model (5). If we remove the Florida site SUM, the average R^2 for models (4) and (5) are 0.69 and 0.63, respectively. This means that 69% of the variability in NH_4^+ concentration in aerosols is explained by seasonality factors in model (4), while 63% of the variability is explained by temperature dependence in model (5). These results suggest that most of the variation in NH_4^+ concentrations in aerosols can be explained by temperature or seasonal effects. In general, Table 7 shows that R^2 values are consistently higher for the seasonality model (4), which is to be expected based on the strong interaction between temperature and seasonality inherent in this model. However, to account fully for spatial variations in ambient NH_4^+ concentrations and deposition, one must also consider such variables as ambient concentrations of NH_4^+ precursors, surface roughness, and vegetation properties, which have large spatial and temporal variability [*Asman*, 1994].

[26] Statistically significant trends were evident at 2 of the CASTNet sites over the period 1990–1998. A positive trend was present at site SUM in Sumatra County, Florida ($p = 0.05$). However, this site performed poorly in the above analyses, so this result may be inaccurate. A negative trend was observed at site SPD, located in Claiborne County, Tennessee. Mean concentrations of NH_4^+ associated with aerosols fell from approximately 2.14 in 1990 to 1.88 in 1998 ($p = 0.06$). Trends in mean surface temperature were investigated at site SPD (Claiborne County, Tennessee). However, no statistically significant trend was present over the period 1990–1998 suggesting that temperature is likely not responsible for the decreasing trend in NH_4^+ concentration at these sites.

3.4. Analysis of Weekly NH_4^+ Concentration Associated With Precipitation

[27] Model (1) was run for all NADP sites (Table 1) to select the best parameter fit. The results from this analysis were low with R^2 ranging from 0.13 to 0.31. Due to the

poor performance of this model, no conclusions could be made regarding the relationship between weekly NH_4^+ concentration in precipitation and local meteorological parameters. However, an investigation of monthly mean volume-weighted NH_4^+ concentration in precipitation proved to be more insightful.

3.5. Analysis of Monthly Mean NH_4^+ Concentration Associated With Precipitation

[28] Models (4) and (5) were applied to all NADP sites (Table 1) using monthly mean volume-weighted NH_4^+ concentration in precipitation. The results for each NADP site are summarized in Table 8. The seasonality dependence in model (4) resulted in R^2 values ranging from 0.25 to 0.62, while the temperature dependence in model (5) had an R^2 range of 0.06–0.46. In general, models performed better when applied to monthly rather than weekly values. Volume-weighted averaging of weekly values to generate monthly averages tends to smooth the noise present in weekly values, resulting in higher R^2 values associated with monthly models. The site FL14, located in Gadsden County, Florida, had the worst overall performance. This site is located near CASTNet site SUM, which also performed poorly in the NH_4^+ associated with aerosols analysis. The exact reason for the poor performance of these sites is not known, although their proximity to the coast and possible

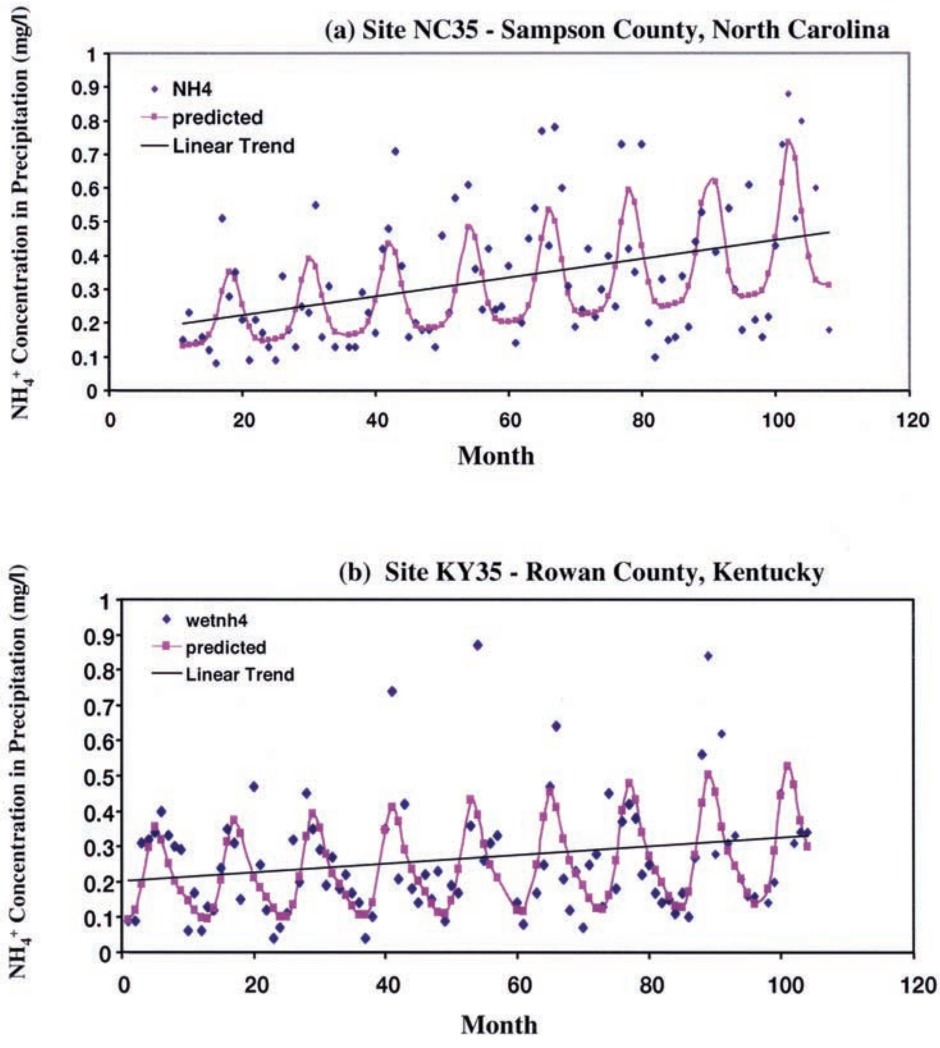

Figure 6. Trends at NADP sites NC35, Sampson County, North Carolina and KY35, Rowan County, Kentucky over the period 1990–1998 where month 0 corresponds to January 1990.

overriding influences of sea and land breezes are considered to be contributing factors [*Arya*, 1999]. Two of the NADP sites showed a statistically significant positive ($p < 0.05$) trend for the period 1990–1998; KY35, located in Rowan County, Kentucky, and NC35, located in Sampson County, North Carolina. The linear trends for these two sites are shown in Figure 6.

[29] At the Sampson County, North Carolina site (NC35), located in Area I (see Figure 2), monthly mean volume-weighted NH_4^+ concentration in precipitation rose from approximately 0.2 mg L^{-1} in 1990 to 0.48 mg L^{-1} ($p < 0.0001$) in 1998. The dramatic increase in NH_4^+ wet deposition is also documented by *Aneja et al* [1998] and *Walker et al.* [2000a, 2000b]. Their findings reveal that no significant increasing trends in temperature or precipitation are present for the period 1990–1996; therefore, meteorology is likely not responsible for the increasing trend in NH_4^+. *Walker et al.* [2000b] go on to relate the increasing trend in NH_4^+ in precipitation to an increase in local NH_3 emissions caused by swine facilities. In fact, the hog population in North Carolina rose from approximately 2 million to 10 million hogs between 1990 and 1998, with 50% of the statewide population, and hence the emissions, located in the concentrated area surrounding Sampson County. The natural summertime peaks of NH_4^+ concentration in this area are further enhanced by the presence of waste from hogs.

[30] At site KY35, the average NH_4^+ concentration in precipitation rose from approximately 0.2 mg L^{-1} in 1990 to 0.35 mg L^{-1} ($p = 0.004$) in 1998. Analyses of precipitation and temperature revealed no statistically significant trend in either variable over the 8-year span; therefore, temperature and precipitation amount do not appear to be responsible for the increasing trend in NH_4^+ concentration in precipitation found at NADP site KY35. The reason behind the increasing NH_4^+ trend at KY35 is less obvious than at NC35, because Rowan County, Kentucky, has an average NH_3 flux of only 131 kg NH_3 km^{-2} yr^{-1}. Based on CASTNet meteorological data, the prevailing wind at site KY35 is from the SW; however, concentrations of NH_4^+ in aerosols, and presumably NH_4^+ in precipitation, are slightly higher when the wind is out of the N. The trend observed at this site likely results from increasing upwind NH_3 source strengths over the period.

4. Conclusions

[31] This study provides insight into the coupling between NH_3 emissions and NH_4^+ concentrations associated with both aerosols and precipitation and how environmental parameters affect these relationships. Regression modeling shows that counties with relatively higher agricultural NH_3 emissions exhibit higher annual average concentrations of NH_4^+ associated with aerosols though the influence on NH_4^+ concentration in precipitation is much less clear. Analysis of NH_4^+ concentration in aerosols at the various CASTNet sites revealed that temperature, precipitation amount, and relative humidity are the most statistically significant ($p < 0.05$) parameters in predicting the weekly concentrations of NH_4^+. Wind speed and direction were also statistically significant ($p < 0.05$) at several CASTNet sites, but the results were less consistent. Investigation into NH_4^+ concentration in precipitation yielded temperature as a statistically significant ($p < 0.05$) parameter. Trends over the period 1990–1998 revealed a slight decrease in ambient NH_4^+ concentration at CASTNet site SPD, Claiborne County, Tennessee (2.14–1.88 μg m^{-3}, $p = 0.06$), while positive trends in NH_4^+ concentration in precipitation were evident at NADP sites NC35, Sampson County, NC (0.2–0.48 mg L^{-1}, $p < 0.0001$) and KY35, Rowan County, Kentucky (0.2–0.35 mg L^{-1}, $p = 0.004$)) over the period 1990–1998. Analyses of NH_4^+ emissions and deposition in the United States are complicated by a lack of data on ambient levels of NH_3 gas and the complex interrelations among NH_3 gas, HNO_3 gas, and SO_4^{2-} and NO_3^- particulate components.

[32] Results from this study provide additional evidence that agricultural NH_3 source strengths are seasonally dependent. Modeling exercises which use annual emissions estimates derived from factors such as those presented in this study should attempt to account for this effect. Furthermore, seasonality in NH_3 emissions may translate to seasonality in ammonium nitrate and ammonium sulfate aerosol concentrations in some areas. This relationship, however, is confounded by seasonality in nitric and sulfuric acid concentrations. Further research (both measurement and modeling) is warranted to investigate such dynamic NH_3/aerosol relationships and the influence of NH_3 on total $PM_{2.5}$. The general form of the parametric models presented here may be useful in examining the temporal variability in NH_3, SO_4^{2-}, NO_3^-, HNO_3, and sulfuric acid to better characterize the seasonal nature of NH_3/NH_4 partitioning.

ATTACHMENT 30

Memo to: NC Division of Water Resources, and NC Environmental Management Commission

From: Dr. Michael A. Mallin, Research Professor, Center for Marine Sciences, University of North Carolina Wilmington, Wilmington, NC, 28409

Date: February 9, 2015

Subject: Comment on the proposed reclassification of the lower Cape Fear River and Estuary to Class Sc-Swamp (Sw) classification.

1) I am very supportive of the statement in the reclassification proposal that states that any further municipal point sources will require the highest level of treatment in North Carolina. I would ask for more specifics regarding industrial discharges – at the least setting some limits on biochemical oxygen demanding agents such as biochemical oxygen demand (BOD), ammonia, total nitrogen (TN) and total phosphorus (TP).

2) An important statement that needs to be clarified is found in the narrative standards where it states that DO should not be less than 5.0 mg/L except that "swamp waters, poorly flushed tidally influenced streams or embayments, or estuarine bottom waters may have lower values if caused by natural conditions" . The issue that requires clarification is who decides, and by what criteria, if such a deviation is caused by "natural" conditions.

3) The proposed CFR reclassification does not adequately address non-point contributions of BOD or nutrients (which lead to BOD increases). If focus on non-point sources potentially contributing to oxygen depletion is continued to be addressed by on-going water quality programs; based on the summer blue-green algal blooms that occurred annually from 2009-2012, this approach has been inadequate and will continue to be inadequate.

4) In the lower Cape Fear River and Estuary, peer-reviewed research published in *Limnology and Oceanography* has demonstrated that BOD is driven by a number of biological and chemical factors (Mallin et al. 2004; Tables 4, 5 and 6) see the following:

- Chlorophyll *a* (the principal measure of algal bloom strength) has been positively correlated with BOD5 in the mainstem river at Lock and Dam #1 ($r = 0.55$, $p = 0.0001$), Browns Creek ($r = 0.45$, $p = 0.007$), Hammond Creek ($r = 0.45$, $p = 0.004$), Great Coharie Creek ($r = 0.51$, $p = 0.001$), Colly Creek ($r = 0.64$, $p = 0.0001$), Barnards Creek ($r = 0.37$, $p = 0.040$), Motts Creek ($r = 0.42$, $p = 0.020$), and Smith Creek ($r = 0.57$, $p = 0.0009$). I note that Browns, Hammond, Barnards and Smith Creeks drain directly into the mainstem river or estuary, while Colly and Great Coharie creeks drain into the lower Black River, a major 5th order tributary of the 6th order Cape Fear River.
- TN has been positively correlated with either BOD5 or BOD20 or both in the 5th-order Northeast Cape Fear River ($r = 0.30$, $p = 0.02$), the Black River ($r = 0.45$, $p = 0.0003$), Hammond Creek ($r = 0.47$, $p = 0.0003$), Six Runs Creek ($r = 0.54$, $p = 0.0005$), Great

Coharie Creek (r = 0.44, p = 0.006), Little Coharie Creek (r = 0.52, p = p = 0.0008), and Colly Creek (r = 0.54, p = 0.0005).

- TP has been positively correlated with either BOD5, BOD20 or both in the Northeast Cape Fear River (r = 0.34, p = 0.008) the Black River (r = 0.33, p = 0.010), Browns Creek (r = 0.40, p = 0.012), Hammond Creek (r = 0.42, p = 0.009), Six Runs Creek (r = 0.49, p = 0.002), Great Coharie Creek (r = 0.66, p = 0.0001), and Colly Creek (r = 0.39, p = 0.015).
- Chlorophyll *a* represents algal blooms, which upon death and decomposition become highly labile sources of BOD. Nutrients drive BOD in two ways: directly and indirectly. A peer-reviewed article in *Ecological Applications* by Mallin et al. (2004) showed that for streams in the Black and Northeast Cape Fear River basins, inputs of dissolved phosphorus directly stimulate BOD5 and BOD20, as well as natural bacteria abundance (the direct driver of BOD). The data also showed that inputs of dissolved nitrogen (nitrate ammonium, and urea) significantly stimulate algal growth, which in turn significantly stimulates BOD. Thus, the correlation between nutrient loading and BOD is not surprising.

5) The proposed reclassification is based on the Bowen (2009) model predicting DO concentrations in the lower Cape Fear River Estuary

- The Bowen model concludes that further reduction of current point sources would have little effect on DO concentrations – I will accept the model's conclusions on that matter.
- But, Bowen's model shows that reducing nutrient, carbon and BOD loads from the incoming rivers, creeks and wetlands by 30% and 70% would <u>increase</u> median DO from 5.6 mg/L to 5.85 and 6.2 mg/L, respectively – and this assumes sediment oxygen demand (SOD) stays the same regardless of reductions! See Bowen (2009) pages 6-4, 6-8, and 6-22 in particular for more on this topic.
- Assuming that such BOD load reduction would similarly reduce SOD, than the model says summer DO violations would decrease from 45% to 22% violations (30% reduction case), down to 7% (with 50% reduction) and down to only 1% violations (70% reduction case).
- I further note that SOD cannot simply be considered "natural" only. A year-long study of several tidal creeks in New Hanover County was published in the peer-reviewed journal *Hydrobiologia* (MacPherson et al. 2007). Results demonstrated that chlorophyll *a* concentrations were positively correlated with SOD (r = 0.35, p < 0.05), as well as BOD5 (r = 0.50, p < 0.05).

6) I note that Bowen does not discuss non-point source pollution sources specifically.

7) Yet, non-point runoff plays a major role in the middle to lower basin of the mainstem Cape Fear River, from crop agriculture, urban runoff and some livestock production. In the lower Cape Fear system I note that livestock waste pollution and crop agriculture are the predominant non-point nutrient and BOD sources in the Black and Northeast Cape Fear River basins.

8) Livestock manures as waste inputs were *not even mentioned* in Bowen's model! However, 2012 livestock counts for Brunswick, Pender, Duplin, Sampson, Cumberland

and parts of Bladen and Onslow Counties (Cape Fear lower watershed) are as follows (information for counties that are partially within the basin, Bladen and Onslow, are estimates):

- Hogs: approximately 5,000,000
- Turkeys: approximately 21,500,000
- Broiler chickens: > 122,000,000
- Other chickens: > 870,000
- Cattle: approximately 72,000

(from NCDA website September 2014)

Livestock wastes are clearly the largest source of BOD-forcing pollutants in the Cape Fear Basin – and remain virtually unregulated (i.e. no required streamside buffers, no required control of ammonia off gassing, etc.).

9) Industrialized swine farms (CAFOs) are a source of large-scale chronic nitrogen and phosphorus loading to nearby soils and receiving water bodies, nutrients which have been directly correlated to BOD in the blackwater streams and rivers of the Cape Fear Basin (Mallin et al. 2006). An peer-reviewed analysis by Cahoon et al. (1999) published in *Environmental Science and Technology* found that vast quantities of nitrogen and phosphorus feed are imported into the watershed annually to feed swine, poultry, and cattle in production facilities (CAFOs), which in turn annually load large quantities of nutrients as waste into the watershed. This analysis found that for the Cape Fear River basin alone, CAFOs produce 82,700 tons of nitrogen and 25,950 tons of phosphorus annually into this watershed. Thus, N and P enter the state as animal feed from elsewhere, but much of it leaves the livestock as manure (or carcasses) and enters soils or waters of the Coastal Plain.

10) Finally, swine waste lagoons, as well as lagoons servicing egg-laying poultry CAFOs, produce copious amounts of ammonia to the atmosphere; NC Division of Air Quality estimates a swine ammonia emission factor of 9.21 kg/hog-year. 9.21 x 5,000,000 head of swine = 46,050,000 kg or 46,050 metric tons of ammonia released to the airshed of the Cape Fear River basin (and coastal ocean) <u>per year</u>, much of which comes to earth within 60 miles of the source (Walker et al. 2000; Costanza et al. 2008). Ammonia is well-known in the environmental engineering literature to exert an oxygen demand (nitrogenous BOD) on waters – that is why it is regulated in wastewater discharges (Clark et al. 1977). Efforts need to be made to control this major source of oxygen-demanding wastes to the Cape Fear system as well.

11) Clearly, non-point sources of BOD, nitrogen, and phosphorus entering the waters of the lower Cape Fear River system are very large and lead to reduced dissolved oxygen levels.

I conclude that the proposed reclassification, as it stands, will be inadequate to produce or maintain proper dissolved oxygen concentrations in the lower Cape Fear River and Estuary due to the lack of attention to non-point sources of nutrients and BOD. The source of much of this pollution is industrial livestock production, along with unknown inputs from traditional agriculture, and some urban runoff in the Fayetteville and Wilmington areas. **Any**

proposed reclassification of the lower Cape Fear River and Estuary must include strong language specifically aimed at reducing such non-point sources of pollution.

Abstract

The Atmospheric Nitrogen Compounds II: Emissions, Transport, Transformation, Deposition and Assessment workshop was held in Chapel Hill, NC from 7 to 9 June 1999. This international conference, which served as a follow-up to the workshop held in March 1997, was sponsored by: North Carolina Department of Environment and Natural Resources; North Carolina Department of Health and Human Services, North Carolina Office of the State Health Director; Mid-Atlantic Regional Air Management Association; North Carolina Water Resources Research Institute; Air and Waste Management Association, RTP Chapter; the US Environmental Protection Agency and the North Carolina State University (College of Physical and Mathematical Sciences, and North Carolina Agricultural Research Service). The workshop was structured as an open forum at which scientists, policy makers, industry representatives and others could freely share current knowledge and ideas, and included international perspectives. The workshop commenced with international perspectives from the United States, Canada, United Kingdom, the Netherlands, and Denmark. This article summarizes the findings of the workshop and articulates future research needs and ways to address nitrogen/ammonia from intensively managed animal agriculture. The need for developing sustainable solutions for managing the animal waste problem is vital for shaping the future of North Carolina. As part of that process, all aspects of environmental issues (air, water, soil) must be addressed as part of a comprehensive and long-term strategy. There is an urgent need for North Carolina policy makers to create a new, independent organization that will build consensus and mobilize resources to find technologically and economically feasible solutions to this aspect of the animal waste problem.

Keywords: Ammonia; Nitrogen compounds; Emissions; Effects; Transport; Transformation; Swine operations and abatement

1. Background

Nitrogen is perhaps the most important nutrient governing the growth and reproduction of living organisms. Nitrogen compound emissions also have a profound effect on air quality. Two major needs that drive the contemporary perturbations of the nitrogen cycle are the seemingly insatiable human appetite for energy, leading to the emission of nitrogen oxides into the atmosphere, and the need for food to sustain growing numbers of people all over the world, leading to the agricultural emission of ammonia. Once released into the atmosphere by either man-made (anthropogenic) or natural sources,

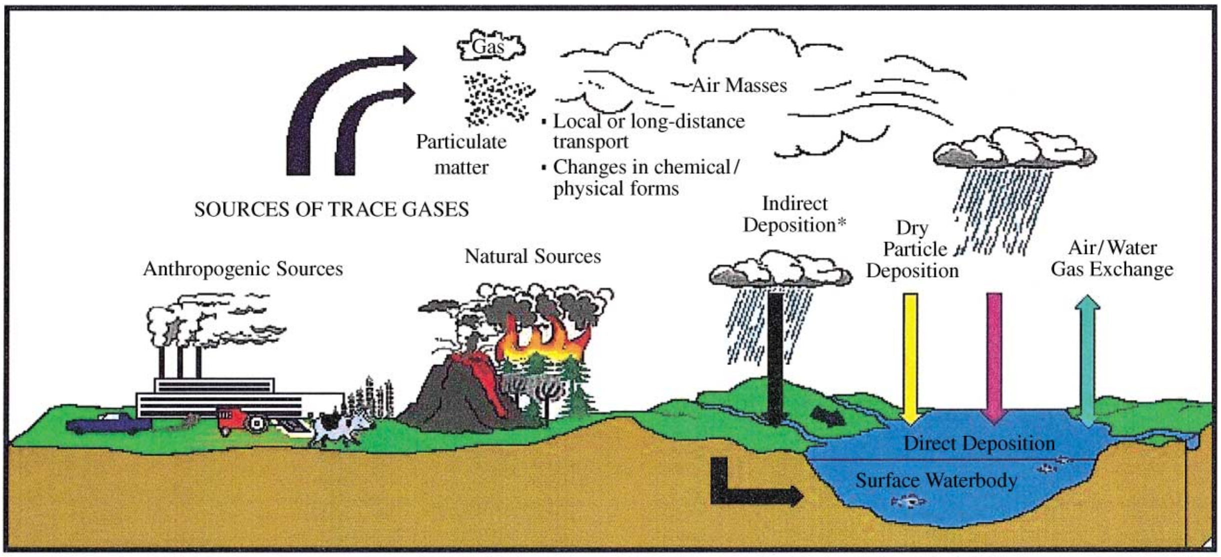

Fig. 1. Atmospheric emissions, transport, transformation and deposition of trace gases.

these nitrogen compounds can undergo several different processes such as transformation due to atmospheric reactions (e.g. gas-to-particle conversion), transport associated with wind, and finally wet and dry deposition (Fig. 1). All of these processes can perturb the environment with a host of beneficial and detrimental effects, such as increased crop yields from nitrogen loading or decreased visibility from increased aerosol production. Table 1 represents the current global estimates for sources and sinks of several key nitrogen species (oxidized nitrogen compounds, nitrous oxide, and ammonia). Scientists have focused recently on the oxidized species of nitrogen ($NO_x = NO + NO_2$) and their role as precursors to ozone (O_3) formation, and the reduced species (NH_x = ammonia + ammonium + amines) and their role in nitrogen enrichment and eutrophication of aquatic ecosystems. Nitrous oxide (N_2O), while contributing to ozone destruction in the stratosphere, is relatively inert in the troposphere and therefore has negligible consequences in tropospheric photochemistry, but does contribute to climate change as a greenhouse gas (Warneck, 1988).

2. Emissions

Fossil fuel combustion has increased to meet growing energy demands. The global amount of fossil fuel use per person (Fig. 2) has increased by more than a factor of 6 over the last 75 years. At the same time, scientists have synthesized nitrogen-based fertilizers to enhance crop development and to maximize production on limited land space. Before the mass production of fertilizers, it can be assumed that there was an approximate balance between the relatively unreactive molecular nitrogen (N_2 comprises approximately 80% of air) in the atmosphere, which was naturally converted to forms used by plants and animals, and the amount of nitrogen returned to the atmosphere via natural processes (Delwiche, 1970). Currently, however, the global production of fertilizer is approximately 100 million metric tons of nitrogen yr^{-1}, compared to approximately one million metric tons only 40 years ago (The Fertilizer Institute, 2000). The results of increased fertilizer and power production have reached a point where the scientific community has major concerns about the fate of the nitrogen produced.

Estimates of NH_3 emissions and the contribution from different source categories given in Figs. 3 and 4 show that hog operations are responsible for a larger percentage of the nitrogen budget in North Carolina than they are in the US as a whole. The relatively large NH_3 contribution from hog operations in North Carolina as compared to the US as a whole can be explained by Fig. 5 which shows the growth of the hog industry during the last two decades. Data presented at the workshop (Fig. 6) revealed that NH_3 emissions in a six-county (Bladen, Duplin, Greene, Lenoir, Sampson, Wayne) area of North Carolina that maintains the state's densest and largest population of hogs (Fig. 7) increased significantly during the same time period that the hog operations increased (Walker et al., 2000). Mean NH_3 emissions from hog operations increased 316% between 1982–1989 and 1990–1997; 84% of the growth from all sources (i.e., hogs, fertilizer, cattle, turkeys, broilers, chickens) can be

attributed to the increase in number of hogs (Walker et al., 2000). Fig. 6 also shows that the ammonium ion concentration $[NH_4^+]$ in precipitation collected at a deposition sampling site in Sampson County also increased throughout this period.

3. Atmospheric behavior

Atmospheric ammonia (NH_3) emissions have garnered increased interest in the past few years, due in part to the detrimental effects of excess nitrogen deposition to nutrient sensitive ecosystems (Aneja et al., 1998; Nihlgard, 1985; van Breemen, 1982). Moreover, NH_3 is the most prevalent gaseous base found in the atmosphere, and is, therefore, fundamental in determining the overall acidity of precipitation (Warneck, 1988), cloudwater (Li and Aneja, 1992), and atmospheric aerosols (Lefer et al., 1999). New gaseous ammonia instruments for monitoring and research are currently in advanced stages of development (Erisman et al., 1999). The ecological impact of atmospheric NH_3 deposition may be substantial as reduced nitrogen species are thought to be the most biologically available of nitrogen species in N-limited coastal and estuarine ecosystems (Paerl, 1997). In the atmosphere, NH_3 reacts primarily with acidic species to form ammonium sulfate, ammonium nitrate or ammonium chloride, or it may be deposited to the earth's surface by either dry or wet deposition processes.

The spatial scale of a particular NH_3 source's contribution to atmospheric nitrogen deposition is governed in part by the gas-to-particle conversion rate of NH_3 to NH_4^+. Because of the short lifetime of NH_3 in the atmosphere ($\tau = 1$–5 days or less) (Warneck, 1988), low source height, and relatively high dry deposition velocity (Asman and van Jaarsveld, 1992), a substantial fraction (20–40%) will likely deposit near its source. However, ammonium (NH_4^+) aerosols, with atmospheric lifetimes on the order of $\tau = 1$–15 days (Aneja and Murray, 1998; Aneja et al., 2000) will tend to deposit at larger distances downwind of sources. Ammonia emissions from animal operations contribute substantially to atmospheric nitrogen loading and may contribute the same order of magnitude as emissions of NO in some parts of the world (Steingröver and Boxman, 1996); highlighting the need for new sustainable technologies for intensively managed animal production.

4. Effects

Although nitrogen is a critical nutrient for the survival of micro-organisms, plants, humans and animals, it can cause detrimental effects when concentrations reach excessive levels (Paerl, 1997; Erisman et al., 1998). Fig. 8 (Gundersen, 1992) illustrates this point by showing how an ecosystem responds to increased N loadings. The horizontal line is a crop which receives no atmospheric N deposition, and as indicated by the vertical axis, has a stable index of productivity. However, as N is initially added to the system, the index of productivity steadily increases to the point of diminishing returns, where any additional N loading actually reduces productivity (Schlesinger, 1997). In addition to the productivity concerns of aquatic and terrestrial ecosystems, oxidized and reduced N compounds each play a specialized role in degrading human health and its welfare. Some of the consequences associated with elevated concentrations and depositions of both oxidized and reduced N species are:

1. Respiratory disease caused by exposures to high concentrations of:
   1.1. Tropospheric ozone.

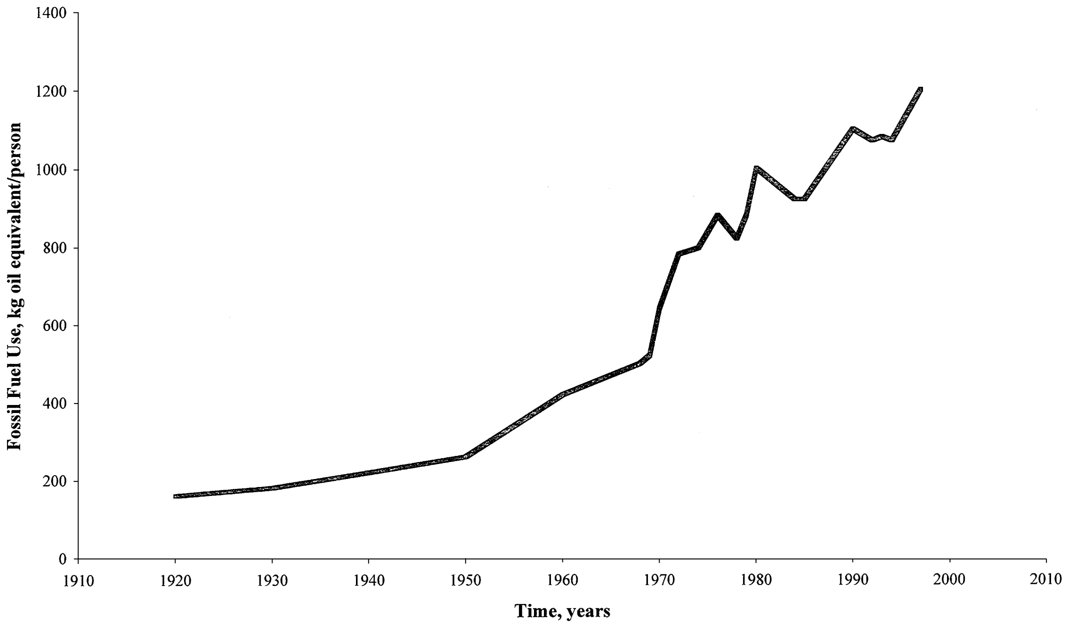

Fig. 2. Trends in global fossil fuel use per person (source: Galloway, 1988).

  - Other photochemical oxidants.
  - Fine particulate aerosol (e.g., PM 2.5).
  - Direct toxicity of NO_2 (on rare occasions).
2. Nitrate contamination of drinking water.
3. Eutrophication, harmful algal blooms and decreased surface water quality.
4. Climatic changes associated with increases in nitrous oxide (greenhouse gas).
5. Nitrogen saturation of forest soils (Erisman et al., 1998).

5. Abatement

Air quality issues associated with intensively managed animal agriculture are now being addressed in Europe and Canada under several initiatives and in consultation and partnership with stakeholders. Emission inventories for several different pollutants including atmospheric nitrogen compounds are maintained by federal governments. For example, the new Air Pollution Protocol for Europe has set reduction targets to be achieved by 2010

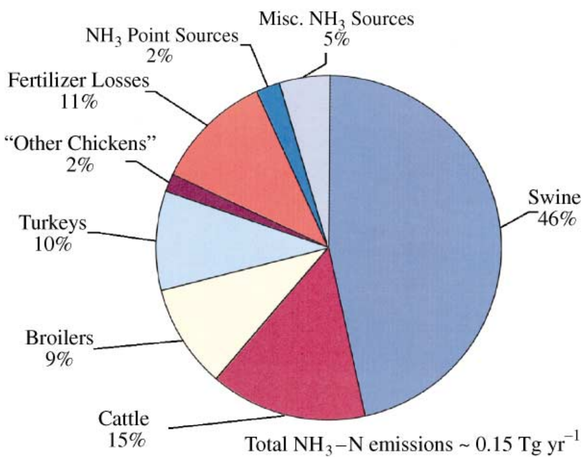

Fig. 3. Percent of ammonia–nitrogen from various sources in North Carolina for 1996 (source: Aneja et al., 1998a).

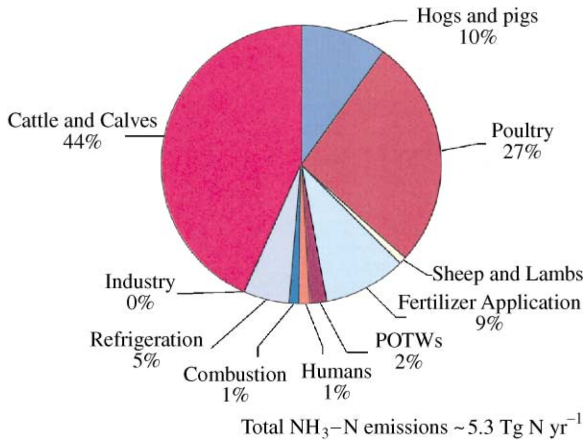

Fig. 4. Relative contribution of ammonia–nitrogen emissions in the US from different source categories (source: Battye et al., 1994).

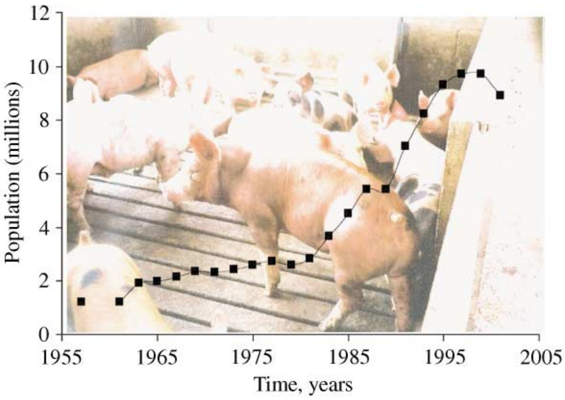

Fig. 5. Hog population in North Carolina (source: North Carolina Agricultural Statistics, 2000).

as compared to 1980 emission levels, for the following: $SO_2 = 63\%$, $NO_x = 41\%$, $VOC = 40\%$, $NH_3 = 17\%$ (http:www.unece.org/press/99env11e.htm). Moreover, in Europe the focus of environmental effects related research is primarily on acidification, eutrophication, biodiversity and groundwater pollution, and the use of critical loads to the ecosystem which accounts for atmospheric deposition pathways.

A "Livestock Environmental Initiative" was launched in Canada during December 1999 in which the livestock industry is working in partnership with the federal government to address environmental concerns through research and development of technology, and for acceleration of technology assessment and transfer. Air quality, including greenhouse gases, is a priority area of concern. Experts from a broad cross-section of government, business and industry, the academic community, environmental groups and non-government organizations have evaluated available information. These options will be reviewed and analyzed to determine the actions needed to reduce emissions.

Improvements in air quality from implementation of the Clean Air Act Amendments (CAAA) of 1990 or other efforts (e.g., Southern Appalachian Mountain Initiative, SAMI) are likely to receive widespread attention only if a target pollutant in question is regulated under the CAAA. At this time, emissions of atmospheric ammonia, ammonium, and organic nitrogen compounds (N_{org}) are not federally regulated, thus minimizing the benefits that might result from the CAAA. In North Carolina, under state law, ammonia is regulated as a toxic air pollutant (15 NCAC 2D.1104(a)(4)).

6. Research needs

The workshop highlighted areas which require further research in North Carolina and elsewhere, such as the further refinement of emission estimates, the role of ammonia and factors that contribute to gas to particle conversion processes (PM_{fine}) in rural/urban and regional areas, computer models to quantify and simulate impacts of deposition, and the establishment of a full scale and continuing monitoring program. Results of the RADM (Regional Acid Deposition Model) and progress that has been made with adapting this model to ammonia deposition were presented at the conference. However, if the main processes and characteristics, specifically

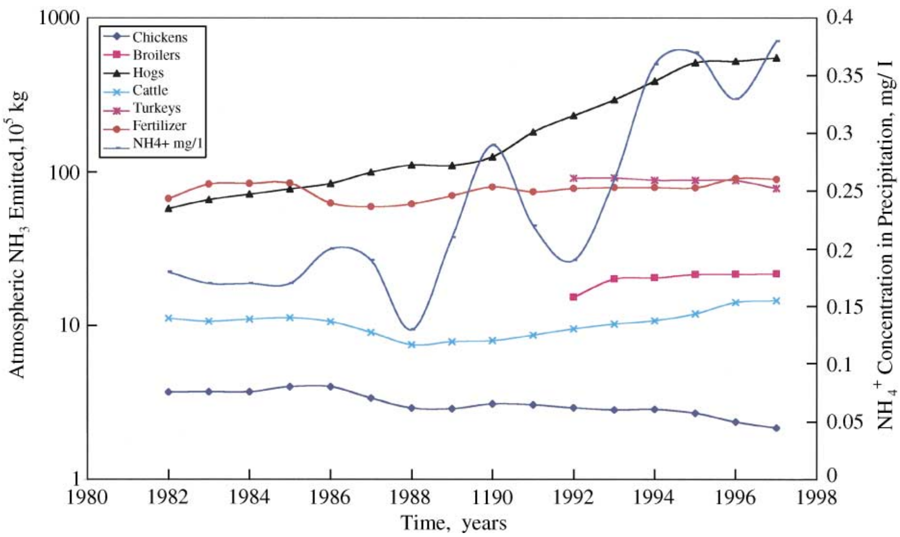

Fig. 6. NH_3 emission estimates by source type in the six North Carolina counties (Bladen, Duplin, Greene, Lenoir, Sampson, Wayne), and annual volume-weighted NH_4^+ concentration in precipitation at Sampson County, North Carolina (source: Walker et al., 2000).

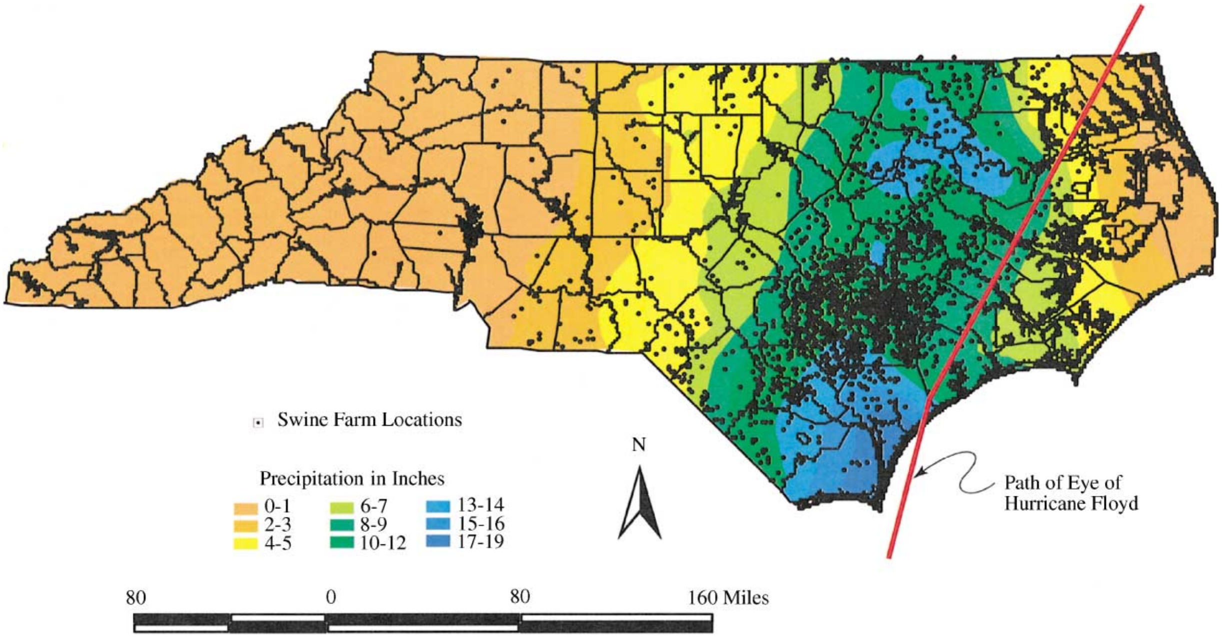

Fig. 7. Map of North Carolina indicating hog sites, rainfall totals associated with Hurricane Floyd (14–16 September 1999), and track of storm.

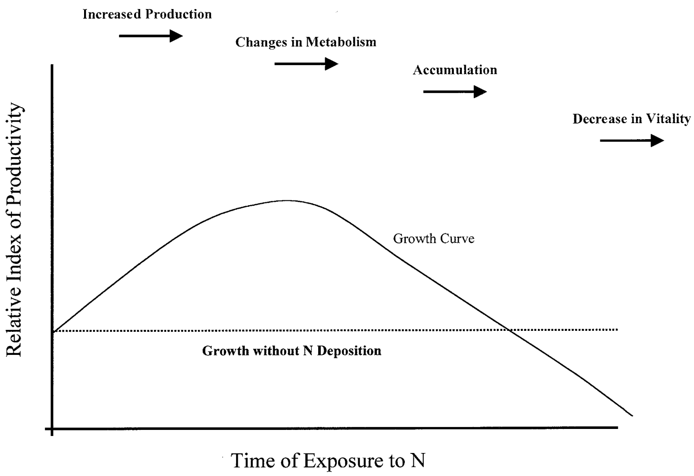

Fig. 8. Hypothetical growth curve for an ecosystem, given different lengths of exposure to nitrogen (source: Gundersen, 1992).

concerning dry deposition, are to be described, then the current grid scaling (20 × 20 km) of this model is still too coarse. Further, a targeted monitoring program in North Carolina needs to be established which includes emissions and both wet and dry deposition at several different land use types. The data collected during this program can then be used to support the modeling effort and assess its performance. A monitoring program will also assist in evaluating any future regulatory policy, which still remains one of the most complicated issues facing North Carolina and the Nation today. Additional research needs are:

1. A detailed understanding of the cycling of atmospheric reduced and oxidized nitrogen compounds, their linkage with emissions of sulphur dioxide (SO_2) and volatile organic compounds (VOCs), and subsequent oxidation products, their spatial and temporal distributions, and their contribution to the chemical composition of aerosols.

Table 2
A comparison of physical and chemical characteristics among the US, North Carolina, and the Netherlands[a]

Parameter	United States	North Carolina	Netherlands
Total land and water area	9,629,000 km^2	136,000 km^2	42,000 km^2
Land area	9,159,000 km^2	126,000 km^2	34,000 km^2
NC coastal plain land area (where majority of hog operations are located)		45,333 km^2	
Inland water area	470,000 km^2	10,000 km^2	6,000 km^2
People	270,312,000 30 km^{-2}	7,651,000 61 km^{-2}	15,731,000 463 km^{-2}
Swine (1996)	56,124,000	9,300,000	14,400,000
Total cattle (1996)	101,656,000	1,100,000	4,412,000
Income from animal agriculture	92.4 billion dollars yr^{-1}	5.7 billion dollars yr^{-1}	4.4 billion dollars yr^{-1}
1995 NO_x emissions	21,600,000,000 NO_x yr^{-1} 6,560,000,000 kgN yr^{-1}	570,000,000 kgNO_x yr^{-1} 173,000,000 kgN yr^{-1}	518,000,000 kgNO_x yr^{-1} 158,000,000 kgN yr^{-1}
1995 NH_3 emissions	2,730,000,000 kgNH_3 yr^{-1} 2,250,000,000 kgN yr^{-1}	155,000,000 kgNH_3 yr^{-1} 127,000,000 kgN yr^{-1}	152,000,000 kgNH_3 yr^{-1} 125,000,000 kgN yr^{-1}

2. Need to know the contribution of atmospheric deposition of ammonia/ammonium to estuarine and coastal N loading.
3. Need to better understand the ecological effects of ammonia/ammonium as a new N source causing eutrophication of N-sensitive waters.

7. Summary and conclusions

Although North Carolina faces many challenges regarding nitrogen issues, the problem is not limited to North Carolina. Many of the issues which face politicians, farmers, citizens, and international researchers are similar. Therefore, much can be gained through collaboration and exchange of ideas. For example, a comparison between various factors which influence the emission and deposition of total fixed nitrogen (Table 2) in the Netherlands and the US reveals striking similarities. Although land size and human and animal populations differ, the estimates for NO_x and NH_3 emissions, income from agriculture, and inland water areas (adjusted for coastal districts in NC) are all very similar (Table 2). Due to the many similarities and the fact that North Carolina's rapid growth in animal husbandry started almost 2 decades later than the Netherlands, North Carolina can significantly benefit from their experiences.

The current technology used in North Carolina to manage the hog waste is known as the Lagoon and Spray System, which consists of an exposed waste lagoon to store the waste (~98% liquid) and mechanisms through which the waste is periodically sprayed onto the crops as a nutrient source. The technology can be subdivided into four distinct processes (Fig. 9), all of which release NH_3 to the atmosphere: Production houses; Waste Storage and Treatment Systems (Aneja et al., 2000) (Fig. 10); Land application i.e., spraying; and Biogenic Emissions

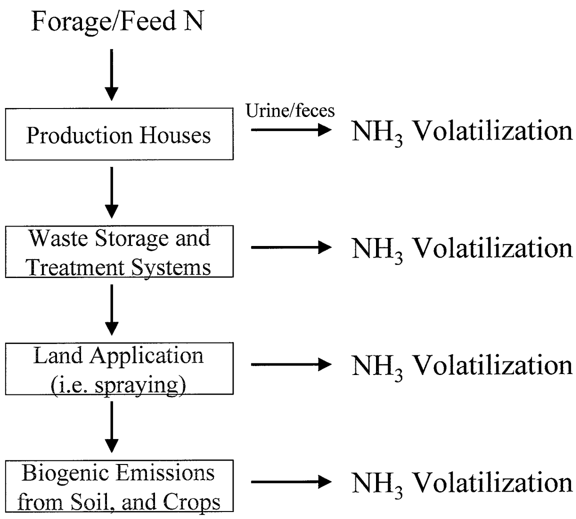

Fig. 9. Major routes for NH_3 emissions from intensively managed animal operations in North Carolina, USA.

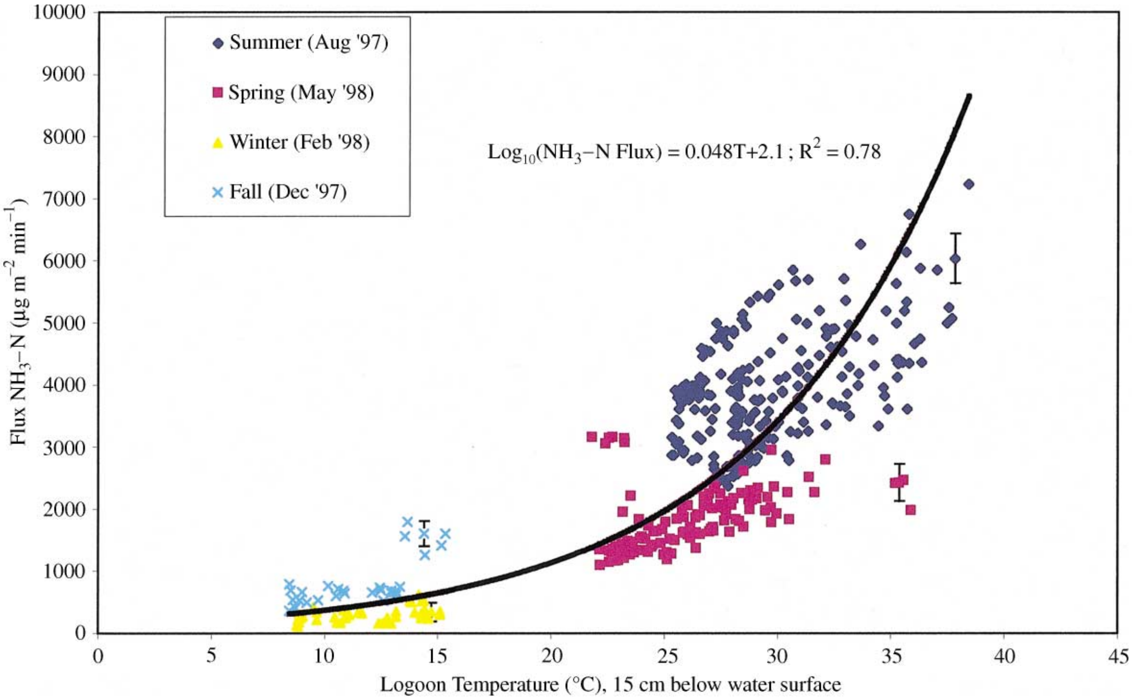

Fig. 10. North Carolina lagoon ammonia–N flux versus lagoon surface water temperature. pH of lagoon: 7–8 pH units, total Kjeldahl nitrogen (TKN) in lagoon: 500–750 mg-N^{-1}. Vertical bars represent one standard deviation (source: Aneja et al., 2000).

from Soil and Crops. Current estimates of NH_3 emissions in North Carolina from hogs alone, utilizing an emission factor (20.3 lb of NH_3 hog^{-1} yr^{-1}) determined by Battye et al. (1994) are: 1994, ~ 195 t of NH_3 d^{-1}; 1996, ~ 258 t of NH_3 d^{-1}; 1999, ~ 264 t of NH_3 d^{-1} (where t = metric tons, and d = day). The lagoon and spray system requires continuous attention due to its susceptibility to flooding, the potential for release of waste to nearby water sources, and also due to odor issues.

The lagoon system recently gained renewed national attention in the aftermath of Hurricane Floyd (15–16 September 1999). The eye of the storm passed over the most intensively managed animal husbandry sites in North Carolina (Fig. 7). The storm resulted in the death of approximately 3 million chickens and turkeys, 880 cattle and 30,000 hogs with many of the carcasses floating in the flood waters; 50 animal operations with waste lagoons were flooded, allowing millions of gallons of animal waste to be spilled into flood waters; and 24 municipal wastewater treatment plants were flooded (WRRI News, 1999). The environmental consequences of this disaster, not yet fully known, include nitrogen release from lagoons and wastewater treatment plants.

Sustainable solutions must be found for managing the animal waste problem in North Carolina. As part of that process, all aspects of environmental issues (air, water, soil) must be addressed as part of a comprehensive and long-term strategy. There is an urgent need for North Carolina policy makers to create a new, independent organization that will build consensus and mobilize resources to find technologically and economically feasible solutions to this aspect of the animal waste problem.

Acknowledgements

The authors wish to thank the North Carolina State University Air Quality Research Group for their effort in organizing this workshop. We would like to express our sincere appreciation to the Division of Air Quality, North Carolina Department of Environment and Natural Resources (Contract No. EA 8001); the North Carolina Water Resources Research Institute (Contract No. EA 7003); North Carolina Department of Health and Human Services, North Carolina Office of the State Health Director; Mid-Atlantic Regional Air Management Association; Air and Waste Management Association, RTP Chapter; the US Environmental Protection Agency and the North Carolina State University (College of Physical and Mathematical Sciences, and North Carolina Agricultural Research Service) for the resources to organize the workshop and the publication of the proceedings. A special thanks to Professor Jerry Whitten, Dean, NCSU; Professor Johnny Wynne, Director, NCARS; Mr. Burton Craige, Honorable Tim Valentine, US Congressman; Mr. Bill Holman, Secretary NCDENR; Mr. Dennis McBride, NC State Health Director and Assistant Secretary of NC Department of Health and Human Services; Ms. Marion Deerhake, Member NC Environmental Management Commission; Mr. Alan Briggs, Executive Director Save-Our-State; Mr. Alan Klimek, Director, NC Division of Air Quality; Mr. Brock Nicholson, NC Division of Air Quality, Chief, Planning Section; Dr. K. Reckhow, Dr. R. Holman, and Ms. J. Gray all of NC Water Resources Research Institute. We greatly appreciate the time and interest of the many researchers, scientists, engineers, policy makers, interest groups and graduate students who shared their knowledge and expertise to make the workshop a success. And finally, the thoughtful comments and suggestions by the reviewer are greatly appreciated.

Natural Resources Defense Council and the Clean Water Network
July 2001

ACKNOWLEDGMENTS

The Natural Resources Defense Council and the Clean Water Network wish to thank The McKnight Foundation, The Pew Charitable Trusts, Wallace Genetic Foundation, Inc., and The Davis Family Trust for Clean Water for their support of our work on animal feedlot issues. NRDC gratefully acknowledges the support of its 500,000 members, whose generosity helped make this report possible.

We wish to thank the reviewers of this report, Nancy Stoner, Melanie Shepherdson Flynn, and Emily Cousins. We also thank a number of individuals for their help with this report, including: Rolf Christen, Kathy Cochran, Rick Dove, Scott Dye, Pat Gallagher, Nicolette Hahn, Marlene Halverson, Suzette Hafield, Susan Heathcote, Karen Hudson, Julie Jansen, Jack Martin, and Neil Julian Savage.

ABOUT NRDC

NRDC is a nonprofit environmental organization with more than 500,000 members. Since 1970, our lawyers, scientists, and other environmental specialists have been working to protect the world's natural resources and improve the quality of the human environment. NRDC has offices in New York City, Washington, D.C., Los Angeles, and San Francisco.

ABOUT THE CLEAN WATER NETWORK

The Clean Water Network is an alliance of over 1,000 organizations that endorse its platform paper, the *National Agenda for Clean Water*. The *Agenda* outlines the need for strong clean water safeguards in order to protect public health and the environment. The Clean Water Network includes a variety of organizations representing environmentalists, family farmers, commercial fishermen, recreational anglers, surfers, boaters, faith communities, environmental justice advocates, tribes, labor unions, and civic associations.

TABLE OF CONTENTS

EXECUTIVE SUMMARY

Animal waste from large factory farms is threatening our health, the water we drink and swim in, and the future of our nation's rivers, lakes, and streams. This report documents the public health and environmental risks associated with the use of the lagoon and sprayfield system, which is commonly used by many types of factory farms to dispose of animal waste. The problems with lagoons and sprayfields described in this report are documented through scientific studies, records of pollution events, and victims' accounts of their experiences.

Lagoons and Sprayfields of the Largest Companies Pollute the Environment

Multi-million dollar corporations control many factory farms. The factory farms owned or controlled by these corporations are plagued with pollution problems. Lagoons at many of these operations have broken, failed, or overflowed, leading to major fish kills and other pollution incidents. Operators have sprayed waste in windy and wet weather, on frozen ground, or on land already saturated with manure. More and more, local communities and environmental groups are looking to the courts to remedy environmental violations.

Lagoons and Sprayfields Threaten Public Health

People living near factory farms are placed at risk. Hundreds of gases are emitted by lagoons and the irrigation pivots associated with sprayfields, including ammonia (a toxic form of nitrogen), hydrogen sulfide, and methane. The accumulation of gases formed in the process of breaking down animal waste is toxic, oxygen consuming, and potentially explosive, and farm workers' exposure to lagoon gases has even caused deaths. People living close to hog operations have reported headaches, runny noses, sore throats, excessive coughing, respiratory problems, nausea, diarrhea, dizziness, burning eyes, depression, and fatigue.

The pathogenic microbes in animal waste can also infect people. Water contaminated by animal manure contributes to human diseases such as acute gastroenteritis, fever, kidney failure, and even death. Nitrates seeping from lagoons and sprayfields have contaminated groundwater used for human drinking water. Nitrate levels above 10 mg/l in drinking water increase the risk of methemoglominemia, or blue baby syndrome, which can cause deaths in infants, and contamination from manure has also been linked to spontaneous abortions. Moreover, the practice of feeding huge quantities of antibiotics to animals in subthereapeutic doses to promote growth has contributed to the rise of bacteria resistant to antibiotics, making it more difficult to treat human diseases. Scientists recently found bacteria with antibiotic resistant genes in groundwater downstream from hog operations.

The Lagoons and Sprayfields Harm Water Quality

Lagoons and sprayfields pose a grave danger to the water we use for drinking and swimming. Lagoons filled with manure have spilled and burst, dumping thousands and often millions of gallons of waste into rivers, lakes, streams, and estuaries. In addition, the impact of runoff from sprayfields can be severe over time since manure is often over-applied or

NRDC
THE EARTH'S BEST DEFENSE

misapplied to cropland and pastures. There are also often cumulative effects from sprayfield runoff within local watersheds because multiple large-scale feedlots cluster around slaughterhouses. Watersheds as far as 300 hundred miles away are also affected by the atmospheric deposition of ammonia that is emitted from lagoons and sprayfields.

Lagoons and sprayfields are often located in close proximity to waterways and floodplains, which increases the likelihood of ecological damage. Lagoon spills and leaks and runoff from sprayfields have killed fish, depleted oxygen in water, contaminated drinking water, and threatened aquatic life. In many cases, lagoons leak because they are not lined, but leakage may even occur with the use of clay liners, with seepage rates as high as millions of gallons per year. How much a lagoon or sprayfield seeps depends, in part, upon where it is sited. In many places, lagoons and sprayfields have been permitted for places where groundwater can be threatened, such as over alluvial aquifers and in locations with shallow groundwater tables. The lagoon system also depletes groundwater supplies by using large quantities of water to flush the manure into the lagoon and spray it onto fields.

Alternative Approaches to the Lagoon and Sprayfield System Exist but Are Rarely Used by Factory Farms

A wide range of alternatives to the lagoon and sprayfield system currently exist, which illustrates that it is not the lack of other options that is driving factory farms to rely almost exclusively on the lagoon and sprayfield system. Instead, factory farms continue to use this polluting system because they have been allowed to use farmland, rural waterways, and air as disposal sites for untreated wastes. Alternative approaches include sustainable agriculture practices that prevent pollution, such as management intensive rotational grazing, hoop houses, and composting. Alternative technologies that treat the wastewater, including anaerobic digestion, wetlands treatment, and sequencing batch reactors also mitigate some of the risks to surface water, groundwater, air, and public health.

Recommendations

Despite the growing body of evidence that the lagoon and sprayfield system pollutes the environment in numerous ways, the Environmental Protection Agency's (EPA) proposed technology rules under the Clean Water Act would allow the riskiest lagoons to continue to operate and also allow new lagoons to be built. Instead, EPA should ban new lagoons and sprayfields from being built, and phase-out existing systems. The agency should encourage new concentrated animal feeding operations to use sustainable animal production systems. In addition, EPA's final regulations should include controls that address all air, surface water, and groundwater pollution that can contaminate our lakes, streams, and coastal waters, including ammonia, bacteria, viruses, heavy metals, salt, antibiotics, and other toxins.

CHAPTER 1

FACTORY FARM POLLUTION IS A GROWING PROBLEM

American livestock production has changed dramatically over the past sixty years. Like other agricultural enterprises, raising animals has been influenced by new technologies and scientific advancements. But the forces that have had the greatest impact on the business are intensive confinement and the conglomeration of small farms into large corporations. These two changes have had grave impacts on the ecosystems and human communities that surround livestock farms.

Intensive livestock operations first appeared in the 1940s with poultry production.[1] In the egg production segment of the industry, the shift went from chicken houses with bedding to bird confinement in cages. In the swine industry, farmers made a shift from pasture-based and open-lot or production systems to totally controlled confinement. The dairy industry replaced stanchions with free-stall barns. All of these moves to greater confinement decreased or eliminated the need for bedding. While this reduction in bedding materials reduced production costs, it created new problems in disposing manure. To address this problem, producers began adding water to manure and handling it like it was a liquid or pumpable slurry.

It is now common for intensive livestock operations to raise thousands–and sometimes even hundreds of thousands–of animals that produce enormous quantities of manure. A single hog produces two to four times the amount of waste as a human produces, while a dairy cow produces 23 times the waste of a human. In total, these animals generate 220 billion gallons of waste each year. (See Table 1-1.) In our country, 130 times more animal waste is produced than human waste.[2]

Currently, most swine and many dairy and egg-laying poultry concentrated animal feeding operations (CAFOs) in the United States collect the waste produced by their animals with scrapers, flushing systems, or gravity flow gutters, and then store the wet livestock manure in vast open-air pits. Producers use a variety of lagoon systems for liquid manure, including anaerobic lagoons, aerobic lagoons, and temporary storage bins.[3] These lagoons have a size as great as six to seven-and-a-half acres and can contain as much as 20 to 45 million gallons of wastewater.[4] In North Carolina, a facility of 2,500 swine may generate 26 million gallons of lagoon liquid, close to one million gallons of lagoon sludge, and 21 million gallons of slurry. (See Table 1-2.) The operation of the lagoon system may differ depending upon the type of animal waste placed in the lagoon. For example, dairy waste may contain fibrous bedding and grit that is separated before the waste and flush water are placed in the lagoon.[5] For swine manure, such separation is not customary.

TABLE 1-1
Animal Waste Summary in the United States

Animal Type	Number of Head	Waste Amount Tons/Year	Waste Volume Gallons/Year	Amount of Pounds/Year	Nitrogen Lost to Atmosphere Pounds/Year
Hogs	57.5 million	110 million	27 billion	1.3 billion	960 million
Cattle	99.3 million	750 million	180 billion	8.2 billion	4.1 billion
Poultry	1.3 billion	50 million	12 billion	1.3 billion	530 million
Sheep	7.6 million	3 million	730 million	64 million	46 million
TOTAL	1.5 billion	910 million	220 billion	11 billion	5.7 billion

National totals are compiled using 1997 Census of Agriculture data.
Source: Environmental Defense, Animal Waste Summary, http://www.hogwatch.org/maps/index_wherethehogsare.html; Pollution Locator, Animal Waste, http://www.scorecard.org/env-releases/aw/us.tcl#summary (visited May 15, 2001).

Liquid manure stored in a lagoon is typically sprayed untreated on cropland or pastures through a large sprinkler system. This land-application practice is known as the sprayfield system. While the nutrients in manure can help build and maintain soil fertility when applied at agronomic rates, CAFOs often overapply animal waste. Excess manure can harm crop growth, contaminate soils, cause surface and groundwater pollution, and waste valuable nutrients.

The trend towards confinement as an animal production method has been coupled with domination of the nation's animal production system by large, corporate entities. About 50 large pork producers are responsible for about 45 percent of the industry's product.[6] Industry officials predict that their market domination will rise to 75 percent within the next few years.[7] The trend in industrialized animal production has meant that more animals are being raised in fewer operations. In the pork industry, for example, the number of hog farms has fallen from 600,000 to less than 100,000 over the past fifteen years, while the number of hogs produced has stayed about the same.[8] In Iowa, the nation's number one hog producing state, from 1998 to 1999, 17 percent of the hog producers exited from the business.[9]

EPA NOW HAS THE OPPORTUNITY TO MOVE BEYOND THE LAGOON AND SPRAYFIELD SYSTEM

For more than twenty years, the Clean Water Act has specified that CAFOs are industrial point sources of pollution that must obtain Clean Water Act permits before discharging into lakes, rivers, and streams. However, EPA has failed to implement and enforce these statutory requirements. For example, according to EPA, approximately 13,000 operations should be permitted under existing EPA regulations, yet only an estimated 2,520 CAFOs (19 percent) are actually covered under either a general or an individual permit.[10]

The Clean Water Act also specifies that dischargers must meet technology standards, known as effluent guidelines, for their discharges. Effluent guidelines specify wastewater treatment technology, monitoring, and discharge requirements for specific industrial sources.

TABLE 1-2

Average Swine Waste Generated Annually by Different Types of North Carolina Facilities with 2,500 Swine[i]

Production Unit[ii]	Animal Unit	Animal Unit Equivalent Live Weight (pounds)	Lagoon Liquid[i] (gallons per animal unit/year)	Lagoon Sludge[iv] (gallons per animal unit/year)	Slurry[v] (gallons per animal unit/year)
Feeder-to finish	Per head capacity	135	2,317,500	82,500	1,877,500
Farrow-to weanling	Per active sow	433	8,007,500	195,000	6,595,000
Farrow-to feeder	Per active sow	522	9,652,500	235,000	7,950,000
Farrow-to finish	Per active sow	1,417	26,202,500	955,000	21,585,000

i. Swine feeding operations with 2,500 swine weighing over 55 pounds each are considered to be CAFOs (if they also meet the other operational requirements of the Clean Water Act). Many CAFOs are significantly larger.
ii. Assumes 400-pound sow or boar on limited feed, 3-week old weanling, 50 pound feeder pig, 220 pound market hog, and 20 pigs/sow/year.
iii. Estimated total lagoon liquid included total liquid waste plus average annual rainfall surplus falling on lagoon.
iv. Net solids removal prior to lagoon input.
v. Six month accumulation of waste, urine excess water usage; does not include fresh water for flushing or lot runoff.
Figures were derived from Table 3-1, *Average Swine Waste Generation Values for Different Production Units*, North Carolina Cooperative Extension Service, College of Agriculture and Life Sciences, North Carolina State University, Certification Training for Operators of Animal Waste Management Systems, AG-538 (April 1996), and were based upon a model by Nicolette Hahn, Water Keeper Alliance.
Note: Citing these figures does not imply endorsement. Instead they are being used for illustrative purposes.

The current effluent guidelines applicable to CAFOs are 25 years old and severely outdated. However, pursuant to a consent decree in settlement of litigation with the Natural Resources Defense Council, EPA has agreed to issue new technology standards by the end of 2002. EPA has authority to consider non-water quality impacts (such as air pollution) as well as water quality concerns in setting technology standards. The NRDC-EPA agreement requires that EPA evaluate a range of non-lagoon systems for CAFOs and study the effects on surface water, groundwater, air quality, and public health of any technology the agency recommends. It also requires the new rules to cover not only manure storage, but also the land application of manure.[11]

These rules provide the best opportunity on the national level in over twenty years to ensure that factory farms protect the environment and public health. In its new effluent guidelines, EPA has the opportunity to require that CAFOs adopt a technology different than the lagoon and sprayfield system. In fact, EPA has a legal obligation to require the best technology economically achievable. The question remains whether EPA will fully account for the environmental and economic harm caused by the present manure storage and application system and recommend an approach that better protects the environment.

The Lagoons and Sprayfields of the Largest Corporations

In 1999, almost 20 percent of the hogs sold in the United States were produced by four corporations: Smithfield Foods, Inc., Contigroup (Continental Grain and Premium Standard Farms), Seaboard Corporation, and Prestage Farms.[1] These companies operate feedlots themselves or under contracts with producers. The contracts state that the corporation owns the animals, but under most state permit programs, the contractor owns the waste. Thus, the contract system allows corporate owners to avoid responsibility for the waste. These corporations have no responsibility to contribute financially to clean-up or pollution control. Many of the largest corporations have taken advantage of the contract system; facilities under their control have had numerous pollution problems, but the companies have often been able to evade responsibility.

SMITHFIELD FOODS, INC.

Smithfield Foods, Inc. is the nation's largest pork producer, with sales of $3.8 billion in 1999, ownership of about 700,000 sows (four times more than the company's biggest competitor), and the capacity to produce 12 million hogs per year.[2] The company processes pork, contracts with smaller producers to raise hogs, and also produces hogs on its own factory farms and those of the company's subsidiaries: Brown's of Carolina, Inc., Carroll's Foods, Inc., Carroll's Foods of Virginia, Inc., Quarter M Farms, and Murphy Family Farms, Inc.[3] There have been numerous pollution problems from slaughterhouses the company operates in North Carolina and Virginia. The company was fined $12.6 million for dumping pollutants from a Virginia slaughterhouse into the Pagan River–a fine that, as of 1997, was the largest ever imposed under the Clean Water Act.[4] A Smithfield slaughterhouse in North Carolina has polluted the Cape Fear River nearly 40 times.[5] However, the company, its subsidiaries, and contractors have also been responsible for many pollution problems attributed to lagoon spills, polluted runoff from sprayfields, and general mishandling of liquid hog waste. Even when actual discharges have not occurred, practices such as overfilling lagoons ("inadequate freeboard") present a substantial risk that a discharge could occur and also indicate problems with operator error and the generation of too much liquid waste. Some of the incidents are listed below.

August 1995: Two million gallons of liquid hog waste from a Brown's Inc. lagoon in New Hanover County spilled into a tributary of the Cape Fear River in North Carolina.[6]

1996: One million gallons of liquid hog waste from a Smithfield hog factory spilled into the Trent River in Jones County, North Carolina.[7] Also, at a Brown's of Carolina facility in Bladen County, North Carolina, inspectors found ponding of waste on fields, indicating that wastewater had been overapplied, and that waste had been applied when the ground was wet or frozen.[8]

1997: Smith Farms, a finishing operation for Brown's of Carolina, flooded over an acre of wetlands bordering the New River with hog waste from its Onslow County, North Carolina operation.[9]

July 1997: North Carolina inspectors found that a lagoon or lagoons had been overfilled at a Brown's of Carolina facility in Bladen County ("inadequate freeboard"). Also in July 1997, state inspectors found that areas around the dikes at the facility might erode if improvements were not made.[10]

September 1998: State inspectors from North Carolina noted that the waste management system of a Brown's of Carolina facility in Jones County was in disrepair.[11]

March 1998: Inspectors from the state of North Carolina found trash floating in the lagoons and inadequate lagoon storage capacity at a Brown's of Carolina facility in Jones County.[12]

March and May 1998: At a facility in Duplin County under contract with Smithfield Foods, North Carolina inspectors found numerous deficiencies including ponding of animal waste in sprayfields that indicated over-application, lagoon seepage, and the pointing of a spray mechanism towards a ditch that led to a waterway.[13]

April 1999: A hole in a lagoon at a Murphy Family Farms factory farm in Duplin County, North Carolina spilled 1.5 million gallons of manure and urine into a swamp adjoining the Persimmon Branch, a tributary of the Northeast Cape Fear River.[14]

Operators of a hog factory farm dumped waste into this stream in Duplin County, North Carolina. This stream leads to the Cape Fear River. This was discovered and reported by a local citizen activist.

Rick Dove

June 1999: At two Brown's of Carolina facilities in Bladen County, North Carolina, inspectors found that the discharge pipes that carried waste from the confinement buildings to the storage pond or lagoons were not functioning properly.[15]

September 1999: A state inspection of a Brown's of Carolina facility in Jones County, North Carolina found that the lagoon storage capacity was inadequate.[16]

October 1999: At a facility under contract with Smithfield Foods in Duplin County, North Carolina, inspectors found that animal waste had been discharged to navigable waters during flooding. In July of that year, the overfilling of lagoons had been identified as a problem by inspectors.[17]

November 1999: A Duplin County, North Carolina factory farm owned and operated by Murphy Family Farms,[18] spilled 5,000 gallons of hog waste into wetlands, and then into a tributary of Persimmon Branch. Whether the problem originated from waste applied to saturated fields or a lagoon leak was unclear. This same facility spilled 1.5 million gallons of manure in April of the same year.[19]

December 1999: A Carroll's Foods lagoon in Sampson County, North Carolina spilled nearly 200,000 gallons of hog waste into Turkey Creek and a nearby swamp. The waste spill was caused by a pump that was left running overnight between a lagoon and a field where waste was applied. By the time the pump was shut down, the four-acre lagoon had dropped by two inches.[20]

1999-2000: At a Brown's of Carolina facility in Bladen County, North Carolina, inspectors found insufficient storage levels at lagoons three times.[21]

February 2000: Inspectors from the state of North Carolina found trash floating in the lagoons, evidence of over-application of waste, ponding, and inadequate lagoon storage capacity at a Brown's of Carolina facility in Jones County.[22]

March and July 2000: Neighbors saw waste coming from pipes at a Brown's of Carolina facility and entering into White's Creek, a tributary of the Cape Fear River. At other times, neighbors had reported the spraying of waste in windy and wet weather.[23]

March 2000: At a facility under contract with Smithfield in Duplin County, the Riverkeepers documented discharges of waste from the waste management system into a waterway.[24] During that same month, North Carolina inspectors noted that waste had been sprayed into woods and near the edge of a forest close to a waterway.[25]

April, May, September 2000: At four separate times, North Carolina inspectors found inadequate lagoon storage capacity at a Brown's of Carolina facility in Bladen County.[26]

May 2000: The Riverkeepers documented that swine waste coming from a facility under contract with Smithfield Foods in Duplin County was flowing into woods next to a waterway.[27] Later that month, North Carolina inspectors found on several occasions that wastewater from sprayfields was flowing into woods and waterways. In August of the same year, inspectors observed excessive ponding in fields and woods near the facility.[28]

August 2000: Smithfield agreed to convert its existing open-air lagoon systems on company-owned farms in North Carolina to "environmentally superior technologies" within five years.[29] Several non-lagoon technologies have already been identified for installation under the terms of the agreement, including constructed wetlands treatment and a sequencing batch reactor.[30] (See Chapter Five.) However, this agreement does not apply to the hundreds of thousands of sows raised at hog farms in South Carolina, Virginia, Utah, Colorado, Texas, Oklahoma, South Dakota, Missouri, Illinois, Mexico, and Brazil.[31]

December 2000 and February 2001: Water Keeper Alliance, supported by environmental, family farm, and animal welfare organizations, launched a legal campaign against the hog industry, sending notice-of-intent-to-sue letters to Smithfield producers in North Carolina and Missouri, filing two lawsuits in North Carolina federal court based on company violations of the federal Clean Water Act and Resource Conservation and Recovery Act, a lawsuit in North Carolina state court based on public nuisance and the public trust doctrine, and a lawsuit in Florida federal court based on violations of the Racketeer Influenced and Corrupt Organizations law (RICO).[32]

SEABOARD CORPORATION

Seaboard Corporation is currently the third largest pork producer in the United States,[33] despite the fact that, as of 1989, the company did not own a single hog.[34] According to *Time Magazine*, the growth of the company has been achieved, in part, through $150 million in economic incentives the company received from federal, state, and local governments from 1990 to 1997, including various types of financial assistance to its poultry and hog processing plants in the U.S.[35] Despite all that support, Seaboard continues to violate environmental laws.

February 1999: A Seaboard factory farm in Texas County, Oklahoma sprayed effluent in the air during a windy day. The facility was later fined $5,000 by the state.[36]

October 1999: Seaboard Farms' Dorman Sow Farm had three manure spills in one month. In one spill, over-application of manure onto already over-saturated fields resulted in one pool of manure that was 250 feet by 100 feet and over six feet deep. In another incident, a hole was punched in the irrigation line creating a pool 150 feet long by six feet wide and a foot deep. The final incident that month occurred when an underground pipeline failed and produced a waste stream that ran almost a mile and ended within 300 feet of the Beaver River Wildlife Sanctuary in Oklahoma.[37]

February 2000: The Sierra Club filed a notice of intent to sue Seaboard for 12 separate violations of the Clean Water Act at the Dorman Sow Farm. Violations cited include pouring waste directly into streams, over-applying waste to the land, and being unable to properly store manure.[38]

November 2000: The Sierra Club filed another notice of intent to sue Seaboard's Dorman Sow Farm under the Superfund law for its failure to report ammonia emissions. The

Superfund law Comprehensive, Environmental Response, Compensation, and Liability Act) provides that any site that releases more than 100 pounds of ammonia per day is required to report its releases.[39]

The facility's record of violations is of a particular concern because of its close proximity to the 23 square-mile Beaver River Wildlife Management Area, home to pheasants, quail, turkeys, rabbits, deer, and other animal life.[40] The decision by the state of Oklahoma to grant an operating license to Seaboard is the subject of a lawsuit by adjacent landowners and the Oklahoma Department of Wildlife Conservation (operator of the Beaver River Wildlife Management Area). The suit charges that a license to operate the facility should never have been issued in the first place, because of the risk to the Beaver River and wildlife.[41]

PRESTAGE FARMS

Prestage Farms is the nation's fourth largest hog corporation.[42] The company's facilities in Mississippi have raised concerns among neighbors. One facility in particular in Oktibbeha County, a 7,040-head operation under contract with Prestage, has been the focus of controversy because of its location adjacent to the Noxubee Wildlife Refuge, home to many endangered species and a local tourist attraction. Neighbors believe that polluted runoff from a manure lagoon or from fields sprayed with liquid hog manure could foul adjacent Browning Creek and ultimately the Noxubee River, which runs through the wildlife refuge. Despite community objections, the state granted the facility a permit and the facility has been in full operation since October 1997.[43] Odor and contaminants from the facility were the subject of a $10 million lawsuit brought by a neighbor–a father who claimed that the pollutants aggravated his teenager's asthma.[44] In 1997, a chancery court judge ruled that because of the particulate air pollution emitted from the facility, the state was obligated to issue an air quality permit to the contract farm. However, the Mississippi Department of Environmental Quality has not enforced the decision.[45] This ruling prompted the state's legislature to exempt hog farms from air quality standards, but allowed local governments to establish local controls.[46] Since the establishment of the original facility two years ago, more facilities have requested permits to establish operations near the refuge.[47] Fifty-two counties established rules for CAFOs, but Prestage Farms sued the six counties in which the company had facilities. Concerned about the expenses of litigation, five of the counties eliminated their ordinances. One county, Monroe County, defended its ordinance and won the legal challenge. Then a state moratorium on the building of new CAFOs was established until January 2000. After the Health Department decided to take a cautionary approach regarding possible health impacts of these facilities, the moratorium was extended. The factory farms in Mississippi controlled by Prestage produce 300,000 hogs per year. If the moratorium is lifted, the corporation plans to establish 33 more facilities.[48]

November 1994: In Lowndes County, Mississippi, several discharges from over-application of manure onto the land from Prestage Farms into James Creek resulted in a $15,000 state fine that was then reduced to $6,375.[49]

January 2000: Over 500 neighbors of Prestage Farms hog factory farms, processing plants, and meat packers in Chicksaw and Clay counties in Mississippi filed a $75 million class action lawsuit claiming that air pollution from the facilities has led to unusually high levels of asthma, migraines, and other illnesses. The families that have brought the lawsuit have the backing of the Sierra Club.[50]

CONTIGROUP COMPANIES/PREMIUM STANDARDS FARMS

Contigroup, formerly Continental Grain, became a top hog producer and processor when it acquired a majority interest in Premium Standard Farms in 1998.[51] As of 1999, Contigroup was the second largest pork producer in the United States.[52] Prior to its acquisition, Premium Standard Farms was itself ranked in the top five pork producers,[53] and the company has facilities in Missouri, North Carolina, and Texas.[54]

1995: Six spills at Premium Standard Farms facilities killed more than 268,000 fish. One spill resulted in the loss of all aquatic life in an 11-mile stretch of Mussel Fork Creek in Missouri.[55]

March 1997-July 1998: Premium Standard Farms facilities in Missouri were responsible for 20 spills of liquified feces and urine totaling over a quarter-million gallons.[56]

July 1999: A valve was left open on spraying equipment at a Premium Standard Farms facility in Missouri resulting in about 2,000 gallons of manure spilling into Raccoon Creek.[57]

Throughout 1999: Twenty-five animal waste spills from Premium Standards Farms facilities in Missouri caused the discharge of over 224,000 gallons of manure, wastewater, and liquids from dead animals.[58]

Ongoing Legal Action Against Premium Standard Farms: In 1997 and 1998, the Citizens Legal Environmental Action Network (CLEAN) filed legal action against Premium Standard Farms and Continental Grain. CLEAN's lawsuit alleged Premium Standard Farms violated the Clean Water Act by discharging animal wastes into waterways, violated the Clean Air Act by failing to obtain permits, and failed to report releases of hazardous substances in violation of the Comprehensive Enviornmental Response, Compensation, and Liability Act.[59] EPA intervened in the suit in 1999, taking the citizens' position against Premium Standard Farms. Also in 1999, the Missouri attorney general filed a lawsuit against Premium Standard Farms for manure spills and other environmental violations; the settlement agreement on the case resulted in a $1 million fine and a commitment by the company to invest $25 million in new technology to reduce pollution.[60] In late April 2000, EPA issued a Notice of Violation under the Clean Air Act against seven Premium Standard Farms facilities in Missouri stating that the facilities "emit, in addition to odors, regulated pollutants such as particulate matter and hydrogen sulfide."[61]

DECOSTER EGG FARMS

With the production of 12 to 14 million eggs a week from 3.5 million chickens and with $40 million in sales, DeCoster Egg Farms of Turner, Maine, is one of the largest egg producers in the United States. The firm also has facilities in Iowa, Ohio, and Minnesota, some of which produce pork.[62]

DeCoster has been the subject of numerous federal fines and legal actions for workplace and civil rights violations from 1988-2000. In 1988, the company was fined $46,250 for 184 workplace violations. Eight years later, a fine of $3.6 million was levied for bad working and housing conditions. This second fine prompted Labor Secretary Robert Reich to say that conditions at DeCoster are "as dangerous and oppressive as any sweatshop we have ever seen." In 1997, the company agreed to pay $2 million in fines for a range of health and safety violations. The company was set back $24,000 for failing to pay workers on time and failing to compensate workers for overtime hours in 1999. In 2000 DeCoster agreed to pay $850,000 in worker overtime claims dating from 1991 through 1997.[63] The company's civil rights violations have included restrictions on visitors to the company-owned trailer park that housed Hispanic migrant workers (1992) and the use of force by supervisors against worker-tenants living on DeCoster's property (1995).[64]

The company, which has used lagoons to store manure, has also had environmental violations.

September 1996: State inspectors found evidence of faulty construction at 19 DeCoster hog farms in north-central Iowa. Lagoons at many of the sites were below the water table, lagoon walls had eroded, and many of the operations were built in sandy soil that is unsuitable for manure lagoons. The Iowa Department of Natural Resoures threatened to shut down a 16,000 hog nursery in north-central Iowa after a state inspection found part of the lagoon sat more than 20 feet below the groundwater level.[65]

July 1997: The Maine Board of Environmental Protection levied a $75,000 fine against DeCoster for installing a wastewater disposal system at a 77-acre Leeds site without first obtaining the required state approvals.

November 1997: The Maine Board of Environmental Protection approved a consent agreement drafted by the Department of Environmental Protection (DEP) and signed by the Attorney General's Office and DeCoster president Austin "Jack" DeCoster. The 13-page consent agreement, which carries a $68,500 fine, acknowledges wrongdoing by the company at its egg-processing plants in Turner, Maine. According to the consent agreement, the company had built a large uncovered manure pit without approval, stored septage material in unapproved tanks in unapproved locations, and installed a mobile home and septic system without approval.[66]

Related Action, June, 2000: In a settlement agreement with the state of Iowa over DeCoster's operation of hog CAFOs in Iowa, DeCoster agreed to pay a $150,000 fine and build additional manure storage facilities to settle two pending environmental cases. The fine is the largest ever assessed against a livestock producer for violating environmental laws. DeCoster had previously been fined $69,000 for three previous violations and accrued enough environmental violations to be designated as a “habitual offender” under Iowa law– the first such designation in Iowa history. It prohibits DeCoster from expanding or building a new hog confinement operation for five years and puts the company’s current operations under increased regulatory scrutiny.[67]

DAIRY OPERATIONS

Presently most dairy operations are not controlled by large corporations through contract arrangements. Instead, many operate within cooperatives, like Land O Lakes. Ten cooperatives produced half of the nation’s milk in 1998.[68] However, when pollution incidents occur, the operator, rather than the cooperative to which the facility is a part, is held responsible. Thus, it is difficult to identify pollution incidents that happen in multiple states attributed to a single cooperative. Moreover, despite the increasing power of the cooperatives, many independent dairies continue to operate in many states. There are numerous examples of pollution problems from dairies attributed to the lagoon system, the application of liquid manure to the land, and liquid manure systems generally. A few examples are noted below.

March 1998: In the first imposition of jail time for dairy water pollution, Pete Hetinga of the 3H Dairy Farm in Oakdale, California was sentenced to 90 days of jail time, 90 days of home confinement, and four years probation for Clean Water Act violations. Hetinga also had to pay a $100,000 fine and make $101,000 of improvements on his farm. The defendant admitted that over a four-year period, he discharged wastewater polluted with cow urine, feces, and wash water into streams that flow into the Tuolumne River and the Sacramento Delta.[69]

Spring 1998: In the state of Washington, two dairy feedlot operators reported catastrophic lagoon failures. Each of the spills dumped the contents of an entire lagoon. One spill dumped 1.3 million gallons of waste, while the other dumped 700,000 gallons. Within one week of each other, both spills polluted the Yakima River. Meager fines of $2,000 and $3,000 respectively, were levied by the state.[70]

March and April 1999: Inspection by Washington state inspectors found spills at a dairy near Little Rock. The fecal coliform bacteria in the water in one of the facility’s drainage swales was 23,000 colonies per 100 ml; another one registered at 130,000 colonies per 100 ml. (The state water quality standard is 100 colonies per 100 ml of water.) Liquid dairy waste was also observed covering a road, pooled in ditches surrounding the property, and seeping on to a neighbor’s property.[71]

March 2000: A Washington state inspection of a dairy operation in Orting identified five streams of manure and wastewater entering Horse Haven Creek from the dairy. Manure was running off the confinement areas and over the top of a manure storage lagoon. Also, a pipe from field drainage tiles surrounding the manure storage lagoon was discharging wastewater directly into the creek.[72]

Karen Hudson

In February 2001, Inwood Dairy, LLC, near Elmwood, Illinois, pumped and dumped waste via long hoses across fields into a ditch from a lagoon.

February 2001: Inwood Dairy, near Elmwood, Illinois, pumped two million gallons of cattle waste into a nearby ravine.[73] Earthen dams along the ravine failed to retain the waste, which killed fish in a nearby pond and drained into Kickapoo Creek. At the time, the dairy was under a court-ordered injunction to keep its 8.3-acre, 40-million-gallon lagoon from overflowing. The Illinois attorney general sought the injunction after state inspectors found dairy employees sandbagging the berm of the lagoon and applying wastewater onto saturated fields to stop the lagoon from overflowing.[74]

March 2001: NRDC filed a lawsuit in Florida state court on behalf of three environmental groups and a Florida activist against the Florida Department of Environmental Protection (DEP). The civil action alleges that DEP has failed to require large-scale dairies to obtain permits mandated by the Clean Water Act and Florida law.[75] The groups are concerned that attempts at voluntary compliance by the unpermitted dairies are not preventing water pollution. Under Florida law, citizens have the power to sue the state to compel the agency to enforce its laws and regulations designed to protect surface and groundwater.[76] Florida's failure to regulate large-scale dairies is one example of a regulatory shortfall prevalent in many states across the country.

The litany of violations by these large hog, egg, and dairy producers provides an indication of the environmental harm caused by industrial livestock productions through the use of the lagoon and sprayfield system. Every year, millions of gallons of waste spills from lagoons into rivers and wetlands, is sprayed into waterways, and kill countless fish. Yet, despite the ample financial resources of the largest corporations, lagoons continue to be constructed poorly and waste management systems are not adequately maintained.

Health Effects of Lagoons and Sprayfields

Lagoons are a common feature of the growing number of factory-sized animal operations located in more than 30 states across the United States. Hundreds of gases from these lagoons can pollute the air around the operation. Researchers indicate that feedlot odor may contain 170 separate chemical substances.[1] A report released by the Minnesota Pollution Control Agency (MPCA)[2] indicates that lagoon emissions contain toxic constituents and greenhouse gases, including hydrogen sulfide, ammonia, and methane.[3] Large scale feedlots also emit particulate matter from confinement buildings. In late April 2000, EPA issued a Notice of Violation under the Clean Air Act against seven Premium Standard Farm factory farms in Missouri stating that the facilities "emit, in addition to odors, regulated pollutants such as particulate matter and hydrogen sulfide."[4] Pathogens, including bacteria, viruses, and parasites from ruptured, overflowing, and leaching lagoons, are a major concern when they flow into streams, rivers, and bays, and poison drinking water supplies.

Another threat associated with lagoons comes from sprayfields. Once manure is stored in open-air lagoons, it is periodically pumped out to be sprayed on fields surrounding the factory farm, ostensibly to be used as fertilizer. The spray emits the same gases as lagoons. Spraying the wastes increases evaporation and volatilization of pollutants into the air.

Manure applied to crops is helpful as a fertilizer; however, factory farms often produce too much manure for the amount of land available to use it. Manure is often over-applied and misapplied to land, which causes it to run off the fields, polluting our rivers and streams with pathogens and leaching into groundwater and poisoning our drinking water supplies. This poses a problem even if the manure is applied in dry form; however, the likelihood of runoff increases when the manure is in liquid form as it is with the sprayfield system.

AIR EMISSIONS

Studies consistently show that lagoons emit toxic airborne chemicals that can result in human health problems through inflammatory, immunologic, irritant, neurochemical, and psychophysiologic mechanisms.[5] The emissions are the result of the decomposition of liquid manure by anaerobic bacteria during storage and treatment. This process releases 400 volatile organic compounds,[6] including hydrogen sulfide, ammonia, dusts, endotoxins,[7] and methane.

Ammonia. Up to 80 percent of a lagoon's nitrogen may change from a liquid into a gas in the process known as ammonia volatilization.[8] This process also causes a sprayfield's nitrogen to be lost to the atmosphere.[9] In contrast, dry manure systems lose 15 to 40 percent of their nitrogen to the atmosphere.[10] Once the ammonia is volatilized, it may be redeposited onto land and water as far away as 300 miles.[11]

Although ammonia can cause eye irritation or even death at high levels, ammonia emissions associated with the lagoon system may not be at levels as toxic as other gases emitted. Nonetheless, European studies have found that reducing ammonia levels reduces the levels of odors across-the-board.[12] Ammonia may adsorb dust particles that may be then carried into the lungs.[13]

Hydrogen Sulfide. Among the many feedlot emissions, hydrogen sulfide is one of the most threatening.[14] Hydrogen sulfide is a gas that can cause eye, nose, and throat irritation, diarrhea, hoarseness, sore throat, cough, chest tightness, nasal congestion, heart palpitations, shortness of breath, stress, mood alterations, sudden fatigue, headaches, nausea, sudden loss of consciousness, comas, seizures, and even death.[15] Even when exposure is at a low level, health impacts can be irreversible.[16] A recent study by the Minnesota Pollution Control Agency (MPCA) revealed that manure storage methods appear to affect the amount of hydrogen sulfide emitted into the air. Earthen lagoons had the greatest hydrogen sulfide emissions, with averages greater than 30 parts per billion, while stockpiling manure had a rating of 20 parts per billion.[17] Another study by the same agency evaluated hydrogen sulfide emissions from 42 animal feedlots that used lagoons and cement pits in a nine-township area targeted for hog-farm expansions. The study found that concentrations of hydrogen sulfide, estimated by using a standard EPA approach to model emissions, exceeded the state standard significantly, even as far away as 4.9 miles.[18]

Air quality monitoring by the Minnesota Department of Health affirmed that toxic gas emanating from the manure lagoon of ValAdCo in Renville County, one of the state's largest operations for finishing hogs for market, posed a potential threat to human health. After two years of testing the swine facility, the state found hydrogen sulfide levels far exceeding the state standard (50 parts per billion), 53 times in 1998, and 271 times in 1999 and 2000. The violations in 2000 occurred despite a 1999 settlement between the company and state pollution officials designed to reduce odor and prevent health problems. The latest violations have prompted a new agreement between the company and state officials, which includes a penalty of $125,000, new technology to cover fourteen lagoons, additional air quality monitoring, and more expeditious resolutions of odor problems. The facility is already required to install covers over some of its lagoons under the 1999 settlement agreement.[19] For most of the violations that have occurred over the last two years, the hydrogen sulfide reading was 90 parts per billion. In 2000, Kathy Norlien of the Health Department's Health Risk Assessment stated that "without delay, actions should be taken to reduce the emissions for the protection and well-being of human health."[20] The monitoring was done under a 1997 law by the Minnesota legislature that required the MPCA to monitor hydrogen sulfide emissions from feedlots.

MINNESOTA HOG FARM SICKENS CHILDREN

When the poison control center official spoke to Julie Jansen, his words were shocking: "Ma'am, the only symptoms of hydrogen sulfide poisoning you're not experiencing are seizures, convulsions, and death. Leave the area immediately." Panic-stricken, Jansen grabbed her six children and her friends' two children and drove away from her home.

Jansen first thought the 11-year-old, home-based day care center she owned in Olivia, Minnesota had been hit by a flu bug. In the spring of 1995, 17 children ranging in age from newborn to 13 shared a long list of symptoms–diarrhea, nausea, headaches, vomiting, teary eyes, and stuffy noses. She soon noticed that it only happened when the wind blew from the south. Two factory-scale hog farms had recently located not more than a mile and a half away. It turned out the hog operations were poisoning the air with toxic wastes.

As a result, Jansen fought with state politicians and officials, helped pass a law to ensure that the state's air quality standards for hydrogen sulfide were applied to factory farms, and forced the Minnesota Pollution Control Agency to monitor the air quality of neighboring hog factories. In 1998, a massive hog operation in Renville was cited for 46 violations of air quality standards and was ordered to improve the way it stored hog manure.[21] In 1999, an agreement with state pollution authorities for violations required the company to install covers over many of its lagoons, and demanded the payment of a $32,000 fine. However, the violations have continued, resulting in a new agreement with state officials in June 2001.[22]

Carbon Dioxide. Organic matter in livestock manure is converted to carbon dioxide and methane during the anaerobic decomposition process that occurs in lagoons. The most abundant gas produced during this process is carbon dioxide,[24] although oceans, plants and soils are constantly absorbing it from the atmosphere.[24] Carbon dioxide is not highly toxic itself, but contributes to oxygen deficiency, or asphyxiation.[25] Health problems associated with elevated levels of carbon dioxide include respiratory problems, eye irritation, and headaches.[26] Carbon dioxide is also a greenhouse gas.[27]

Methane. Methane generated during anaerobic decomposition is released from lagoons into the air. Methane is toxic at high levels, levels that typically are not found surrounding open-air lagoons, but which may be found at the top of unventilated areas such as closed manure pits. Moreover, persons exposed to toxic amounts may be unaware of the danger because methane is colorless, odorless, and tasteless.[28] In August 2000, three farm workers in Canada died after they climbed into a liquid manure tank used to spread manure on a farm field; police believe that the cause of the deaths was inhalation of the methane gas.[29] In high temperatures, the methane in the air can be highly combustible and thus extremely dangerous.[30] The level of methane concentration along a waste lagoon's berm is greater than that at a surface coal mine.[31] Methane is also a potent greenhouse gas implicated in global climate change. EPA estimated that nearly 13 percent of the total U.S. methane emissions was from livestock manure in 1998.[32] Methane emissions from manure management activities increased 53 percent from 1990 to 1998 and EPA attributes the increase in methane emissions to the growing number of large hog and dairy operations and their use of liquid manure systems.[33] EPA claims that liquid manure systems produce conditions that result in large quantities of methane emissions.[34]

STUDIES FIND PHYSICAL AND MENTAL HEALTH OF NEIGHBORS AFFECTED BY LARGE-SCALE LIVESTOCK OPERATIONS

Steven Wing and Susanne Wolf of the University of North Carolina at Chapel Hill's School of Public Health conducted a detailed survey of residents in three eastern North Carolina communities. One community was located close to a 6,000-head hog factory farm with a lagoon, another community lived close to two large dairy operations with two lagoons, and the third community served as the control group because there were no intensive livestock operations nearby. More than half of the respondents living within two miles of the intensive swine operation with an open lagoon reported not being able to open windows or go outside even in nice weather because of the noxious smell. Also, the people living close to the hog operation reported headaches, runny noses, sore throats, excessive coughing, diarrhea, and burning eyes significantly more often than the other groups in the study.[35]

Another study, led by Kendall Thu, former associate director of the University of Iowa's Center for Agricultural Safety and Health, evaluated the health of 18 neighbors living within a two-mile radius of a 4,000-head hog confinement facility. Their physical and mental health was compared to a random sample of comparable rural residents who did not live near livestock facilities. Neighbors reported respiratory problems similar to those of workers on factory farms. Of greatest frequency among the neighbors surrounding the hog facility were symptoms that indicated bronchitis and hyperactive airways, including coughing, shortness of breath, wheezing, and chest tightness. Other common symptoms among this group of residents were nausea, weakness, dizziness, and fainting. Symptoms that were less statistically significant but still mentioned among the neighbors were headaches, burning eyes, runny noses, and scratchy throats.[36]

Finally, a study by Dr. Susan Schiffman from the Duke University Department of Psychiatry study found significantly higher levels of tension, depression, anger, and fatigue among North Carolina residents who lived near large swine factory farms as compared to rural residents located away from these facilities.[37] This study used a standardized scale to quantify objectively the moods of people exposed to odors near large-scale hog operations. According to the study, investigating mood in persons exposed to odors is an important health issue because a negative mood can affect immunity and can influence susceptibility to disease.[38]

HOW PATHOGENS FROM MANURE CAUSE HUMAN DISEASES

As the number of CAFOs increase around the country, scientists and policymakers are becoming more concerned about the presence of pathogens–microorganisms which are a potential source of infection for animals and humans–in livestock waste and wastewater. One of the reasons that pathogens pose a significant concern is that within the next decade, one in five persons will fit into a category considered vulnerable to the impacts of pathogens and chemical pollutants–infants, the elderly, or persons with compromised immune systems.[39] Home drinking water wells near animal waste application sites may become contaminated by pathogens or other pollutants.[40]

Until recently, the microbial quality of feedlot wastewater was not a regulatory issue or research focus. Vincent R. Hill and Mark D. Sobsey of the University of North Carolina at Chapel Hill, one of the few health research teams studying CAFOs, found that a number of the pathogenic microbes in swine and poultry wastes can infect people. These researchers also found that the "bacterial indicator levels in swine lagoon effluents are much higher than allowed for municipal wastewater effluents discharged to land or water." Thus, the land application of swine-lagoon effluent could pose a risk to communities that rely on groundwater for drinking water and could also degrade the microbial quality of nearby surface waters.[41] According to EPA, "bacteria and viruses such as *E. Coli*, salmonella, and giardia found in dairy waste can contaminate drinking water, cause acute gastroenteritis and fever, kidney failure, and even death."[42] Scientist Jeffrey C. Burnham also concludes that water contaminated by animal manure significantly contributes to the occurrence of human disease, especially from water-borne infections.[43] Burnham contends that infectious diseases from manure can result from direct contamination of water, a change in the levels of nutrients found in the environment, or the transfer of drug-resistant pathogens infecting the human population (resistance to antibiotics). Burnham reports that the following contaminants cause dangerous human health problems.

Water contaminated by animal manure significantly contributes to the occurrence of human disease, especially from water-borne infections.

1. *E. Coli*, which is found in the intestines and feces of both animal and humans, is extremely virulent.[44] A recent case, in May 2000, occurred in Walkerton, Ontario, where 1,300 cases of gastroenteritis occurred and six people died. The Ontario Ministry of Health and Long-Term Care determined that the likely source was cattle manure runoff from a farm adjacent to a drinking water supply well.[45]
2. *Cryptosporidium* poses a real problem to manure and wastewater processing because it is resistant to most treatment protocols. In healthy individuals, *cryptosporidiosis* lasts for a few days, causing diarrhea, vomiting, stomach cramps, and fever.
3. *Pfiesteria piscicida* results from an increase in nutrients in water sources. The toxic dinoflagellate causes lesions in fish and neurological damage in infected humans.

Cryptosporidium can cause death in persons with compromised and weak immune systems. It is estimated that five to ten percent of all AIDS patients may have *cryptosporidial* infections each year. In the United States, there have been six outbreaks of *cryptosporidiosis* from drinking water. One of these occurred in Milwaukee in 1993, left 400,000 persons ill,[46] and resulted in $37 million in lost wages and productivity.[47] In

LIFE NEXT DOOR TO A HOG FARM

Neil Julian Savage, Bladen County, North Carolina

"I am a farmer and I have lived with my wife Charlotte on our farm here in Bladen County since 1952. Originally,… this land belonged to my father. Things began to change for my family and me when a large corporate hog farm opened up operations on the property adjoining mine. This took place about 1991…The hog farm, which is owned by Brown's of Carolina (Brown's 91-Smithfield), has a lagoon, ten barns, and multiple sprayfields which are directly connected to my property in many places. Often times, even when they are not spraying hog waste, the smell from the barns and lagoon gets so bad I can smell it in my house with all the doors and windows shut. During these times, it is impossible to stay outside for even short periods. When Brown's is spraying hog waste on the fields, especially when it is near my property, living here is almost impossible.

"The overall situation has been so bad that I have not been able to farm my land for some time and I am forced to live on what little savings I have put aside over the years. My wife and I have been made sick by the rancid odors that are forced upon us. If Brown's is spraying near my house I cannot stand to be outside for more than a few minutes. It makes me so sick that I have fallen to the ground and had to crawl back to the house on several occasions. The same thing has happened to my wife. Sometimes it is so bad that my wife and I feel like giving up. We are getting old and this situation is very difficult to handle….

"Often times, when Brown's is spraying hog waste, they spray within just a few feet of my front yard. Some of the sprayers are so close that the hog waste is sprayed on my property. This happens when the wind blows it over in my direction. Sometimes on windy days, when the hog waste being sprayed, a mist of hog waste gets all over my house, vehicles, equipment, and land. During those times, my family and I are forced to breathe that hog waste into our lungs."[48]

Milwaukee, the likely sources of the infection were cattle manure upstream of the city, slaughterhouses, or human sewage.[49] A Canadian study of the presence of *Cryptosporidium* at ten swine farms found the parasite in liquid swine manure storage structures, surface drain water, and subsurface tile drainage water. Thirty-seven percent of the samples taken of swine liquid manure structures contained the parasite, demonstrating that "conditions in a typical swine liquid manure storage are not such that there is a complete die-off of *Cryptosporidium* oocysts."[50] Forty-four percent of the 32 water samples tested positive for *Cryptosporidium.*[51]

Michael Mallin and JoAnn Burkholder studied the effects of lagoon spills on the surface waters of North Carolina and found that there are high counts of fecal coliform–indicating the presence of bacteria–even 61 days after a spill. Natural or man-made disturbance of contaminated water re-suspend potentially dangerous amounts of bacteria and other microbes back into the water column for weeks after a spill.[52]

Waste can enter surface and groundwater supplies even in dry weather through spills or leaks from lagoons and from over-spraying manure onto croplands. The U.S. Fish and

Wildlife Service reported that elevated levels of fecal coliforms and fecal streptocolli were found on fields on which animal manure was applied.[53] The problem is exacerbated when there is extensive rain and hurricanes resulting in flooding–a problem common to North Carolina and states along the Mississippi River. For example, when Hurricane Floyd hit North Carolina in 1999, at least five manure lagoons burst and approximately 47 lagoons were completely inundated–allowing manure to flow out with the flood waters.[54]

Rick Dove

Brown's 5 & 6, a wholly-owned Smithfield hog factory, lost the contents of one of its cesspools to floodwaters caused by Hurricane Floyd. This factory is located along the Trent River above New Bern, North Carolina.

A study completed by the Centers for Disease Control of nine large Iowa confinement sites found chemical pollutants and pathogens, metals, bacteria, nitrates, and parasites in lagoons and other sites including agricultural drainage wells, tile line inlets, tile line outlets, lagoon monitoring wells, underground water, and a river.[55] Samples from the earthen lagoons contained the highest levels of chemical pollutants and pathogens. Their findings suggest that both chemical pollutants and microbial pathogens may move through soil from the site of the lagoon and flow over the land away from where the manure was applied.[56] The study called for additional research to accurately determine the potential level of risk to human health, possible pathways of exposure, and critical control points to avoid any potential exposure.

NITRATES IN WATER SUPPLIES CAN HARM HUMAN HEALTH

Nitrates above 10 mg/l in drinking water can cause human health risks, especially to children younger than five years old, the elderly, and people with suppressed immune systems. For example, infants who drink nitrate-contaminated water may be at risk of methemoglobin-emia, or baby-blue syndrome, which can cause developmental deficiencies or even death. In 1996, the Centers for Disease Control linked the high nitrate levels in Indiana well water near feedlots to spontaneous abortions in humans.[57] Increased levels of nitrates may be the result of lagoon seepage, lagoon spills or leaks, or the over- or misapplication of manure onto the land. Manure contains nitrogen which changes into nitrates in the soil. After that step, the nitrates may move through the soil and accumulate in water supplies.[58]

Infants who drink nitrate-contaminated water may be at risk of methemoglobin-emia, or baby-blue syndrome, which can cause developmental deficiencies or even death.

A survey of domestic drinking-water wells in nine Midwestern states by the Centers for Disease Control found that 32 percent of the 5,500 samples taken were above the 3 mg/l level for nitrates (assumed to be the background level); 13 percent were above the drinking water maximum contaminant standard of 10 mg/l. The study compared the contamination rates of samples from wells that, in the past five years, had manure applied within 100 feet of the wellhead to the rates of samples where no applications had occurred. This analysis found that the use of manure doubled the likelihood of an elevated nitrate level.[59]

EPA ISSUES EMERGENCY ORDER TO HOG FARMS CONTAMINATING DRINKING WATER

On June 7, 2001, EPA Region 6 exercised rarely used emergency powers under the federal Safe Drinking Water Act to compel five hog operations in Kingfisher and Major Counties in Oklahoma to provide area residents with safe drinking water.

In March and May 2001, EPA sampled drinking-water supply wells and found nitrate concentrations as high as 15.7 mg/l, where the acceptable level is 10 mg/l. Nitrates from the hog operations contaminated the surficial aquifer, which serves as an underground source of drinking water for four nearby households. EPA warned one area resident, a pregnant woman, to drink only bottled water, when an investigation team visited her home on May 30, 2001.

The hog facilities continue to contaminate the surficial aquifer by spraying waste and/or leaking waste lagoons. EPA's order clearly states, "[n]itrate contamination in the soil and ground water at the facility and in the vicinity will continue to threaten human health and the environment until the source of the contamination is removed and the site is remediated."

EPA issued the Emergency Order to Seaboard Farms, Inc., Shawnee Funding Limited Partnership, and PIC International Group, Inc. The order requires the companies to deliver an emergency supply of water for human consumption to area residents and hog farm employees. In addition, the companies must sample and test wells to determine the presence of nitrate, ammonia, bacteria, and other contaminants.[60]

ANTIBIOTICS IN LAGOONS MAY CONTRIBUTE TO ANTIBIOTIC RESISTANCE

Antibiotic resistance poses a major public health concern. Many antibiotics can no longer effectively fight infectious diseases because bacteria resistant to them. Exposure of the elderly, children, and immune-compromised individuals to antibiotic-resistant bacteria can be deadly. Even for healthy adult-human populations, antibiotic resistance makes it take longer to treat an infection and increases the cost of treatment.

Low doses of antibiotics are routinely added to livestock feed and water to promote growth and prevent disease in crowded conditions. The Union of Concerned Scientists estimated that livestock producers in the United States use 24.6 million pounds of antimicrobials each year for nontherapeutic purposes, compared to just 3 million pounds used by humans to treat diseases.[61] Recognizing the increasingly serious public health threat caused by bacterial resistance, the American Medical Association (AMA) passed a resolution in June 2001 opposing nontherapeutic uses of antibiotics in agriculture. The resolution states, the "AMA is opposed to the use of antimicrobials at nontherapeutic levels in agriculture or as pesticides or growth promoters and urges that non-therapeutic use in animals of antimicrobials (that are also used in humans) should be terminated or phased out."[62]

“THE SMELL ALMOST KNOCKS YOU OVER”

Rolf Christen, family farmer who raises cattle, chickens, and various crops in Green City, Missouri

“I moved from Switzerland in 1983 to my part of Missouri because of the wide-open spaces and clean environment. When Premium Standard Farms purchased 4,000 acres next to my farm in 1993, I knew nothing about the company. But when I heard about the type of hog facility that they were intending to build there, I immediately opposed them. The facility next to my property has a 80,000 hog head capacity, which is replaced 2.8 times a year. This facility and others nearby generate so much waste that they have turned our land into waste handling facilities, which is an immoral and unethical way to use the land.

“I can’t describe how terrible the odor from the lagoons, sprayfields, and barns often is. We can’t keep our windows open, and sometimes you can even smell the odor through the shut windows. You open the door and the smell almost knocks you over. One of the worst parts of it is that the odor hits at unpredictable times so it is a constant threat. Breathing in such a terrible stench makes you feel desperate. One time I was planting soybeans on a field and I got so sick to my stomach that I had to stop planting. My wife has allergies which are aggravated by the odor. She is in the health field, and she believes that many of her patients are also suffering from worse allergies from the hog odor. A year or so ago, I went on vacation to a beautiful national park; when I entered my house upon my return and smelled the terrible odor, I broke down and cried.”[63]

According to EPA’s National Research Exposure Laboratory, “in some cases as much as 80 percent of antibiotics administered orally pass through the animal unchanged into bacteria-rich waste lagoons and is then spread on croplands as fertilizer leaving antibiotics available for entry into groundwater and runoff into surface waters carrying both the drugs and resistant bacteria or genetic material to other bacteria in soils and waterways.”[64]

The Centers for Disease Control study of nine large Iowa confinement sites found antibiotics in the lagoons and other sites including agricultural drainage ditches, agricultural drainage wells, tile line inlets, tile line outlets, lagoon monitoring wells, underground water, and a river.[65] Examples of the antibiotics identified included tetracyclines, beta lactams, and macrolides. Researchers from the University of Illinois have found bacteria resistant to tetracycline in soil and groundwater near two hog facilities that use antibiotics as growth promoters.[66] The research team concluded that, “the presence of the tetracycline resistance genes is due to seepage and movement of groundwater underlying the lagoon,” and cautioned, “the occurrence of antibiotic resistance genes in drinking water provides a possible way for antibiotic resistance to enter the animal and food chain.”[67]

According to Environmental Defense, effluents from German sewage treatment works and groundwater/surface waters were found to contain antibiotics in the microgram per liter range.[68] Given that CAFO effluents undergo even less treatment than human waste, these effluents also are likely to contain antibiotics. Even if the antibiotics have short half-lives,

MANURE LAGOONS KILL

In December 1999, a man drowned in a six-acre, 25 foot-deep, Murphy farm manure lagoon in Ellis County, Oklahoma. The man was transferring pig effluent from a malfunctioning lift station near the hog facility when he and his truck went over the bank of the lagoon and fell in. It took 18 days for the body to be recovered. A jury in a federal civil trial found Murphy Farms to be negligent and awarded the man's widow close to $2 million.[69]

In another incident, a farm worker entered a lagoon to make a repair. When he attempted to climb out, he was overcome and fell to the bottom. His 15-year-old nephew went into the lagoon to try to rescue him and collapsed. The boy's father, his cousin, and his grandfather, the owner of the operation, entered the lagoon one by one and, tragically, all five family members died. In August 1992, two separate instances took the lives of four men. Two men were overcome, fell into the lagoon and died of hydrogen sulfide poisoning. Another two men died from asphyxiation. In both cases, one man fell in the lagoon while making repairs or removing obstructions and the second man died in rescue attempts.[70]

the supply is replenished and thus they may continue to contaminate the environment, kill susceptible bacteria, and allow resistant bacteria to multiply, potentially exposing people who boat, swim, or drink water.

WORKER DEATH AND INJURY

Nineteen people have died due to hydrogen sulfide emissions from manure pits.

According to the National Institute for Occupational Safety and Health (NIOSH) of the Centers for Disease Control, manure pit and lagoon systems always hold the potential to kill farm workers, particularly in the hot summer months. In 1998, the National Institute of Health notes that some 19 people died due to hydrogen sulfide emissions from manure pits.[71] NIOSH warns that the accumulation of gases formed in the process of breaking down the waste are toxic, oxygen-consuming, and explosive.[72] Though NIOSH has issued warnings to workers, no Occupational Safety and Health Administration standard exists for work around manure pits.[73]

There are four dangerous gases emitted from lagoons of concern to farm workers:

Methane: Usually found at the top of the pit, this gas is highly flammable and explosive at concentrations of five to 15 percent. At high concentrations, methane can displace enough oxygen to suffocate a worker.[74] In addition to concerns about methane from lagoons, methane-related deaths have been attributed to entering liquid manure tanks used to spread manure on farm fields.[75]

Hydrogen Sulfide: This highly toxic gas usually settles at the bottom of a pit and, at low concentrations, can cause severe eye irrititation, dizziness, headache, nausea, and irritation of the respiratory tract. At high concentrations, the gas can result in unconsciousness, respiratory failure, and death within minutes. The gas is also explosive at concentrations ranging from 4.3 to 46 percent by volume.[76]

Carbon Dioxide: Carbon dioxide, an odorless gas, can settle at the bottom of the pit. A worker exposed to low concentrations of this gas can have headaches, labored breathing, and drowsiness. At high levels of concentration, this gas will displace oxygen and suffocate a worker.[77]

Ammonia: This gas can result in severely irritated eyes, nose, throat, and lungs and, in high concentrations, can be fatal.[78]

Because of the hazards posed to workers, NIOSH recommends that a number of precautionary steps be taken, including alerting workers to the possible dangers.

WATER QUALITY IMPACTS OF THE LAGOON AND SPRAYFIELD SYSTEM

There are multiple ways that the lagoon and sprayfield system causes water pollution, kills fish, degrades aquatic habitats, and threatens drinking water supplies. Lagoons can break, spill, or fail, sending wastewater into streams, lakes, rivers, or estuaries. Liquid waste can be over-applied or inappropriately applied to farm fields through irrigation pivots with resulting runoff into lakes, rivers, and streams or seepage into groundwater. Lagoon linings can allow liquefied manure to seep into groundwater, and cracks in the linings can make the problem worse. Pipes and hoses connecting to lagoons or sprayfields may fail or leak. Finally, ammonia emissions from lagoons and sprayfields may result in atmospheric deposition, which sends a toxic form of nitrogen through the air miles away, where it is then deposited in waterways.

Siting and cumulative effects are particular concerns with the lagoon and sprayfield system. States and the federal government have allowed lagoons and sprayfields to be located in places where environmental harm is likely, such as in floodplains and wetlands, near water bodies, and on sandy soils, agricultural drainage wells, and karst topography that provide direct access to groundwater sources. Additionally, when multiple sprayfields cluster around slaughterhouses, as is common, their runoff causes cumulative effects within local watersheds.

The pollution from animal waste can harm waterways, human health, and aquatic life. The primary pollutants of concern for water quality purposes are the nutrients nitrogen and phosphorus. At a 2,500 hog operation in North Carolina, the slurry, which is the liquid from the lagoon that will be land applied, can contain between 58,000 and 700,000 pounds of nitrogen and 41,000 and 475,000 pounds of phosphorus depending upon the live weight of the pigs raised at the facility.[1]

While nutients are essential for plant, animal, and human life, excessive amounts can be harmful. Impacts include drinking water contamination; toxic and nontoxic algal blooms that impair recreational waters and kill fish; climatic changes from greenhouse gas increases (due to the process in which nitrates are converted to nitrous oxide); changes to coastal marine fisheries; acidification of soils and terrestrial and aquatic ecosystems; and increases in ozone and particulate matter that may harm human health and the productivity of crops and forests.[2] Nutrient pollution fosters the growth of a type of algae known as *Pfiesteria piscicida*, which has been implicated in the death of more than one billion fish in coastal waters in North Carolina.[3] The nation's primary expert on *Pfiesteria*, Dr. JoAnn Burkholder from North Carolina State University, has stated that one of the sources of pollution respon-

A CREEK THE COLOR OF HOG WASTE

Neil Julian Savage, Bladen County, North Carolina

"There is a little creek called Whites Creek that runs alongside of the Brown's hog farm, then downstream to my farm. It eventually goes into Hammonds Creek and the Cape Fear River. The creek has a wide spot next to my property. It is a special place, a place that my family and I used to be able to enjoy. Before the hog farm opened next to us, my family would go there to sit and recreate in many different ways. It was a wonderful place for the family to get together, but not any more. Since the hog farm opened it has become nearly impossible to enjoy this family treasure…

"What has happened to Whites Creek is one of our major concerns. Since the hog farm began operating, I have seen changes in this creek which are not good. Now the creek often clogs up with vegetative growth that was not seen prior to when the farm was there. The look and smell of the water has changed for the worst. There is nothing else I can think of that would account for the changes in the condition of the creek besides the Brown's hog farm. Much of the sprayfield areas at the Brown's hog farm are on a downward slope towards the creek. It is a very bad situation so far as the creek is concerned. Since I live downstream on this creek, I have been directly and adversely impacted by the degradation of Whites Creek.

"On Sunday, March 19, 2000…as I walked back to the Whites Creek and up that creek to where the hog farm was located, I could see that the creek had turned the color of hog waste. There was a strong smell coming from the creek. It was the smell of hog waste. As I continued to walk along the creek, I saw many places where Brown's had put pipes at the end of their sprayfields. These pipes were carrying hog waste from the fields, through an earthen berm, and discharging that waste directly across the land to Whites Creek. At the end of the pipes, which were connected to the sprayfields, I could see hog waste puddled and ponded as deep as 5 or 6 inches. There was a lot of hog waste ponded up everywhere…

"In some places, there was so much hog waste on the ground that it had washed out of the earthen bern and was running across the ground and into Whites Creek… On Sunday night, they sprayed again. I know this because I could hear the pumps running all night. On Monday morning, I walked around and the whole back field next to Whites Creek was heavily ponded with hog waste. It was ponded much worse than the day before. As I looked around, I found several places where it was running into the creek.

"On July 20 and 21, 2000, I heard the pumps once again running all night. On the morning of the 21st, the wind was blowing right, and I took a chance by taking a look at what was taking place. I saw two pipes connected to the lagoon. The pipes ran into the woods. I saw where the hog waste had run through the pipes and into the creek.

"On several occasions, Brown's has over-sprayed so much hog waste next to my property that, during heavy rains, the rainwater and the waste that was carried in it actually ran, in large amounts, right onto my land. A number of times this waste has ponded in my front yard. The waste has come up to my front porch, surrounded my drinking well, and run past my house on to what used to be my farm fields. I have complained to Brown's, but they have done little to correct the problems. We are afraid to drink the water from our well."[4]

sible for the outbreaks is hog waste in coastal areas.[5] Nitrogen also causes the eutrophication of lakes and estuaries, which in turn harms fish and is likely to result in species changes, since plants–and the animals and microorganisms that depend upon them–that are tolerant of low nitrogen conditions diminish while nitrophilous plant species increase.[6]

According to EPA's 1998 National Water Quality Inventory, 30 percent of surveyed rivers, 44 percent of surveyed lakes, and 23 percent of surveyed estuaries suffer from nutrient pollution. The impairment is sufficient to make it unsafe to use the waterbody for the purpose for which it is designated–fishing, swimming, and other activities.[7] Nutrients caused severe pollution problems in 44 of the coastal areas examined by the National Academy of Sciences' National Research Council, including Washington, California, Louisiana, Texas, Florida, North Carolina, Maryland, New York, and Massachusetts.[8] The U.S. Fish and Wildlife Service estimates that in 1995, manure contributed 37 percent of all nitrogen and 65 percent of all phosphorus inputs to watersheds in the central United States.[9] Another example of impairment is the Dead Zone located in the Gulf of Mexico, up to 7,000 square miles of oxygen-deprived water where no aquatic life exists, that is the result of agricultural and municipal wastewater runoff.[10] According to the Committee of Environment and Natural Resources of the White House Office of Science and Technology Policy, animal manure alone contributes 15 percent of the nitrogen to the Gulf of Mexico, while industrial and municipal point sources together contribute only 11 percent.[11]

Rick Dove

Pfiesteria-like sores appearing on fish taken from the Neuse River in North Carolina. In the fall of 2000, nearly 100 percent of the menhaden swimming in a 40-square mile area of the Neuse River below New Bern had these sores. A very high percentage died.

SALT AND HEAVY METALS

Manure may contain trace elements of arsenic, copper, selenium, zinc, cadmium, molybdenum, nickel, lead, iron, manganese, aluminum, and boron. Some of these elements are added to animal feed as growth stimulants, others are present in pesticides applied to livestock to rid the animals of insects. Salts may also be in the manure, passed through the animals in undigested feed.[12] Heavy metals and salts are transported to the environment via wastewater. Additionally, heavy metals accumulate in the solid sludge in the bottom of lagoons, reaching toxic levels until they are emptied out every five to fifteen years, or abandoned after ten or twenty years.[13]

Trace elements of metals and salts from animal manure present risks to human health and ecosystems. Excessive salt can impact ecosystems, making drinking water undrinkable, making irrigation water unusable, and increasing the blood pressure of salt-sensitive individuals. In California's Chino Basin, once the number-one milk-producing area in California and home to 300,000 cows in 50 square miles, groundwater contaminated with high levels of total dissolved salts and nitrates flows into the Santa Ana River, which then is used as a recharge source for the Orange County drinking water aquifer.[14] The application of dairy manure and dairy wastewater is considered the major threat to groundwater. A 1990 study found that dairy operations were responsible for 88 percent of the agricultural salt load within the dairy area.[15]

SPRAYING 348 DAYS A YEAR

Rolf Christen, family farmer who raises cattle, chickens, and various crops in Green City, Missouri

"Premium Standard Farms, my neighbor, assured us that they were building a safe hog facility next to our property and that there would be no problems. But then we discovered a waste spill into Spring Creek and found dead fish and destroyed aquatic life. A neighbor of mine grew up near where I live and used to bathe and drink out of Spring Creek. He keeps on saying that the creek has changed. Now there is a black sediment in the creek that no one can explain. After the first spill into Spring Creek, the Premium Standard Farms facilities in the state had 20 to 30 spills. Within a three-month period, I believe that more fish were killed in the state than had died in the last ten years. I feel an indescribable pain when I see fish killed in creeks and rivers that were once picturesque.

"Until recently, the company sprayed the waste onto the land through irrigation guns. The company used to send me a notice every year that I was being given four holidays on which no spraying would occur, July 4, Memorial Day, Labor Day, and Thanksgiving. I have seen pipes burst and irrigation pivots stuck in ditches. Now the company "injects" the manure, but that does not mean that the manure is sent deep into the soil and knifed in. Instead, tiny shallow holes are pressed into the soil and hoses fill the holes with liquid waste. The excess waste runs off.

"As farmers and human inhabitants of this planet, we are but caretakers of what has been given to us. The tree in front of my house will be here long after I am gone. Every tree I plant will be for my grandchildren to enjoy. Everything I destroy will be gone forever. So will it be with the land."[16]

Manure runoff contaminated with trace elements can end up in waterbodies where the metals become more concentrated as they make their way up the food chain. When heavy metals accumulate in sediments, aquatic biota, and plant and animal tissue, the reproduction and immune systems of many aquatic and avian species may be harmed and waterways may become impaired.[17] For example, feed additives such as zinc can contaminate plants, while arsenic, copper, and selenium in feed additives can poison aquatic and terrestrial life, such as bottom feeding birds.[18]

According to the U.S. Fish and Wildlife Service, concentrations of selenium in lagoons or waste storage pits may be ten times the level that is safe for aquatic life.[19] A 1998 study by that agency found that wetlands in Nebraska that received wastewater from a swine production operation had concentrations of copper and zinc that exceeded the current protective criterion of 121 ug/l; the level of copper even exceeded a proposed aquatic life criterion of 43 ug/l.[20]

Humans can also become impacted by heavy metal contamination. Human illnesses associated with high levels of trace elements include skin and internal-organ cancer and vascular complications from arsenic, liver dysfunction, and hair and nail loss from selenium, and upper deficiency anemia from zinc. While the concentration in animal manure of arsenic, cadmium, chromium, copper, lead, mercury, molybdenum, nickel, selenium, and zinc may be comparable to the levels found in some municipal sludges. EPA regulations restricting levels of heavy metals in human sludge do not apply to animal waste.[21]

Another risk associated with heavy metals is the deterioration of soil quality. In 1995, 10 percent of the soil samples in North Carolina's largest swine-producing counties had zinc levels ten times greater than the levels crops need for their growth. The number of soil samples from these counties that exceeded this level doubled since 1985. Already this level of zinc makes it hard to grow peanuts, and other crops will begin to suffer in future decades as the metals reach higher concentrations.[22]

GROUNDWATER POLLUTION

Federal and most state regulations concerning CAFOs focus on the nutrient content of the wastewater. However, the wastewater generated by lagoon systems contains pollutants other than nutrients, such as metals and salts, that can also adversely affect surface and groundwater quality. Additionally, the pollution strength of raw manure is as much as 110 times greater than that of raw municipal sewage.[23] (See Table 4-1.)

As of 1998, close to 1,600 wells located near factory farms in North Carolina were tested for nitrate contamination. Thirty-four percent of the wells showed nitrate contamination; ten percent of the wells had a nitrate level that exceeded the drinking water standard. The state's Department of Health and Human Services stated that the cause of contamination was leaking hog lagoons and hog wastewater sprayfields.[24]

In many cases, lagoons leak because they are not lined. Only in the last few years have some states required that lagoons be lined. Lagoon linings include clay, concrete, and plastic, with clay linings the most commonly required. But many types of linings still allow seepage to occur. Seepage from lagoons occurs in two ways: vertical seepage along the bottom of the lagoons, and vertical and horizontal seepage at the berms.[25] Moreover, cracks may occur in the lagoon lining. Visual inspections are insufficient to detect when linings have been compromised, because lagoons may be structurally sound in certain places and cracked in others. Groundwater testing wells can detect problems, but groundwater monitoring is rarely required by regulatory agencies.[26]

Studies from across the nation compiled by the Minnesota Pollution Control Agency found numerous incidents of groundwater contamination near unlined, earthen manure-storage basins. Nitrate levels were above the drinking water standard of 10 mg/l in about half of the 42 basins that were monitored; the other half of the facilities

Grasses choke off a part of North Carolina's Trent River due to over-nutrification. There are more than 450 hogs-per-square mile in this watershed.

Rick Dove

TABLE 4-1

BOD_5 Concentrations for Manures and Domestic Sewage

Waste	BOD_5 (mg/l)*
Swine Manure	
Untreated	27,000 to 33,000
Anaerobic lagoon influent	13,000
Anaerobic lagoon effluent	300 to 3,600
Poultry manure	
Untreated (chicken)	24,000
Anaerobic lagoon influent (poultry)	9,800
Anaerobic lagoon effluent (poultry)	600 to 3,800
Dairy cattle manure	
Untreated	26,000
Anaerobic lagoon influent	6,000
Anaerobic lagoon effluent	200 to 1,200
Beef cattle manure	
Untreated	28,000
Anaerobic lagoon influent	6,700
Anaerobic lagoon effluent	200 to 2,500
Domestic sewage	
Untreated	100 to 300
After secondary treatment	20

*The pollution strength of the organic matter in manure or wastewater is expressed as the biochemical oxygen demand (BOD_5).
Source: U.S. Environmental Protection Agency, Office of Water, *Environmental Assessment of Proposed Revisions to the National Pollutant Discharge Elimination System Regulation and the Effluent Guidelines for Concentrated Animal Feeding Operations*, EPA-821-B-01-001 (January 2001).

were found to have no or only slight levels of groundwater contamination.[27] Of particular concern were lagoons with earthen liners that were constructed on sandy soil, from which researchers found "significant" leakage of nitrogen and phosphorus, and leakage that increased greatly over time.[28] This study highlights the importance of soil type. When lagoons are located on coarse soils, seepage is more likely, but if the soil is firm, runoff from sprayfields may result.[29]

A study for the Iowa legislature by Iowa State University found that over 50 percent of the earthen waste-storage structures (slurry pits and lagoons) studied had seepage losses that exceeded current standards.[30] The study also looked at soil cores to measure the migration of waste. The soil cores were tested for a number of contaminants, and most of the sites had at least one of the contaminants present at a high concentration level. The pollution at some of the sites might have been attributed to waste spills or previous use of the areas for livestock production, but the high levels of ammonium nitrogen at five sites was attributed to seepage. The seepage was measured outside of the berm at a distance of 30 to 50 feet from inside the earthen waste-storage structure.[31] Another study in Iowa, by the state's Department of Natural Resources, found that two of three earthen manure lagoons constructed around 1994 on clay soils seeped into the water table. Levels of chloride, organic carbon, and organic-N were increasing over time, while sulfate and nitrate concentrations were decreasing. The three-year study concluded that seepage was continuing and that none of the basins had sealed.[32]

Clay linings, which are made of compacted soil, offer greater protection, but may still seep. For example, Kansas State University researchers studied four swine lagoons and found that all of them leaked between .05 and .08 inches a day, which translates to between .99 million and 4.35 million gallons per year, or between 19.8 and 87.1 million gallons over the twenty-year life of the lagoons. The one cattle lagoon studied seeped at a rate of .094 inches a day, 6.88 million gallons per year, or 137.7 million gallons over the life of the lagoon.[33] Just for nitrogen, seepage losses from a swine waste lagoon could add up to more than 2,600 pounds/acre per year, or 250,000 pounds over the twenty-year life of the lagoon. Nitrogen losses for cattle lagoons were less than those for swine, because the effluent contains a lower concentration of nitrogen.[34]

Also, the seal that exists below and on the sides of the lagoon may weaken over time. Several studies have found that within two to four years, chlorides and ammonium begin to leak through a clay lining.[35] A study of dairy lagoons by the New Mexico Department of Health and Environment found elevated levels of nitrogen in unlined and clay-lined lagoons that were more then ten years old.[36]

Numerous studies have found seepage from and cracking of earthen and clay liners due to wet/dry cycles, the removal of manure from the lagoon, worms, roots, rodents, freeze/thaw cycles, erosion of lagoon berms, agitation during pumping, and liner collapse due to external pressure and groundwater intrusion.[37] A study for the Iowa legislature found that 27 percent of the 33 earthen waste-storage structures studied had compacted clay liners or berms that had eroded, while 6 percent had tree growth on berms.[38] Additionally, clay liners may crack if the dredging of the sludge off the bottom of the lagoon is not done properly. This dredging is typically done every five to fifteen years.[39]

Lagoon siting is critical. The study for the Iowa legislature found that 18 percent of the 34 earthen waste-storage structures (lagoons and slurry pits) studied were located over alluvial aquifers where there was a risk of contaminating private and municipal water supplies. Moreover, the study showed that 65 percent of the site areas were located on soils with seasonal water tables of less than 5 feet. Since earthen waste-storage structures are often deeper than 10 feet, the lagoon bottoms sat below the water table.[40] The study speculated that "a large percentage of earthen waste-storage structures in this study and in the state are probably below the water table or at least in contact with the water table." Moreover, "locating an earthen waste-storage structure and applying manure on permeable soils poses a substantial risk for contaminants to reach the water table."[41]

Concrete liners can offer greater protection, but concrete can crack if builders do not follow specifications related to soil suitability and structural reinforcement. Despite the fact that these specifications contribute to liner stability, there are no requirements that compel builders to follow them.[42] Plastic liners are also not fail-safe. In 1998, two of the plastic lagoon liners used at the huge Circle Four factory farm in Beaver County, Utah developed bubbles and the liners floated to the surfaces of the lagoons.[43]

SURFACE WATER POLLUTION OF LAKES, RIVERS, AND STREAMS

While many recently-built lagoons have been designed to meet the capacity of a 24-hour, 25-year storm event, several days of rain can compromise the system, because the steady rainfall weakens the berms and prevents the excess wastewater from being sprayed on already saturated fields.[44] Bursting and overflowing manure lagoons have spawned environmental disasters around the country, sending animal waste gushing into rivers, groundwater, and coastal wetlands.

▶ Between 1990 and 1994, 63 percent of Missouri's factory farms suffered spills according to Missouri's Department of Natural Resources.[45]
▶ In 1995, an eight-acre animal waste lagoon in North Carolina burst, spilling 25 million gallons of animal waste into the New River. The spill killed 10 million fish and closed 364,000 acres of coastal wetlands to shellfishing.[46]
▶ In 1997, animal feedlots were responsible for 2,391 spills of manure in Indiana.[47]
▶ In 1998, a 100,000-gallon spill into Minnesota's Beaver Creek killed close to 700,000 fish.[48]
▶ In 1996, 40 spills killed close to 700,000 fish in Iowa, Minnesota, and Missouri.[49]
▶ From 1995 to 1998, there were at least 1,000 spills or other pollution incidents at livestock feedlots in ten states, and 200 manure-related fish kills that resulted in the death of 13 million fish.[50]

The spills listed above can be attributed to a host of problems, but they point to the inherent risks of the lagoon and sprayfield system. Some problems are due to poor management. A 1999 study for the Iowa legislature found that of the 33 earthen waste-storage structures (lagoons and slurry pits) studied, over half had minor spills when manure was being unloaded, 12 percent had flow inlet pipes that were plugged or frozen, and 6 percent had inadequate freeboard.[51]

Poor siting of lagoons poses another concern. If lagoons are located near waterbodies, wetlands, floodplains, or other ecologically sensitive areas, spills are more likely to cause harm. The study for the Iowa legislature found that 18 percent of the earthen waste-storage structures studied were located in floodplains, 21 percent of the structures were within 500 of feet of ephemeral streams, and 12 percent of the structures were within 500 feet of perennial streams. A Kansas State University study speculated that in areas with high rainfall, nitrates which are highly mobile and accumulate in significant amounts in the soil beneath lagoons, could seep deeper into the soil and closer to groundwater. This happens particularly when lagoons are closed or abandoned and their bottoms dry out.[52]

A study by the U.S. Geological Survey found that in 88 percent of the 2,056 watershed outlets, manure contributed more to in-stream total nitrogen than traditional point sources; in 113 watersheds, manure was the single largest contributor.

While spills can cause catastrophic damage, the more common problem is over- or misapplication of waste onto cropland, which sends polluted runoff into waterways and leaches pollutants into groundwater. A 1992 study by the U.S. Department of Agriculture found that "nutrients from confined animals exceed the uptake potential of non-legume harvested cropland and hayland…[R]ecovereable manure nitrogen exceeds crop system needs in 266 of 3,141 counties, and that recoverable manure phosphorus exceeds crop system needs in 485 counties."[53] A study by the U.S. Geological Survey found that in 88 percent of the 2,056 watershed outlets, manure contributed more to in-stream total nitrogen than traditional point sources; in 113 watersheds, manure was the single largest contributor. This study also concluded that manure is a major contributor to in-stream, total phosphorus concentrations, even more so than commercial fertilizers.[54] The Texas Institute for Applied Environmental

Research identified the dairy industry as the primary contributor to nutrient loading in the Upper North Bosque River. The institute also measured elevated phosphorus levels at fields where animal manure had been applied.[55]

A study by the University of Northern Iowa looked at hog CAFOs with lagoons and earthen storage basins, and their field application of manure onto corn and soybean crops. The study asserted that if farm workers had applied manure at the rate at which the crops could have absorbed phosphorus, the CAFOs would need more than nine times the field area used for manure application by these CAFOs.[56] Since clearly the land area for spreading the manure was so much less than that needed for proper application, one can assume that the excess phosphorus was running off. This same study found other practices in manure management plans submitted by most of the CAFOs that would likely lead to over-application of manure, including over-estimating crop yields and underestimating the nutrient content of manure. The study also questioned the common practice of applying manure to soybeans–a crop that traditionally has not been fertilized.[57]

Inactive lagoons pose an additional threat to groundwater. North Carolina's Department of Environment and Natural Resources inventoried 1,142 inactive lagoons. The study determined that only 43 structures were low risk, while 39 lagoons were judged to be high risk because they were either overflowing or had a high likelihood of overflowing. Over 90 percent of the lagoons were determined to present a risk for groundwater contamination.[58]

ATMOSPHERIC DEPOSITION

Studies in the United States and Europe show that livestock farms in general have the potential to contribute large amounts of nitrogen to the atmosphere as ammonia.[59] Although the amount varies based on weather, sprayfield application method, type of livestock species, and manure storage method, the impact can be significant. In fact, up to 80 percent of a swine lagoon's nitrogen may change from a liquid into a gas in the process known as ammonia volatilization.[60] In contrast, dry manure systems lose 15 to 40 percent of their nitrogen to the atmosphere.[61] For beef manure, the fewer solids and more liquid that is present in the slurry, the greater the volatilization.[62] Once the ammonia is volatilized, it can be deposited onto land and water 300 miles away.[63] Sprayfields also result in ammonia losses. Several studies have found that if manure is not incorporated into the soil, more than half of the manure is lost, presumably to volatilization.[64] One study "found that soil-incorporated manure may release as little as one-tenth the ammonia emitted from surface-spread manure, other factors being equal."[65]

Up to 80 percent of a swine lagoon's nitrogen may change from a liquid into a gas in the process known as ammonia volatilization.

In North Carolina, swine operations contribute nearly half of the total atmospheric ammonia in the state coming from all other industrial and livestock sources combined; lagoons in eastern North Carolina are responsible for a third of the total swine ammonia emissions.[66] In the six-county area of North Carolina that has the most concentrated hog production, a comparison of ammonia emission levels from hog operations in two seven-year periods, 1982-1989 and 1990-1997, showed an increase of 316 percent.[67] The increase tracks the period of rapid growth in North Carolina's hog industry which occurred starting in 1989.[68] North Carolina Environmental Defense estimated that the nitrogen from atmospheric emissions from sprayfields into rivers alone ranged from eight to 38 percent in the Neuse River basin and 16 to 38 percent in the Cape Fear River basin.[69]

In addition to threatening groundwater with pollutants, the lagoon system also causes its depletion. The lagoon system relies upon a steady supply of water. It needs water to clean the barns, cool the animals, and provide drinking water for the animals. Most significant, the system requires sufficient water to make the manure wet enough to flush into the lagoon and spray onto fields.[70] Missouri activists estimate that a swine operation that finishes 80,000 animals per day consumes over 200,000 gallons of water per day, or 73 million gallons per year.[71] In many areas in which factory farms are located, the water that is utilized is groundwater–which is provided to the factory farm for free.

ALTERNATIVE APPROACHES TO THE LAGOON AND SPRAYFIELD SYSTEM

The lagoon and sprayfield system presents numerous risks to surface and groundwater quality, air quality, and public health. A number of alternative approaches are being used by sustainable operations. Researchers are studying many alternative technologies, at least on a pilot level. The list of approaches described below illustrates one important point–it is not the lack of alternatives that is driving factory farms to rely almost exclusively on the lagoon and sprayfield system. Factory farms continue to use this polluting system because they have been allowed to use our farmland, rural waterways, and air as disposal sites for untreated wastes. With its effluent guidelines, EPA has a historic opportunity to move feedlots beyond the lagoon and sprayfield system, but it has not yet chosen to do so. Instead, the agency may allow factory farms to continue to pass the cost of waste disposal on to the public. The wealth of approaches increasingly available across the country shows that pollution from these facilities can be eliminated or reduced, but only if we require facilities to use them.

Unfortunately, many of the systems that are being evaluated presume that it is necessary to liquify and then treat the liquid manure. There is another approach–one based upon the principle of pollution prevention and proper manure management. The sustainable agriculture approach dries the manure and often adds other dry material to keep waste from running off, or seeping into water supplies. Sustainable agriculture practices that embody these approaches benefit the environment, the producer, the animals themselves, and the communities that surround them.

It is important to note that some of the alternatives to the lagoon and sprayfield system are still in the development stage and have not necessarily been evaluated for all pollution risks. Moreover, while some of the technologies have been in use for the treatment of human waste for years, they have not been widely used for animal waste. Thus, studies on pollution reductions may only be based upon a limited sample, pilot projects, or a limited history of use. Also, many university studies evaluate certain chemical parameters, but not others, so risks could be high for pollutants not measured, such as heavy metals, which, even at low concentrations, can be toxic to plants and animals. Finally, many impacts on the environment have not been measured, for example, the likelihood of groundwater contamination. For the purposes of simplicity, "public health impacts" are identified as pathogen reduction, even though reductions in surface water, groundwater, and air contamination can all benefit public health.

SUSTAINABLE AGRICULTURE APPROACHES

Management Intensive Rotational Grazing

The use of an intensive rotational grazing system provides environmental benefits, such as enhanced soil quality, minimal soil erosion, improved stream bank quality, and enhanced wildlife habitat.

Intensive rotational grazing represents a return to the practice of using managed pasture to supply at least a portion of the nutritional needs of animals with growing grasses and legumes. Animals (dairy cows, beef cattle, egg layers, broilers, hogs and others) graze on sections of pasture that are divided into paddocks. In the pasture sections that do not contain animals, forage is allowed to grow. Using fences, animals move into different sections of the pasture where they graze, but are moved before the pasture section is over-grazed.[1] The use of an intensive rotational grazing system provides environmental benefits, such as enhanced soil quality, minimal soil erosion,[2] improved stream bank quality,[3] and enhanced wildlife habitat.[4]

Assessment of Pollution Risks:

▶ To surface water quality: If the animal ratio is appropriate for the acreage and stream banks are fenced, the system reduces agricultural runoff.[5] The potential for accumulation of soil phosphorus is also reduced if the animals' diet is not supplemented with purchased feed or mineral supplements–both of which can be significant sources of phosphorus inputs to individual operations.[6]

▶ To groundwater quality: The potential for groundwater contamination remains low as long as the site is not located in an area with karst geology or other preferential flow paths to groundwater.[7]

▶ To air quality: Ammonia volatilization is minimal.[8]

▶ To public health: Pathogen transport is minimal due to the reduced volume of surface runoff, which is further reduced if combined with filter strips.[9]

Hoop Houses

Hoop houses are structures that house hogs indoors, but allow them freedom of movement. Hoop houses are built on arched metal frames covered with a tarp. Sidewalls reach four to six feet above ground level on the sides, while end walls are typically tarps or plywood doors that can be opened for ventilation.[10] The houses are bedded deeply with straw to absorb urine and moisture in feces. The straw binds with manure and urine, keeping the waste in a more solid form than liquid-flushing systems used by industrial confinement facilities. Typically, pigs are not confined in pens in hoop houses.[11]

In a system invented by Virginia farmer Joel Salatin, egg layers are allowed to graze through the use of a mobile "eggmobile."

Joel Salatin

Assessment of Pollution Risks:

▶ To surface water quality: Hoop houses eliminate the risk of accidental discharges from manure storage ponds and lagoons during precipitation events because the manure/straw mixture is in a more solid form and the tarp provides rain protection.[12]

However, once the bedding is cleared out of the house (two or three times a year), it is either composted or, having been composted in the house, it is directly spread on fields. Proper land application of the manure is needed to prevent polluted runoff.[13]

▶ To groundwater quality: In order to prevent seepage of nitrate to groundwater, an impermeable barrier, such as a concrete floor, should be constructed between the bedding/ manure mixture and the underlying soil. The potential for the downward movement of this accumulated nitrate nitrogen to groundwater can be reduced by proper siting.[14]

▶ To air quality: If the accumulating bedding/manure mixture is not overly compacted, ammonia nitrogen mineralized from organic nitrogen compounds may oxidize to nitrate nitrogen. If the potential for nitrification is high, the potential for the formation and release of hydrogen sulfide will be low. The likelihood of the release of both ammonia nitrogen and hydrogen sulfide to the atmosphere depends on the ability to maintain conditions in the bedding/manure mixture that are conducive to aerobic microbiological activity.[15]

▶ To public health: Some producers have found that the use of hoop houses eliminates the need for the routine incorporation of antibiotics in feed, because this method of production produces healthy hogs.[16] Additionally, weaning the pigs on deep straw may prevent them from being exposed to pathogens that exist on bare, urine- or manure-covered floors.[17] Pathogens generally are poor competitors in environments with diverse microbial populations and especially in aerobic environments because pathogens usually are anaerobes. Thus, significant pathogen reduction in the bedding/ manure mixture in hoop houses is a reasonable expectation if the mixture is removed infrequently and especially if there is an elevation in temperature due to microbial heat production.[18]

Weaning pigs on deep straw may prevent them from being exposed to pathogens that exist on bare, urine- or manure-covered floors.

Diane Halverson

Composting

Composting is a biological process in which aerobic bacteria convert organic material into a soil-like material called compost that reduces erosion and enhances organic matter, soil quality, and nutrients.[19] In a simple composting system, material is laced in long rows called windrows and turned occasionally to ensure that the material is mixed well. In a complex system, odoriferous materials can be processed in drums, trenches, or tunnels for initial processing, and then cured in a covered facility.[20] Several universities are studying the use of complex systems for swine and dairy waste that involve some dewatering of the waste and adding dry materials or earthworms.[21] Most composting is aerobic, but some producers are turning to anaerobic composting systems in which methane gas is produced for electricity.[22] As with other treatment systems, proper siting of the composting away from waterways and wells is essential to prevent pollution.[23]

Assessment of Pollution Risks:

▶ To surface water quality: Composting reduces the nitrogen content of manure.[24] A roof over the compost site and a system to capture and dispose of leachate and runoff can protect adjacent surface waters.[25] Threats to water quality can be prevented by off-site disposal of composted waste when land resources for on-site utilization of manure are limited.[26]

▶ To groundwater quality: Paving and covering sites used for composting help prevent groundwater contamination.[27]

▶ To air quality: With proper management, release of objectionable odors can be minimized. However, significant odor problems can occur during the start-up of the composting process. Due to the low carbon/nitrogen ratio of animal manure, some volatilization of ammonia nitrogen is unavoidable.[28] To minimize ammonia nitrogen volatilization, readily biodegradable organic carbon, e.g., paper, leaves, or sawdust, must be added to increase the carbon/nitrogen ratio to about 30:1. Otherwise, nitrogen levels in both wet and dry atmospheric deposition will increase with subsequent adverse surface water quality impacts.[29]

▶ To public health: When thermophilic temperatures are achieved, pathogen densities are reduced substantially.[30]

TECHNOLOGY-BASED APPROACHES

Anaerobic Digestion

Anaerobic digestion uses microbes to convert the carbon fraction of livestock and poultry manures to methane and carbon dioxide, commonly referred to as biogas.[31] Digesters create an effluent that has a different chemical composition than raw manure.[32] In all digesters, liquid effluent remains after the process that must be stored until it can be applied to crops.[33] Anaerobic digestion has been used for more than 50 years to stabilize wastewater treatment sludges, and at the same time, reduce pathogen densities.[34]

Releases of noxious odors, ammonia nitrogen, and methane from anaerobic lagoons can be controlled using a flexible, gas-tight cover resulting in a covered lagoon digester.[35] Other types of digesters used successfully with animal wastes include completely mixed and plug-flow digesters. A complete mixed digester treats slurry manure in above- or below-ground tanks.[36] A plug-flow digester typically is an in-ground rectangular trench lined with an impermeable material and covered with a gas-tight flexible membrane cover.[37] These types of digesters are usually insulated and heated using a fraction of the biogas recovered as fuel. Thus, stabilization and the total yield of biogas are constant throughout the year. In contrast, the degree of stabilization and biogas yield from covered lagoon digesters varies with time of year, particularly in colder climates.

Assessment of Pollution Risks:

▶ To surface water quality: Anaerobic digestion can significantly reduce the concentration of oxygen demanding carbon compounds in animal manure. However, the concentration of these compounds will still exceed concentrations in untreated municipal wastewaters.[38] The process converts organic forms of nitrogen to ammonia nitrogen, but does not reduce phosphorus.[39] Reports of phosphorus reduction associated with anaerobic digestion are the result of phosphorus in settled solids accumulated in digesters.[40] The use of anaerobic digesters requires storage tanks or ponds. Therefore, the potential for accidental discharges due to mismanagement or during extreme precipitation events is not eliminated.

▶ To groundwater quality: The risk associated with lined covered-lagoon digesters varies and depends on soil type, geology, depth to seasonally high groundwater, and the method, quality, and management of the liner.[41]

▶ To air quality: Anaerobic digestion with biogas utilization or flaring substantially reduces methane and noxious odor emissions.[42] The system also results in lower ammonia emissions than open-air lagoons, although there still may be some volatilization when the digested manure is stored in a pond prior to land application or when it is land applied without proper injection.[43]

▶ To public health: Risk can be variable, depending upon whether the digesters are heated. Pathogenic bacteria can be significantly reduced or even essentially eliminated if the digesters are heated.[44]

Wetlands Treatment

Constructed wetlands have been used successfully for the tertiary treatment of municipal and industrial wastewaters to further reduce concentrations of nitrogen, phosphorus, biochemical oxygen demand, and suspended solids before discharge to surface waters.[45] These reductions are the result of a combination of microbial activity, plant uptake of nitrogen and phosphorus, and physical/chemical processes such as ammonia volatilization and phosphorus adsorption.[46] In this system, a wetland is constructed that filters wastewater using plants, soil, and water. After treatment, the effluent is sprayed onto crops. Seasonal weather conditions, such as cold and drought, may make the system less reliable.[47] For relatively dilute waste streams, such as swine and dairy flush waters after removal of manure solids, constructed wetlands may be a viable management option prior to storage.[48] For other animal waste, solids must be removed before the wastewater is put in the wetland and pretreatment is necessary to ensure that high ammonia concentrations do not kill off plant life.[49] These steps can be accomplished through the use of an anaerobic or aerobic lagoon, a sequencing batch reactor, a digester, or another system. Thus, constructed wetlands should be viewed as a component of a larger system to treat waste.[50]

Assessment of Pollution Risks:

▶ To surface water quality: Under normal weather conditions, any polluted runoff that results will be far less toxic than that of an anaerobic lagoon. Studies vary on pollutant reduction results, with some studies reporting reductions of half or more in nitrate, ammonia, and oxygen-depleting substances and suspended solids for dairy waste. For swine waste, some studies have found that the system removes most of the nitrogen, phosphorus, and suspended solids,[51] while other studies have found less phosphorus reduction.[52] However, excess rainwater could flood the system, so a holding pond should be constructed near the wetland to accept stormwater and act as a settling basin for removing solids.[53]

▶ To groundwater quality: The risk wetlands treatment poses to groundwater is unknown. However, like lagoon systems, siting may be a concern. If a wetland is located on porous soils, karst geography, or areas near agricultural drainage wells, groundwater contamination may be a high risk.

▶ To air quality: Wetlands may emit some ammonia, which could be reduced if the wastewater is nitrified prior to wetland treatment.[54]

▶ To public health: The risk is unknown.

Sequencing Batch Reactor

The aerated sequencing batch reactor (SBR) process is a variant of the activated sludge process, which has been used for over 75 years to treat municipal and industrial wastewater. The SBR maintains an adapted microbial population to convert the fraction of organic compounds in solution into microbial biomass that subsequently can be removed by settling or filtration. With the conventional activated sludge process, a portion of solids separated by settling after aeration is returned to the aeration basin to maintain the desired microbial population and to minimize wastewater retention time and tank size.[55]

Wastewater treatment using the conventional activated sludge process uses a continuous flow mode of operation. In contrast, SBRs are operated as batch reactors with the following sequence of operations. First, the reactor is filled with untreated wastewater, which is mixed with some fraction of the settled solids from the previous batch. Second, there is a period of aeration that also provides mixing. Third, aeration is terminated to allow suspended solids (particulate matter) to settle and separate. Finally, the clarified effluent is discharged, a fraction of the settled solids is removed, and the process sequence is repeated. The principal advantage of this batch mode method of operation, especially in municipal and industrial wastewater treatment, is that it offers more precise process control. With operating conditions conducive for nitrification, a substantial degree of nitrogen reduction through nitrification-denitrification can be achieved.[56]

Assessment of Pollution Risks:

▶ To surface water quality: The water pollution potential of clarified effluent from a SBR treating animal wastes is substantially lower than untreated waste. A university pilot program for swine waste found that the system removed chemical oxygen demand and total nitrogen by more than 90 percent, and volatile solids and phosphorus by more than 70 percent.[57] Another pilot project showed that over 60 percent of the nitrogen was removed using this system.[58] Since wastewater is in a tank, there is little likelihood of breaches.

▶ To groundwater quality: Risk is lower than using a lagoon since the manure is in a tank.

▶ To air quality: With nitrification, ammonia nitrogen emissions will be reduced. However, nitrous oxide emissions resulting from denitrification and noxious odors from stored solids may occur.[59]

▶ To public health: Significant reductions in pathogen densities in the clarified effluent are obtainable. However, there will be a concurrent concentration of these organisms in the settled solids due to sorption onto particles.[60]

Lagoon Covers

Placing a cover over a lagoon offers an approach that can reduce emissions. A number of different covers have been studied, each of which have benefits and drawbacks. The least costly option entails the use of biofilters, readily available materials that are blown onto the surface of the lagoon, such as peat, moss and straw. Other materials that may be used include plastic mats, polystyrene foam, air filled clay balls, geo-textile membranes, such as high-density polyethylene or reinforced polypropylene materials, and pumice or construction matting.[61] The problem with biofilters is that they need to be replaced often to prevent the material from sinking to the bottom of the lagoon.[62] Other cover options include rigid concrete or wood lids or roofs made of fiberglass.[63]

Assessment of Pollution Risks:

▶ To surface water quality: The risk is unknown, but it is unlikely that biocovers could prevent a major lagoon breach or spill. Impervious covers might sink during a storm event. Rigid covers and impervious covers would divert rainwater.

▶ To groundwater quality: Covers are not designed to address groundwater quality.

▶ To air quality: One study showed that straw covers reduce ammonia emissions, while peat moss absorbs ammonia and reduces nitrogen losses by 40 to 60 percent.[64] Another study found that a straw cover with a thickness of 12 inches reduced ammonia and hydrogen sulfide emissions by 80 percent, while putting straw on top of a thin geo-textile cover also resulted in significant reductions in the emissions of these gases.[65] However, in Renville County, Minnesota, ValAdCo, a large hog farming cooperative, continued to have air quality violations depsite the use of straw and cloth covers, which may be the result of the failure of the cover systems or mismanagement of them.[66] Rigid covers can reduce ammonia emissions between 80 and 95 percent.[67]

▶ To public health: The risk is unknown.

Lagoon Liners

Many earthen lagoons and storage ponds used for livestock and poultry manure have been constructed without any attempt to prevent seepage through the soil profile to groundwater except by compaction of the soil. Neither clay nor concrete liners are risk free with respect to seepage. Clay liners can crack if allowed to dry after a lagoon or storage pond is emptied. Concrete liners can also crack due to thermal expansion and contraction and settling. Also, reliable sealing of necessary expansion joints can be problematic.

Assessment of Pollution Risks:

▶ To surface water quality: Lagoon liners will not protect surface water quality directly but will prevent the base flow discharge of contaminated groundwater to adjacent surface waters.

▶ To groundwater quality: Numerous studies have found seepage through clay liners due to: 1) cracking during wet/dry and/or freeze/thaw cycles, 2) penetration by worms, roots, or rodents, 3) physical damage due to erosion of lagoon berms and agitation during pumping, and 4) liner collapse due to external pressure and groundwater intrusion.[68] Geo-textile materials are less permeable than clays but proper installation is essential. Geo-textile lagoon liners also are subject to the possibility of physical damage during agitation and pumping and due to burrowing animals.[69] Concrete liners can offer greater protection, but concrete can crack if specifications related to soil suitability and structural reinforcement are not followed; however, there are presently no such requirements.[70] Plastic liners composed of impervious materials, like those presently required by EPA for solid waste lagoons, but not for animal waste lagoons, are another option.[71] However, plastic liners also must be constructed properly to prevent problems.

▶ To air quality: Liners are not designed to address air quality.

▶ To public health: Where seepage from lined or unlined lagoons can enter groundwater without filtration through unsaturated soil, discharge of bacterial pathogens to groundwater is likely. Even where seepage is filtered through unsaturated soil, viral pathogens may be transported to groundwater.[72] (See Chapter Four.)

Many of the alternatives to the lagoon and sprayfield system for managing livestock and poultry manure described in this chapter are viable, and provide substantially greater protection to public health and the environment than the lagoon and sprayfield system. The options are available, but factory farms will not begin to use them as long as they are able to continue to externalize their pollution costs by dumping manure into the environment. However, for any method, surface water, groundwater, and public health will only be protected if manure is applied properly to the land.

CHAPTER 6

POLICY RECOMMENDATIONS

The numerous studies summarized in this report make it clear that the reliance on lagoon and sprayfield systems to store and treat animal wastes harms the health of nearby communities and pollutes the environment in numerous ways. The promulgation of EPA's new technology rules ("effluent guidelines") under the Clean Water Act presents a major opportunity to phase out open-air lagoons and sprayfields on large-scale animal operations, and to promote a more sustainable animal production system. Sustainable facilities limit the number of animals that they confine to generate only the amount of waste that can be used as fertilizer. For that reason, sustainable systems generate much less pollution and are at much less risk of catastrophic failure than lagoon and sprayfield operations.

PHASE OUT THE USE OF LAGOONS

The concentration and industrialization of animal production in this country has resulted in single facilities that produce thousands of animals and generate millions of gallons of manure. Industry trends indicate the likelihood of further concentration, resulting in more and larger lagoons if regulations are not tightened.[1]

EPA's existing technology standard allows lagoons that pollute surface water in a variety of ways indirectly to claim that they do not discharge and, therefore, that they do not need a Clean Water Act discharge permit. This has been a major factor in widespread lagoon adoption by concentrated animal feeding operations (CAFOs). (Another factor has been the fact that lagoons have been considered the least costly manure storage option.) When the existing technology standard was promulgated over twenty years ago, animal operations were smaller and lagoons were built on a much smaller scale. Today with the enormous quantities of manure that is generated and stored in lagoons, there are multiple ways for discharges to occur through the air, surface water, and groundwater. However, despite the growing body of evidence that these huge lagoons pollute the environment in numerous ways, EPA's proposed regulations would allow the riskiest lagoons to continue to operate and new lagoons to be built. Moreover, EPA envisions little or no water quality monitoring to determine if pollution problems are occurring.

Ban New Lagoons To protect the environment and public health, EPA should use all regulatory avenues possible to ensure that no new lagoons will be built. It is not enough to simply require that new lagoons to be lined and covered. While these measures may be appropriate as an interim step for existing operations to mitigate some potential problems, these approaches fail to address problems associated with lagoon breaches and overflows. For example, cracks can develop even in lagoons lined with concrete, and seepage can be a problem for lagoons lined with clay, and neither liners nor covers will prevent overflows in significant rain events. (See Chapter Four.) The storage of vast quantities of liquid manure in lagoons presents an unacceptable risk to public health and the environment. Weather events, human error, and system failures have resulted in numerous problems. EPA should not allow any CAFOs to build new lagoons.[2]

Encourage the Use of Sustainable Animal Production Systems There are sustainable animal production systems that do not impose high risk of pollution and other harms and that minimize cumulative impacts from animal production. A key component of a sustainable animal production system is that the scale of the system does not exceed the capacity of the local region to use the waste from the system beneficially. In other words, the total number of animals in a watershed should not exceed the nutrient requirements of available crop and/or timberland in that watershed. Generally, sustainable animal production systems are integrated with crop, forage, or pasture production and on-farm, best-management practices to prevent stormwater runoff from farm fields and barns. These sustainable systems are true pollution prevention systems.

While the U.S. Department of Agriculture and EPA Unified Strategy for Animal Feeding Operations[3] included an overarching principle that sustainable livestock systems be supported, this concept has not been incorporated into EPA's proposed regulations for new CAFOs. The new technology rules should encourage all new CAFOs to adopt sustainable livestock systems that protect air, surface, and water resources.

Phase Out Existing Lagoons Existing lagoons should be phased out over a five-year period. The corporations that own the animals and reap most of the profit can and should be held responsible for paying the costs of installing technologies that do not rely on lagoons and sprayfields. Alternatives to lagoons are available and now in use at farm operations that turn a profit. During this period, existing operations should be required to monitor their surface and groundwater quality to ensure that no discharges occur, and be required to line and cover their lagoons to prevent further contamination. Berms should be required to be built surrounding existing lagoons and be large enough to hold the entire contents of lagoons should they burst. Existing operations should be prohibited from expanding their lagoon systems in the 100-year flood plain or in any area in which there is a potential for seepage into groundwater that may be hydrologically connected to surface water.

The idea of a phaseout has already gained acceptance in North Carolina, a state that ranks second among hog producing states.[4] In 1999, former Governor Hunt proposed a widespread conversion of swine waste lagoons and sprayfields to new technologies.[5] Although North Carolina's Governor Easley has not publically endorsed former Governor Hunt's phaseout plan since he took office, it is worth mentioning that Governor Easley himself initiated the agreement with Smithfield, requiring the company to convert to "environmentally superior technologies," when he was the state's attorney general.[6]

BAN SPRAYFIELDS AND LIMIT LAND APPLICATION

Sprayfields constitute an integral feature of many lagoon systems, in which the waste is sprayed onto crops or pastureland. The sprayfield system poses significant risks to the environment. Since the waste is sprayed in massive quantities, polluted runoff into surface and groundwater presents a recurring problem, and the spray pollutes the air. EPA's proposed rules attempt to address the land application of manure from CAFOs. However, to do so adequately, the regulations must ensure that manure from CAFOs is applied in a manner that protects the environment and public health. The multitude of environmental risks associated with sprayfields should be comprehensively evaluated.

Rather than allowing manure to be sprayed onto fields, EPA should require that manure that is land applied be injected or incorporated into the soil. Manure should be applied at the rate at which it can be absorbed, and the rate should be based on the most limiting nutrient–whether that is nitrogen or phosphorus–found in recent soil tests. Manure should not exceed safe levels of pathogens, metals, salts, or antibiotics. Manure application should be prohibited in sensitive areas, including floodplains, wetlands, areas that drain into groundwater and drinking water sources, areas close to waterbodies, and highly erodible lands. Finally, manure should not be applied to saturated or frozen ground.

All of the requirements listed above should be explicitly mandated in Clean Water Act NPDES permits, not just in a self-drafted, largely unenforceable nutrient management plan. EPA should also require feedlots meeting the current animal unit threshold to obtain a Clean Water Act permit. All the loopholes that have allowed the majority of large feedlots to evade permitting requirements for almost three decades should be eliminated.

CONTROL ALL CAFO POLLUTION

Control All Surface Water Pollution EPA's primary focus on direct discharges into surface water ignores the harm from the lagoon and sprayfield system on air quality, even when air pollutants degrade surface water quality. Up to 80 percent of a lagoon's nitrogen escapes into the air either from the lagoon or during land application as ammonia, which is then deposited into streams or coastal waters and causes fish kills and algal blooms.[7]

The agency also directs little regulatory attention to groundwater quality, though seepage from lagoons and sprayfields is a major public health concern. In many places, groundwater connects with surface water or is used for drinking water. Numerous studies have found groundwater impacts from the use of lagoons due to events such as wet/dry cycles, worms, roots, and freeze/thaw cycles.[8] In 1996, the Centers for Disease Control linked the high nitrate levels in Indiana well water near feedlots to spontaneous abortions in humans.[9] EPA should require monitoring and controls to prevent groundwater contamination of surface water.

EPA Should Address All Clean Water Act Pollutants The regulatory action focuses almost exclusively on nutrients, ignoring resistant bacteria, antibiotic residues, and other pollutants in manure than can cause gastroenteritis and other illnesses. Though swine manure contains 100 to 10,000 times the number of pathogens in crop-applied hog waste than are allowed in treated human waste, lagoons are not designed to reduce concentrations of these pathogens.[10] Yet EPA's proposed standards for land application do not even address pathogens. EPA should set limits for pathogens and heavy metals in land-applied waste, as it does now for sewage sludge, and also require reductions in the levels of other pollutants. Discharges from land application areas should be considered violations of a Clean Water Act permit.

In addition to ensuring that the technologies that the agency recommends do not harm surface water, directly or indirectly, the agency should also provide an incentive to facilities that take proactive steps to minimize other impacts on the environment. Under this approach, multi-media permit holders that agree to monitor and control all discharges into air, water, and groundwater in advance of federal requirements would obtain benefits like a longer compliance period or a longer permit term.

Finally, EPA should join other federal agencies in a comprehensive examination of the multiple problems generated by concentrated, industrialized animal production systems. This review should include the costs and risks imposed on society and the federal subsidies expended in promoting these systems. Where EPA lacks legal authority under the Clean Water Act to address CAFO pollution, EPA should evaluate other legal avenues, including use of the Safe Drinking Water Act and the Clean Air Act.

ENDNOTES

Chapter 1—Factory Farm Pollution is a Growing Problem

1. J. Mason and P. Singer, *Animal Factories: The Mass Production of Animals for Food and How It Affects the Lives of Consumers, Farmers, and the Animals Themselves* (New York: Cronin Publishers, 1980).

2. Minority Staff of the U.S. Senate Committee on Agriculture, Nutrition and Forestry, *Animal Waste Pollution in America: An Emerging National Problem*, Washington, D.C. (December 1997), p. 1.

3. Donald L. Pfost and Charles D. Fulhage, Department of Agricultural Engineering, "Lagoons for Storage/ Treatment of Dairy Waste," Water Quality Initiative, Publication WQ 304, University of Missouri, Columbia, Missouri (October 1, 1993).

4. In Iowa, the largest lagoon is a 15,000 head swine finishing operation that holds 45 million gallons and is 7.5 acres. Source: Linda Appelgate, Iowa Environmental Council (November 25, 1998), quoting information from the Iowa Attorney General. In Oklahoma, a typical lagoon for a 10,000 head swine finishing operation holds 20 million gallons or more, and is about 5.7 acres. Source: Kathy Martin, Professional Engineer, Oklahoma (November 24, 1998).

Community Health and Socioeconomic Issues Surrounding Concentrated Animal Feeding Operations

Kelley J. Donham,[1] Steven Wing,[2] David Osterberg,[1] Jan L. Flora,[3] Carol Hodne,[1] Kendall M. Thu,[4] and Peter S. Thorne[1]

[1]College of Public Health, The University of Iowa, Iowa City, Iowa, USA; [2]Department of Epidemiology, University of North Carolina, Chapel Hill, North Carolina, USA; [3]Department of Sociology, Iowa State University, Ames, Iowa, USA; [4]Department of Anthropology, Northern Illinois University, DeKalb, Illinois, USA

A consensus of the Workgroup on Community and Socioeconomic Issues was that improving and sustaining healthy rural communities depends on integrating socioeconomic development and environmental protection. The workgroup agreed that the World Health Organization's definition of health, "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity," applies to rural communities. These principles are embodied in the following main points agreed upon by this workgroup. Healthy rural communities ensure *a*) the physical and mental health of individuals, *b*) financial security for individuals and the greater community, *c*) social well-being, *d*) social and environmental justice, and *e*) political equity and access. This workgroup evaluated impacts of the proliferation of concentrated animal feeding operations (CAFOs) on sustaining the health of rural communities. Recommended policy changes include a more stringent process for issuing permits for CAFOs, considering bonding for manure storage basins, limiting animal density per watershed, enhancing local control, and mandating environmental impact statements. *Key words:* animal confinements, environmental impact, livestock, mental health, odor, poultry, right-to-farm legislation, swine. *Environ Health Perspect* 115:317–320 (2007). doi:10.1289/ehp.8836 available via *http://dx.doi.org/* [Online 14 November 2006]

Background and Recent Developments

The agricultural community in areas of large-scale livestock production. The rural and agricultural community has changed dramatically over the past half century. The trends include an overall reduction in the number of farms, an increase in size of the farms, and economic concentration in the industries that supply inputs and purchase commodities from farms. The structure of the pork industry has also changed dramatically during the past three decades. The number of hog producers in the United States was more than 1 million in the 1960s but fell to about 67,000 by 2005 [U.S. Department of Agriculture (USDA) 2005]. Although the total inventory of hogs has changed little over the years, the structural shift toward concentration has been dramatic with the 110 largest hog operations in the country, each of which has over 50,000 hogs, now constituting 55% of the total national inventory (USDA 2005). The swine industry includes the following types of producers: small independent "niche" operators who often market organic pork to local markets, traditional independent operators, and large family or unaffiliated corporations. Former independent operators are increasingly raising livestock on contract for larger corporations. According to the U.S. Government Accountability Office, in 1999 contract production constituted more than 60% of total hog output and 35% of the cattle market (U.S. Government Accountability Office 2005), while poultry is produced almost entirely via contracts. Corporate producers or incorporated family-based operations employ from a few individuals to several hundred. Most often upper management and many of the workers in such operations do not come from or live in the vicinity of concentrated animal feeding operations (CAFOs).

The community of people living in the region of large-scale livestock production consists of residents of small family farms (that may or may not produce pork), workers at the production facilities, rural nonfarm residents, and the residents of neighboring towns. The challenges CAFOs place on neighbors were extensively reviewed in 1996 (Thu 1996) and again in a 2002 report accompanied by a number of consensus recommendations for the future of the hog industry in Iowa (Iowa State University and University of Iowa 2002). A number of additional scientific reviews and symposia summaries have been issued (Centers for Disease Control and Prevention 1998; Cole et al. 2000; Donham 2000; National Academy of Sciences 2002; Schiffman et al. 2000; Thu 2002).

Economic health. Economic concentration of agricultural operations tends to remove a higher percentage of money from rural communities than when the industry is dominated by smaller farm operations, which tend to circulate money within the community. Goldschmidt (1978) documented this as early as 1946 in California, one of the first states where industrialized agriculture developed. Specifically, he compared two agricultural communities, one dominated by larger industrialized farms with absentee ownership and a high percentage of hired farm labor, and the other community was dominated by smaller owner-operated farms. The latter community was found to have a richer civic and social fabric with more retail purchases made locally and with income more equitably distributed. A similar study by MacCannell (1988) of comparable types of communities found that the concentration and industrialization of agriculture were associated with economic and community decline locally and regionally. Studies in Illinois (Gomez and Zhang 2000), Iowa (Durrenberger and Thu 1996), Michigan (Abeles-Allison and Conner 1990), and Wisconsin (Foltz et al. 2002) demonstrated decreased tax receipts and declining local purchases with larger operations. A Minnesota study (Chism and Levins 1994) found that the local spending decline was related to enlargement in scale of individual livestock operations rather than crop production. These findings consistently show that the social and economic well-being of local rural communities benefits from increasing the number of farmers, not simply increasing the volume of commodity produced (Osterberg and Wallinga 2004).

Physical health. There have been more than 70 papers published on the adverse health effects of the confinement environment on swine producers by authors in the United States, Canada, most European countries, and Australia (Cormier et al. 1997; Donham 2000; Donham et al. 1977, 1982, 1986, 1990, 2002; Kirkhorn and Schenker 2002; Kline et al. 2004; Preller et al. 1995; Reynolds et al. 1996; Rylander et al. 1989; Schiffman

Received 10 November 2005; accepted 13 November 2006.

et al. 1995; Schwartz et al. 1992; Thu et al. 1997; Wing and Wolf 2000). It is clear that at least 25% of confinement workers suffer from respiratory diseases including bronchitis, mucus membrane irritation, asthmalike syndrome, and acute respiratory distress syndrome. Recent findings substantiate anecdotal observations that a small proportion of workers experience acute respiratory symptoms early in their work history that may be sufficiently severe to cause immediate withdrawal from the work place (Dosman et. al. 2004). An additional acute respiratory condition, organic dust toxic syndrome, related to high concentrations of bioaerosols in livestock buildings occurs episodically in more than 30% of swine workers.

Environmental assessments of air quality inside livestock buildings reveal unhealthful concentrations of hydrogen sulfide, ammonia, inhalable particulate matter, and endotoxin (Iowa State University and University of Iowa 2002; Schenker et al. 1998). While there is less information on adverse effects among residents living in the vicinity of swine operations, that body of literature has been growing in recent years (Avery et al. 2004; Bullers 2005; Centers for Disease Control and Prevention 1998; Kilburn 1997; Merchant et al. 2005; Mirabelli et al. 2006a; Reynolds et al. 1997; Schiffman et al. 1995, 2000; Thu 2002; Thu et al. 1997; Wing and Wolf 2000).

Thu et al. (1997) documented excessive respiratory symptoms in neighbors of large-scale CAFOs, relative to comparison populations in low-density livestock-producing areas. The pattern of these symptoms was similar to those experienced by CAFO workers. Wing and Wolf (2000) and Bullers (2005) found similar differences in North Carolina. A case report associated with hydrogen sulfide exposure from a livestock processing facility in South Sioux City, Nebraska, revealed excessive diagnoses of respiratory and digestive disturbances in people living nearby (Campagna et al. 2004). Schiffman and colleagues reported that neighbors of confinement facilities experienced increased levels of mood disorders including anxiety, depression, and sleep disturbances attributable to exposures to malodorous compounds (Schiffman et al. 1995, 2000). Avery et al. (2004) found lower concentration and secretion of salivary immunoglobulin A among swine CAFO neighbors during times of moderate to high odor compared with times of low or no odor, suggesting a stress-mediated physiologic response to malodor (Shusterman 1992).

Community environmental air quality assessments have shown concentrations of hydrogen sulfide and ammonia that exceed U.S. Environmental Protection Agency (U.S. EPA) and Agency for Toxic Substances and Disease Registry recommendations (Reynolds et al. 1997). A recent study revealed that children living on farms raising swine have an increased risk for asthma, with increasing prevalence of asthma outcomes associated with the increased size of the swine operation (Merchant et. al. 2005). Children in North Carolina attending middle schools within 3 miles of one or more swine CAFOs and children attending schools where school staff report CAFO odors in school buildings were found to have a higher prevalence of wheezing compared with other middle school children (Mirabelli et al. 2006a, 2006b). It should be noted that these studies (although controlled) lack contemporaneous exposure assessment and health outcomes ascertainment. Additional research to include environmental exposure data related to biomarkers of response is needed.

Mental health. Living in proximity to large-scale CAFOs has been linked to symptoms of impaired mental health, as assessed by epidemiologic measures. Greater self-reported depression and anxiety were found among North Carolina residents living near CAFOs (Bullers 2005; Schiffman et al. 1995). This finding was not corroborated in a small study by Thu et al. (1997) of depression among people living near to or far from CAFOs. However, it should be noted that the study of Thu et al. differed in that residents were not asked to report on their mental state during an actual odor episode as was the case in the study by Schiffman et al. (1995).

Greater CAFO-related posttraumatic stress disorder (PTSD) cognitions have been reported among Iowans living in an area of CAFO concentration compared with Iowans living in an area of a low concentration of livestock production (Hodne CJ, unpublished data). PTSD cognitions were consistent with interviewees' multiple concerns about the decline in the quality of life and socioeconomic vitality caused by CAFOs, in areas of CAFO concentration with declining traditional family farm production.

Social health. One of the most significant social impacts of CAFOs is the disruption of quality of life for neighboring residents. More than an unpleasant odor, the smell can have dramatic consequences for rural communities where lives are rooted in enjoying the outdoors (Thu 2002). The encroachment of a large-scale livestock facility near homes is significantly disruptive of rural living. The highly cherished values of freedom and independence associated with life oriented toward the outdoors gives way to feelings of violation and infringement. Social gatherings when family and friends come together are affected either in practice or through disruption of routines that normally provide a sense of belonging and identity—backyard barbecues and visits by friends and family. Homes are no longer an extension of or a means for enjoying the outdoors. Rather, homes become a barrier against the outdoors that must be escaped.

Studies evaluating the impacts of CAFOs on communities suggest that CAFOs generally attract controversy and often threaten community social capital (Kleiner AM, Rikoon JS, Seipel M, unpublished data; 2000; Ryan VD, Terry Al, Besser TL, unpublished data; Thu 1996). The rifts that develop among community members can be deep and long-standing (DeLind 1998). Wright et al. (2001), in an in-depth six-county study in southern Minnesota, identified three patterns that reflect the decline of social capital that resulted from the siting of CAFOs in all six rural communities they studied: *a*) widening gaps between CAFO and non-CAFO producers; *b*) harassment of vocal opponents of CAFOs; and *c*) perceptions by both CAFO supporters and CAFO opponents of hostility, neglect, or inattention by public institutions that resulted in perpetuation of an adversarial and inequitable community climate. Threats to CAFO neighbors have also been reported in North Carolina (Wing 2002). Clearly, community conflict often follows the siting of a CAFO in a community. What is not known is if community conflict resulting from the siting or presence of CAFOs has an impact on the ability of communities to act on other issues.

Environmental injustice. Disproportionate location of CAFOs in areas populated by people of color or people with low incomes is a form of environmental injustice that can have negative impacts on community health (Wing et al. 2000). Several studies have shown that a disproportionate number of swine CAFOs are located in low-income and nonwhite areas (Ladd and Edwards 2002; Wilson et al. 2002; Wing et al. 2000) and near low-income and nonwhite schools (Mirabelli et al. 2006a, 2006b). These facilities and the hazardous agents associated with them are generally unwanted in local communities and are often thrust upon those sectors with the lowest levels of political influence. CAFOs are locally unwanted because of their emissions of malodor, nutrients, and toxicants that negatively affect community health and quality of life. Low-income communities and populations that experience institutional discrimination based on race have higher susceptibilities to CAFO impacts due to poor housing, low income, poor health status, and lack of access to medical care.

Failure of the political process. In 2005 the U.S. Government Accountability Office issued a report on the effectiveness of U.S. EPA efforts in meeting its obligations to regulate concentrated animal feeding operations (U.S. Government Accountability Office 2005). The report identified two major flaws:

a) allowing an estimated 60% of animal feeding operations in the United States to go unregulated, and *b*) lack of federal oversight of state governments to ensure they are adequately implementing required federal regulations for CAFOs. Additionally, many states have not taken a proactive stance to comply with the U.S. EPA regulations. Therefore, the concentration of livestock production, most noted by CAFO-style production, has continued to expand in most states. This has resulted in many rural communities and individuals taking action on their own, through local ordinances or litigation, as they have not been able to find access through usual governmental channels.

Several studies have found that property values decrease when CAFOs move into a community (Abeles-Allison and Conner 1990; Hamed et. al. 1999; Herriges et al. 2003; Palmquist et al. 1997). Neighbors of CAFOs are interested in preventing loss of property value, loss of their homes and land, forced changes in their life style, adverse changes in their communities, and threats to their health (Thu and Durrenberger 1998). The democratic process offers citizens access to lawmakers, to the courts, and to direct action to redress their grievances. However, the legislative process in many states has often been unresponsive to citizen wishes concerning CAFOs (Cantrell et al. 1996). For example, 13 states have enacted laws that inhibit citizens from speaking freely about agriculture if it is disparaging. A representative example can be seen in a South Dakota law that defines disparagement as

> dissemination in any manner to the public of any information that the disseminator knows to be false and that states or implies that an agricultural food product is not safe for consumption by the public or that generally accepted agricultural and management practices make agricultural food products unsafe for consumption by the public. (South Dakota Codified Laws 2006)

All 50 states have some form of right-to-farm legislation. This legislation serves to protect farming operations from zoning laws or lawsuits that would overly restrict the ability of farmers to do business (Chapin et al. 1998; Hamilton 1998). Right-to-farm legislation varies from state to state but may include laws that prevent zoning from limiting farm practices that have substantial detrimental effects on neighbors, such as CAFO production. Right-to-farm laws may also include preemption of other actions of local government that normally could limit what businesses are allowed to do, known as home rule. For example, the Iowa Supreme Court has ruled that county governments cannot use home rule powers or protection of public health to promulgate laws that are more restrictive than state laws currently in force (Worth County Friends of Agriculture v. Worth County, Iowa, 2004). Although local governmental action has been limited by the bias toward agricultural producers, individual actions have not. Courts in several states have ruled that right-to-farm laws give only limited protection from nuisance action. The Iowa Supreme Court in June 2004 found that CAFO immunity provisions written in Iowa statutes were unconstitutional (Gacke v. Pork XTRA 2004). A district court in Illinois granted a temporary injunction stopping the construction of a nearby CAFO based on an anticipatory nuisance premise (Nickels et al. vs. Burnett 2002) that such a facility would constitute reasonable interference with neighbors' quality of life.

Most states have enacted some forms of environmental laws aimed at protecting the environment from agricultural discharges or emissions. One form of these laws requires establishment of manure management plans. Typically, these laws call for certain sizes of operations to apply for permits. These permits may include the filing of a manure management plan, which calls for a plan for CAFO operators to manage their manure in a manner to prevent water and soil pollution. However, there is little if any performance inspection or enforcement of these plans (Jackson et al. 2000). Nonenforcement is primarily due to the lack of personnel and technical resources at state environmental agencies. For example, some states may have 2,000 or more such operations but not enough staff to efficiently process permit applications, much less get out into the field to inspect performance of these operations.

Workshop Recommendations

Priority research needs. **Community health studies**. Although sufficient research supports actions to protect rural residents from the negative impacts of CAFOs on community health, additional research could be conducted to further delineate mechanisms of effects and impacts on susceptible subgroups. These areas include psychophysiologic impacts of malodor; impacts of malodor on mental health and quality of life; and respiratory impacts of bioaerosol mixtures, especially among asthmatics, children, and the elderly. Wider and more effective application of community-based participatory research will be important to advance research in these areas.

Sustainability of livestock production. Federal funding for agricultural research should be reoriented to promote innovation in sustainable livestock production.

Translation of science to policy. Requirements for issuing permits for CAFOs should include increased protections for health and the environment including the following:

- CAFOs should be sited and issued permits on the basis of total animal density allowed in a given watershed as determined by the carrying capacity.
- Environmental impact statements should be mandated for all new CAFOs. These should include environmental health, social justice, and socioeconomic issues.
- Decisions to issue permits for CAFOs should be considered in public meetings and decided at the local level.
- CAFOs should be regulated using standards applied to general industry based on the level of emissions and type of waste handling.
- Permits for manure storage basins should require bonding for performance and remediation.
- The current state of knowledge of community impacts of CAFOs warrants support for the American Public Health Association recommendation for a moratorium on all new CAFO construction.

The Effect of Environmental Odors Emanating From Commercial Swine Operations on the Mood of Nearby Residents

SUSAN S. SCHIFFMAN,[1] ELIZABETH A. SATTELY MILLER, MARK S. SUGGS AND BREVICK G. GRAHAM

Department of Psychiatry, Duke University Medical Center, Durham, NC 27710

[Received 1 June 1994; Accepted 22 December 1994]

ABSTRACT: The effect of environmental odors emanating from large-scale hog operations on the mood of nearby residents was determined using the POMS (Profile of Mood States). The scores for six POMS factors and the TMD (total mood disturbance score) for 44 experimental subjects were compared to those of 44 control subjects who were matched according to gender, race, age, and years of education. The results indicated a significant difference between control and experimental subjects for all six POMS factors and the TMD. Persons living near the intensive swine operations who experienced the odors reported significantly more tension, more depression, more anger, less vigor, more fatigue, and more confusion than control subjects as measured by the POMS. Persons exposed to the odors also had more total mood disturbance than controls as determined by their ratings on the POMS. Both innate physiological responses and learned responses may play a role in the impairment of mood found here.

KEY WORDS: Odors, Mood, Pollution, Swine, Psychological effects, Brain-immune connections.

INTRODUCTION

Odors have always been associated with livestock and poultry production [24,55,72,78,79,86,88]. However, odors have recently become a major challenge for the livestock industry due to the present trend toward intensive livestock operations in which large numbers of animals are confined on small areas of land [8,19,51,69,120,122–124,127]. Environmental odors can have a considerable impact upon a population's general well-being, affecting both physiological and psychological status [93,103,128]. Miner [70] concluded that unpleasant odors can affect well-being by "eliciting unpleasant sensations, triggering possible harmful reflexes, modifying olfactory function and other physiological reactions." He also reported that annoyance and depression can result from exposure to unpleasant odors along with nausea, vomiting, headache, shallow breathing, coughing, sleep disturbances, and loss of appetite. Odorous compounds associated with livestock production that are at low concentrations but above odor thresholds are still likely to generate complaints [18,52].

Neutra et al. [77] studied people living near hazardous waste sites, and found that those complaining of odors had a higher number of symptoms than those who did not complain, regardless of proximity to the site. Shusterman [103] reviewed several studies [e.g., 4,37,47,95–97] in which there was a direct relationship between nontoxicological odors and symptomatology. In a variety of settings (municipal, agricultural, and industrial) where airborne toxicants were negligible and odors had been complained about, there was a strong relationship between reported symptoms and odor exposure.

The sources of the odors from swine operations include ventilation air released from swine buildings, waste storage and handling systems including lagoons, and land application of manure to fertilize fields [15]. The odors are produced by a mixture of fresh and decomposing feces, urine, and spilled feed. The more objectionable odors appear to result from anaerobic microbial decomposition of the feces [90]. A broad range of compounds has been identified in livestock manure including volatile organic acids, alcohols, aldehydes, amines, fixed gases, carbonyls, esters, sulfides, disulfides, mercaptans, and nitrogen heterocycles [30,70,71,73,104]. It is likely that the mixture of compounds rather than a single component contributes to the mood changes measured here.

A variety of techniques for reducing odor have been evaluated, but overall the results have been disappointing [123]. Aerobic treatment has been found to be the most effective method to date for deodorizing pig slurry [2,9,11,54,105–107,127]. Odorous compounds can be carried in a plume, and the concentration of these compounds in the plume may not be significantly reduced at distances of 750–1500 feet or more downwind from a source [36]. Dispersion models have been developed to predict the peak and mean concentrations of odors and environmental air pollutants at various distances from the source [20,36,46,80], and complaint patterns at a variety of distances from an odor source have been studied [21].

The purpose of the present study was to use a well-standardized scale to quantify objectively the moods of people living near large-scale hog operations who are exposed to odors. The Profile

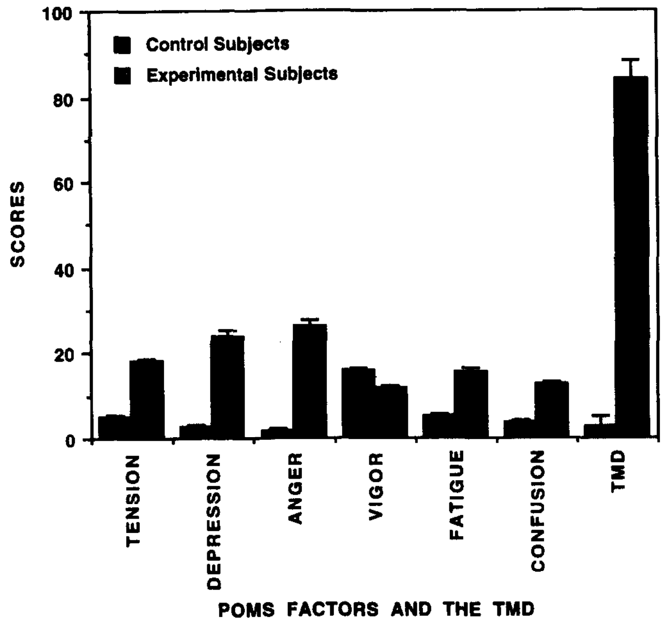

FIG. 1. Mean POMS scores of each factor and the total mood disturbance score (TMD) for experimental and control subjects.

of Mood States questionnaire [65,66] was used to assess mood in persons living near swine operations and in control subjects. This scale has been used extensively in many situations including previous studies that evaluated the effect of pleasant odors on mood [98,99]. The study of mood in persons exposed to odors is important because negative mood has been found to play a role in immunity [16,81,111,125] and can potentially affect subsequent disease.

METHOD

Subjects

Forty-four experimental (persons living near hog operations) and 44 control subjects participated in the study; all of the subjects were residents of North Carolina. The subjects in the two groups (control and experimental) were matched according to gender, race, age, and years of education. Twenty-six subjects in each group were female, and 18 subjects were male. The mean age of the experimental group was 52.0 ± 13.4 years, and the mean age of the control group was 51.7 ± 8.3 years. The experimental group had an average of 12.8 ± 3.3 years of education, and the control group had an average of 13.0 ± 3.1 years of education. The majority of subjects in both groups were employed as skilled laborers. The groups were also matched for the number of chronic illnesses that they had experienced; 14 subjects in each group suffered from allergies. The experimental group lived an average of 5.3 ± 6.5 years near hog operations, with a maximum of 27 years and a minimum of 8 months.

Materials

Subjects in both groups signed a consent form and filled out a general information questionnaire that asked demographic, medical, and dietary information. Mood ratings were obtained from all subjects by filling out Profile of Mood States questionnaires (POMS). The POMS was chosen to measure the impact of the hog odors on mood because it has been shown to be sensitive to transient mood shifts [65,66]. There are 65 adjectives/feelings on the POMS, most of which may be grouped into one of six factors: tension/anxiety, depression/dejection, anger/hostility, vigor/activity, fatigue/inertia, and confusion/bewilderment. Each feeling is rated on a scale from 0 (not at all) to 4 (extremely). The feelings for each factor were added together, according to the POMS manual, to get a total score for that factor. The totals for each factor were then added together, with the vigor/activity factor weighted negatively, to derive a total mood disturbance score (TMD).

Procedure

At the beginning of the study, all subjects filled out the consent form as well as the general information questionnaire. Experimental subjects were asked to complete one POMS questionnaire per day on 4 days when the hog odor could be smelled. The 4 days did not have to be consecutive, and subjects had as long as needed to complete all four POMS questionnaires. Control subjects were asked to complete one POMS per day for 2 days. All subjects were asked to complete the POMS based upon how they recently had been feeling, including at that particular time.

RESULTS

Figure 1 shows the means and standard errors for the experimental group vs. the control group for all POMS factors and the TMD. An analysis of variance was performed to determine if there were any main effects or interactions between group (control or experimental) and gender for each POMS factor and the TMD. Subjects were nested within group and gender. Table 1 gives the results of the analysis. There was a significant difference (at $p < 0.0001$ level) between the control group and the experimental group for all of the POMS factors as well as the TMD. The experimental group had significantly worse scores than the control group for every factor and the TMD. There was a significant main effect of gender for the anger factor, $p < 0.01$, and a significant gender × group interaction for the confusion factor, $p < 0.005$. Males had significantly higher (worse) anger scores than the females. For the confusion factor, scores for experimental males were significantly higher than those for experimental females and control males and females; scores for ex-

perimental females were significantly higher than those of control males and females. Only scores for control males and control females were not significantly different from each other.

DISCUSSION

The main finding of this study is that persons living near the swine operations who experienced the odors had significantly more tension, more depression, more anger, less vigor, more fatigue, and more confusion than control subjects as measured by the Profile of Mood States (POMS). In addition, persons exposed to the odors also had more total mood disturbance than controls as determined by their ratings on the POMS. These findings are consistent with previous studies in which odors of varying hedonic properties have been found to affect mood [7,32,93,98,99,103,128]. In other settings, odors have also been reported to affect cognitive performance [57,62] and physiological responses including heart rate and electroencephalographic patterns [56,58–61,64].

Possible Causes of Altered Mood

A variety of factors may play a role in the altered mood of residents who are exposed to odors from nearby swine operations. These factors include: a) the unpleasantness of the sensory quality of the odor; b) the intermittent nature of the stimulus; c) learned aversions to the odor; d) potential neural stimulation of immune responses via direct neural connections between odor centers in the brain and lymphoid tissue; e) direct physical effects from molecules in the plume including nasal and respiratory irritation; f) possible chemosensory disorders; and g) unpleasant thoughts associated with the odor.

At moderate to high odor intensities, most persons rate the quality of the odor from the swine operations as unpleasant. The odor is not only perceived while breathing outdoor air but can also be perceived within the homes of nearby residents due to air circulation through open windows and air conditioning systems. The odorant molecules can be absorbed by clothing, curtains, and building materials which act as a sink; the molecules are then released slowly over a period of time from textiles and other materials after the plume has passed the house increasing the temporal exposure to the odor. The intermittent nature of the odors may also be a factor in the mood of persons living near swine operations. Studies of noise have shown that intermittent stimuli produce more arousal and are more likely to affect performance negatively than constant noise [22]. This is due in part to feelings of lack of control over the timing of unwanted transient stimuli. Differences in responses to irregular noise and predictable noise are not only found in humans but in animals as well [27].

Learning (via conditioning) may also play a role in the psychological and physical effects from odors. Conditioned aversions to odors are well-documented in the scientific literature [31,38,44,67,75,119]. Aversive conditioning can occur if environmental odors are associated with an irritant or other toxic chemicals such as pesticides [103]. In addition, conditioned alterations in immune responses using chemosensory (smell and taste) stimuli provide strong evidence for functional relationships between chemosensory centers in the brain and the immune system [1]. Both conditioned immunosuppression and immunoenhancement have been reported using chemosensory stimuli as the conditioned stimulus [1,31,42,43,109,110].

There is a potential for unpleasant odors to influence physical health without involvement of learning or conditioning due to the direct anatomical connections between the olfactory system and the immune system. Brain structures broadly involved in smell [12,35,39,49,82–85,101,112,114–116] can modulate immune responses, especially via the integrated circuitry of the limbic cortex, limbic forebrain, hypothalamus, and brain stem [13,25,26,48,50,76,92,118]. These studies provide an anatomical basis for the possibility that sensory stimulation of the limbic forebrain, hypothalamus, and other odor projection areas of the brain can directly alter immune status. The links between the brain and the immune system are bidirectional [108] so that immune responses can also affect odor centers in the brain [10,94].

Components in the odorous plume may also have direct physical effects on the body. Some of the odorant molecules implicated in malodor from hog farms can cause nasal and respiratory irritation [15,23,29,70,103]. Nasal irritation has been shown to elevate adrenalin [3] which may contribute to feelings of anger and tension. The volatile organic compounds (VOCs) responsible for odors may also be absorbed directly by the body (into the bloodstream and fat stores) via gas exchange in the lungs. Many VOCs that are inhaled into the lungs are known to reach blood and adipose tissue [4,6,53,63,126]. Persons who have absorbed odorants through the lungs can sometimes smell the odor for hours after exposure due to slow release of the odorants from the bloodstream into expired air activating the olfactory receptors. Volatile organic compounds are well known to be eliminated in breath after exposure [89,121], and methods for measuring VOCs in breath have been described [87,89,117]. It is also theoretically possible for some compounds in the plume to be transmitted to the brain via olfactory neurons because a range of agents have been found to reach the brain through the nasal route [28,33,45,74,91,102]. Endotoxin, a component of bacteria, found in the swine house air environment [29], may also be present in the plume. Persons with olfactory dysfunction caused by factors unrelated to swine odor such as concurrent medical conditions, drugs they are taking, or pesticide exposure [100], may find the odor even more objectionable due to their abnormal smell functioning.

Finally, odors may alter mood because they are associated with unpleasant thoughts. Some persons consider the smell from hog farms a taboo odor, which they should not have to endure. For other persons, the odors generate environmental concerns, fear of loss of use and value of property, or a conviction that odors interfere with their enjoyment of life and property. Livestock odors may also be considered inappropriate in certain environments. Odor complaints have been reported to be most frequent among new, large, or recently expanded facilities that are located near existing residences or shopping areas [70,113]. Part of the motivation for odor complaints may be the increased awareness of other environmental agents, such as tobacco smoke, which is malodorous and is considered dangerous to one's health.

Lack of Legislation to Monitor Odor Levels

Odors are not regulated by the Clean Air Act because they are generally regarded as nontoxic [15]. In addition, nonfederal legislation for controlling odors from swine operations is imprecise or lacking in many states. For example, North Carolina Administrative Code Title 15A-02D.0522(c) specifies that "a person shall not cause, allow, or permit any plant to be operated without employing suitable measures for the control of odorous emissions including wet scrubbers, incinerators, or such other devices as approved by the Commission." This regulation is subjective because it gives no provision for either emission standards or ambient air standards. Under this regulation, it appears that as long as a plant has suitable control devices, it is lawful for them to emit offensive odors. In addition, it is unclear what type of operation is to be considered a plant. In contrast, Connecticut's laws on odor emissions set specific standards, as shown in Table

* Exceeds the Threshold Limit Value adopted by the American conference of Industrial Hygienists for 1971.

2 [17]. Similarly, in the Netherlands, regulations are based on accurate records of manure production and bookkeeping, and violations are considered a criminal offense [14].

Regulations need to be established in all 50 states because animal wastes contain high levels of volatile organic compounds that can produce strong odors. The annual production of animal manure in the US in 1987 was estimated at 1.5 billion tons per year, which is enough to apply one ton per acre on each of the 1.9 billion acres of the continental US [14].

Persons exposed to high levels of odor from agricultural sources generally use nuisance laws to protect their rights. However, there are many caveats in nuisance laws that consider a) which party was there first; b) the character of the neighborhood; c) the reasonableness of the use of the land; and d) the nature and degree of the interference [40]. In addition, most states have right-to-farm statutes that supersede nuisance laws in some circumstances [40]. Strong support against nuisance suits involving agriculture is not specific to the United States but is found in the laws of many countries [5]. Suits against agricultural activities based on odor nuisance are harder to prove than those based on water pollution [68]. In addition, nuisance claims fall under state laws, while suits on water pollution are most frequently filed in federal courts.

Conclusion

Odors from swine operations have a significant negative impact on mood of nearby residents. Methods must be found to lower the concentrations of compounds responsible for the odors so that swine operations do not affect the emotional lives of residents in the local vicinities. This may involve legislation that sets standards for odor. In addition, technological solutions must be found to reduce the concentrations of the offending compounds.

Notice

The U.S. Environmental Protection Agency through its Office of Research and Development funded and managed the research described here. It has been subjected to the Agency's review and has been approved for publication as an EPA document.

Foreword

The U.S. Environmental Protection Agency (EPA) is charged by Congress with protecting the Nation's land, air, and water resources. Under a mandate of national environmental laws, the Agency strives to formulate and implement actions leading to a compatible balance between human activities and the ability of natural systems to support and nurture life. To meet this mandate, EPA's research program is providing data and technical support for solving environmental problems today and building a science knowledge base necessary to manage our ecological resources wisely, understand how pollutants affect our health, and prevent or reduce environmental risks in the future.

The National Risk Management Research Laboratory (NRMRL) is the Agency's center for investigation of technological and management approaches for preventing and reducing risks from pollution that threaten human health and the environment. The focus of the Laboratory's research program is on methods and their cost-effectiveness for prevention and control of pollution to air, land, water, and subsurface resources; protection of water quality in public water systems; remediation of contaminated sites, sediments and ground water; prevention and control of indoor air pollution; and restoration of ecosystems. NRMRL collaborates with both public and private sector partners to foster technologies that reduce the cost of compliance and to anticipate emerging problems. NRMRL's research provides solutions to environmental problems by: developing and promoting technologies that protect and improve the environment; advancing scientific and engineering information to support regulatory and policy decisions; and providing the technical support and information transfer to ensure implementation of environmental regulations and strategies at the national, state, and community levels.

This publication has been produced as part of the Laboratory's strategic long-term research plan. It is published and made available by EPA's Office of Research and Development to assist the user community and to link researchers with their clients.

1. Introduction and Overview

The trend in animal production has shown a dramatic shift in the last 50-60 years from small family farms and grazing operations towards large commercial confinement operations. Since 1982, animal production at these facilities has nearly doubled while at the same time they have become more spatially concentrated (U.S. Department of Agriculture, National Resources Conservation Services (USDA-NRCS), 2000). Recently, the U.S. Department of Agriculture (USDA) reported that more than 80% of all livestock revenues are generated in confinement facilities that account for a scant 18% of all livestock operations (USDA-NRCS, 2002). In fact, more than 43% of all beef cattle, dairy cattle, swine, and poultry are raised in the largest two percent of operations (Goellehon *et al.*, 2001). The concentration of animals into confinement facilities poses many environmental challenges, among which pathogenic microorganisms of fecal origin are of concern.

The U.S. Environmental Protection Agency (USEPA) defines a concentrated animal feeding operation (CAFO) as an animal feeding facility that houses more than 1,000 animal units (AU), has 300 to 1000 AU but meets certain conditions, or is designated a CAFO by the state (USEPA, 2001). The number of animal units are based on an equivalent number of beef cattle. Therefore, 1,000 AU equals 1,000 beef cattle, 700 mature dairy cattle, 2,500 swine, 5,000 ducks, 10,000 sheep, 55,000 turkeys, or between 30,000 and 100,000 laying hens or broilers depending on the animal waste management system employed. According to National Resources Conservation Service (NRCS) estimates, 11,398 CAFOs (>1000 AU) were in operation in the U.S. in 1997, and comprised five percent of all livestock facilities (USDA-NRCS, 2002). These CAFOs were largely commercial operations (94%) with large revenues. Total agricultural sales for 97.9% of CAFO owners exceeded $500,000 per year. In comparison, non-commercial livestock facilities (intermediate or rural-residence farms) earned 22.3% of all livestock revenue, generating on average $18,500 per farm. Figure 1 shows the distribution of confined poultry, swine, dairy cattle, and feed cattle operations in the U.S. in 1997.

Animal agriculture results in the production of copious amounts of manure, much of which is ultimately used as fertilizer for crops or spread onto land. On a per weight basis, livestock animals produce between 13 and 25 times more manure than humans. Comparing the most recent U.S. census data and USDA livestock reports, it can be estimated that animals produce somewhere between 3 and 20 times more manure than people in the U.S. each year, as much as 1.2 – 1.37 billion tons (wet weight) (American Society for Microbiology (ASM), 1998; USEPA, 2003; USEPA, 2004). This is enough to cover a land mass the size of Rhode Island with more than twelve inches of manure. Even moderate livestock operations can produce as much manure as a small sized city. For example, a 2,500-head dairy cattle operation can produce a waste load similar to a city of 61,000 people. Two important differences are that livestock CAFO animal wastes can be as much as 100 times more concentrated than human wastes, and the treatment of human wastes is required by law prior to discharge into the environment (USEPA, 2001).

Animal wastes contain zoonotic pathogens, which are viruses, bacteria, and parasites of animal origin that cause disease in humans. Diseases that can be caused by zoonotic pathogens include Salmonellosis, Tuberculosis, Leptospirosis, infantile diarrheal disease, Q-Fever, Trichinosis, Cryptosporidiosis, and Giardiasis to name a few. These diseases typically present as mild

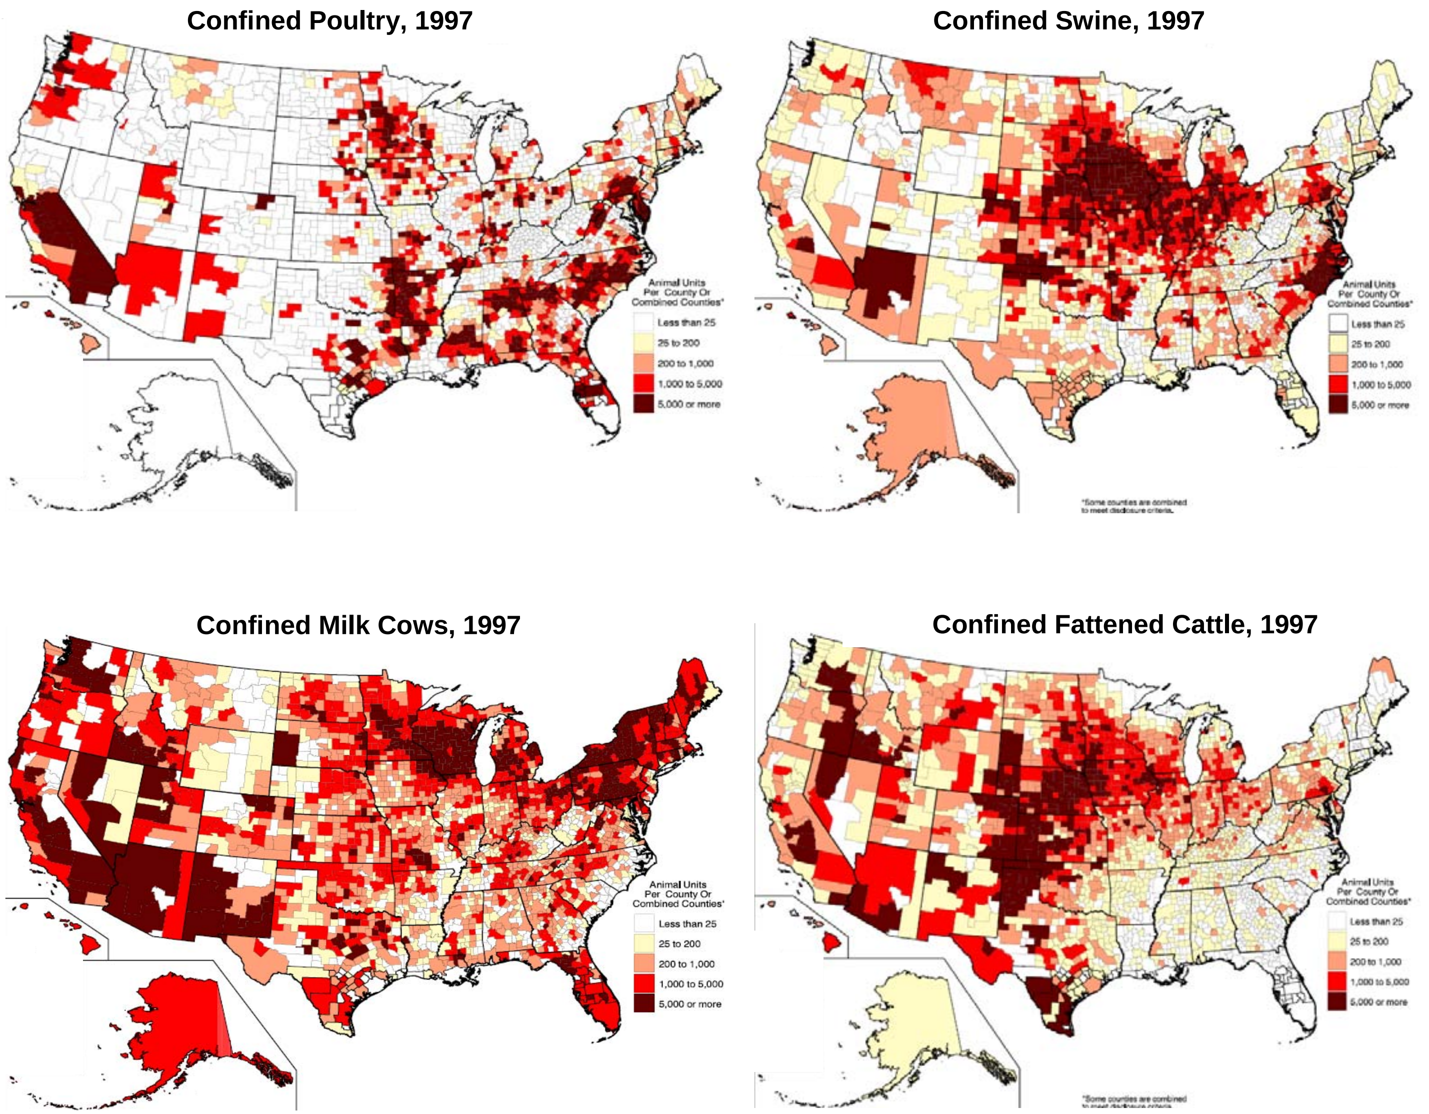

Figure 1. Confined swine, poultry, dairy cattle, and feed cattle per county in 1997 (adapted from USDA-NRCS, 2002).

diarrhea, fever, headaches, vomiting, and muscle cramps. In more severe cases, however, these diseases may cause meningitis, hepatitis, reactive arthritis, mental retardation, miscarriages, and even death, particularly in the immunocompromised. The dosing of livestock animals with copious amounts of antimicrobial agents for growth promotion and prophylaxis may promote antimicrobial resistance in pathogens, increasing the severity of disease and limiting treatment options for sickened individuals (Lee *et al.*, 1994; Marano *et al.*, 2000).

Zoonotic diseases from livestock animals, transmitted through air, water, and food, cause significant human suffering and economic losses in the U.S. every year (Schlech *et al.*, 1983; Besser *et al.*, 1993; MacKenzie *et al.*, 1994; Solo-Gabriele and Neumeister, 1996; Hoxie *et al.*, 1997; Mead *et al.*, 1999; Valcour *et al.*, 2002; Clark *et al.*, 2003). Increasing the concentration of animals in confinement facilities amplifies the potential for localized runoff and contamination, increasing the probability for accidental exposure of susceptible individuals. In fact, living near CAFO operations has been associated with significant deterioration in human health including increased gastrointestinal illness, headaches, sore throats, sinusitis, and childhood asthma (Wing and Wolf, 2000; Merchant *et al.*, 2005). There is increasing evidence that impoverished and nonwhite communities may be burdened with a disproportionate share of not only these negative health outcomes, but also pollution and offensive odors emanating from CAFO facilities (Wing *et al.*, 2000; Wilson *et al.*, 2002; Wing *et al.*, 2002). Based on studies in North Carolina, operations run by cooperate investors may be more likely to be concentrated in poor and nonwhite areas than operations run by independent growers (Wing *et al.*, 2000).

The USEPA recognizes the need to improve manure management practices at confined animal feeding operations (USEPA, 2003). Several other U.S. governmental entities, including the U.S. Department of Agriculture (USDA), U.S. Geological Survey (USGS), and Centers for Disease Control and Prevention (CDC), have also recognized the need for control of pathogens at CAFOs and have robust research and surveillance activities to improve the outcomes for public health and welfare in the U.S. Several recent advances in the fields of medicine, molecular microbiology, engineering, agronomy, and epidemiology are addressing issues pertinent to the control of pathogens from CAFOs at a rapid pace. However, reported literature and research activities can in some cases be divergent between some disciplines and repetitive between others. There is a lack of integration of both knowledge and skills necessary to drive the research in an appropriate direction. As stated by Landry and Wolfe (1999):

> *The range of disciplines conducting fecal bacteria research and the diverse nature of the literature are obstacles to application and synthesis of existing knowledge by animal waste managers and scientists.*

In this report, we synthesize the current state of knowledge regarding pathogen research as it relates to livestock CAFOs, including a summary of research ongoing at USDA and other federal agencies. Pathways for the release of zoonotic agents and antimicrobial-resistant bacteria endemic in animals raised in confinement and their potential to persist in different *milieus* are reviewed. We discuss the impact to the environment and public health and welfare posed by the release of these agents from CAFOs, as well as manure management practices that are employed to mitigate their release into the environment. The objectives of this review are to summarize pathogen issues with regard to livestock CAFOs and identify and discuss gaps in the research that need to be addressed to improve public health.

2. Pathogens

Livestock animals can harbor and shed viruses, bacteria, protozoan parasites, and helminthes that are pathogenic for humans, other domestic animals, and wildlife. Pathogens present in animal carcasses or shed in animal wastes may include rotaviruses, hepatitis E virus, *Salmonella* spp., *E. coli* O157:H7, *Yersinia enterocolitica, Campylobacter* spp., *Cryptosporidium parvum,* and *Giardia lamblia* to name a few (Sobsey *et al.*, 2002). These zoonotic pathogens can exceed millions to billions per gram of feces, and may infect humans through various routes such as contaminated air, contact with livestock animals or their waste products, swimming in water impacted by animal feces, exposure to potential vectors (such as flies, mosquitoes, water fowl, and rodents), or consumption of food or water contaminated by animal wastes (Schlech *et al.*, 1983; Bezanson *et al.*, 1983; Hawker *et al.*, 1998; Valcour *et al.*, 2002; Armand-LeFevre *et al.*, 2005). The consequences of infection by pathogens originating from animal wastes can range from temporary morbidity to mortality, especially in high-risk individuals. Antimicrobial use in animal agriculture may exacerbate the problem by increasing the resistance of these pathogens to therapeutic drugs used to treat human disease.

It has been estimated that 61% of all human pathogens and 75% of emerging human pathogens are zoonotic (Mahy and Murphy, 1998; Murphy, 1998; Taylor *et al.*, 2001; Woolhouse *et al.*, 2002). The overwhelming majority of these pathogenic zoonoses that commonly infect humans are related to animal husbandry practices. Table 1 lists some of the zoonotic pathogens that may be of concern in animal agriculture. Many of these pathogens are endemic in livestock and difficult to eradicate from the animals or their production facilities (Sobsey *et al.*, 2002). For instance, a study of healthy swine on eight farms in Iowa and North Carolina revealed greater than 90% incidence of *Campylobacter coli* in all three growth stages (nursery, grower, and finisher) (Wesley *et al.*, 1998). Similarly, the prevalence of *Salmonella* spp. and *Campylobacter jejuni* have been reported to be as high as 100% in poultry operations, *Yersinia enterocolitica* as high as 18% in swine operations, and *Giardia lamblia* and *Cryptosporidium* spp. as high as 100% in cattle operations (Olson, 2003). The primary reservoir for *E. coli* O157:H7 was determined to be healthy cattle in one study in Canada, although this bacterium is also endemic to swine and sheep (Jackson *et al.*, 1998). In the U.S., *E. coli* O157:H7 infection was widely distributed across all 13 states at an average rate of 1.61% of all cattle when tested in 1994 (Dargatz, 1996). At slaughter, the prevalence of *E. coli* O157:H7 in Scottish cattle may be greater than 13% (Low *et al.*, 2005). Fratamico *et al.*, (2004) tested 687 swine fecal samples from swine operations in 13 of the top 17 swine-producing states and determined that 70% of the samples were positive for shiga-toxin (*stx 1* and *stx 2*) genes. Due to the endemic nature of zoonotic pathogens in livestock, there is a clear need for appropriate management practices at livestock facilities that are protective of human health and the environment and firmly grounded in risk analyses.

The risk of contracting disease following exposure to livestock wastes is dependent on the properties of the infectious agent, the exposed individual, the route of exposure, and the dose. There are a wide range of infective doses for different pathogens as shown (Table 1). For instance, severe gastrointestinal illness may require the ingestion of millions of *Yersinia enterocolitica* bacteria, or as little as 5 to 10 *E. coli* O157:H7 cells (PHAC, 2005). The infectious doses listed in Table 1 were established based on infectivity studies in healthy individuals, and therefore, may not be particularly useful for establishing safe exposure limits for human health. Particularly susceptible individuals such as children, the elderly, or the immunocompromised, which represent nearly 25% of the U.S. population may succumb to infection at much lower doses than the general population (Naumova *et al.*, 2003). For instance, approximately 70% of the diarrhea-associated deaths in the U.S. each year occur among individuals 55 or older.

Regulatory limits on the concentrations of pathogens in the environment protective of human health have not been established. As such, pathogenic organisms are rarely monitored in waste streams from animal feeding operations. Difficulty in quantifying pathogens at relevant concentrations in environmental matrices, the large number of analytical tests that would be required to measure all of the zoonotic pathogens shed in livestock feces, and a lack of epidemiological data to establish appropriate and safe levels of pathogens in the environment have all led to this deficiency. Due to the difficulties in quantifying pathogens, indicators of fecal pollution, including coliform bacteria, fecal coliforms, *E. coli*, and/or Enterococci have been monitored in lieu of overt pathogens for more than 100 years (Smith, 1893; Allen *et al.*, 1952; Kirschner *et al.*, 2004; Byamukama *et al.*, 2005). Epidemiological evidence supports the relationship between the fecal indicator bacteria *E. coli* and enterococci and incidence of gastrointestinal illness following recreational water exposure, and provides the basis for local, state, and federal water quality regulations (USEPA, 1986). However, the works of several researchers has shown that these indicators are not reliable surrogates for many pathogens, including bacteria and most viruses and parasites (Seligmann and Reitler, 1965; Boring *et al.*, 1971; Wetzler *et al.*, 1979; Carter *et al.*, 1987; Geldreich, 1996; Ashbolt *et al.*, 2001; Grabow, 2001; Leclerc *et al.*, 2001; Tillett *et al.*, 2001; Hörman *et al.*, 2004; Harwood *et al.*, 2005). New approaches for detecting pathogens are needed to improve monitoring systems. There also remains a need for epidemiological data to enable the identification of appropriate and safe limits of pathogens in the air, drinking water, recreational water, and in food. Based on surveillance of water and foodborne outbreaks in the U.S., priority for standard methods and recreational and drinking water guidelines should be given to *Salmonella* spp., *Campylobacter jejuni*, *E. coli* O157:H7, *Cryptosporidium*, *Giardia*, and selected viral agents indicative of viral contamination. Priority should be established on the incidence of a particular illness due to a pathogen or the severity of the illness or possibly both.

Table 1. Selected zoonotic pathogens zoonoses that may be of concern for water quality near CAFOs †

Infectious Agent	Infectious Dose	Incubation Period	Disease *Symptoms*	Host Range	Reservoir
Bacterial					
Bacillus anthracis	8000-50000 *(by inhalation)*	2-5 days	**Anthrax, Wool sorter's disease** *Cutaneous – skin lesions, death (5-20%)* *Inhalation – respiratory distress, fever, shock, death* *Intestinal – abdominal distress, fever, septicemia, death (rare)*	Humans, cattle, swine, goats, sheep, horses	Spores remain viable in soil contaminated by animal wastes for years
Brucella spp.	Unknown	Highly Variable 5-60 days	**Brucellosis, Undulant Fever, Bang's Disease, Malta Fever, Mediterranean Fever** *Intermittent fever, headache, weakness, profuse sweating, chills, arthralgia*	Humans, cattle, swine, goats, sheep, deer, caribou, elk, dogs, coyotes	Cattle most common
Campylobacter jejuni	≤500 *(by ingestion)*	1-10 days	**Campylobacter enteritis, Vibrionic enteritis, Traveler's Diarrhea** *Diarrhea, abdominal pain, malaise, fever, nausea, vomiting, septicemia, meningitis, Guillain-Barré syndrome, death (rare)*	Humans, cattle, swine, goats, sheep, poultry, rodents, birds, household pets,	Cattle, swine, sheep, poultry household pets, rodents, birds
Clostridium tetani	Toxin is extremely potent	3-21 days	**Lockjaw, Tetanus** *Painful muscular contractions, abdominal rigidity, spasm, death (30-90%)*	Humans, animals	Intestine of animals and humans, soil contaminated with animal feces
Coxiella burnetii	10 *(by inhalation)*	2-3 weeks	**Q fever, Query Fever, Rickettsia** *Acute febrile disease – chills, headache, weakness, malaise, severe sweats, pneumonitis, pericarditis, hepatitis* *generalized infections – endocarditis*	Humans, cattle, sheep, goats	Sheep, cattle, goats, especially at parturition

† Hazen and Toranaos, 1990; WHO, 1993; DuPont *et al.*, 1995; Morris and Levin, 1995; Geldrich, 1996; ASM, 1998; Haines *et al.*, 2004; PHAC, 2005

Table 1. Selected pathogenic zoonoses that may be of concern for water quality near CAFOs (*Continued*)

Infectious Agent	Infectious Dose	Incubation Period	Disease *Symptoms*	Host Range	Reservoir
Bacterial (*Cont.*)					
Enterohemorrhagic *Escherichia coli* (*E. coli* O157:H7 and others)	5-10	2-8 days	**EHEC, Verotoxin-produding *E. coli*, VTEC, Shiga toxin-producing *E. coli*, STEC** *Hemorrhagic colitis, abdominal pain, bloody diarrhea, fever, hemolytic uremic syndrome, thrombocytopenic purpura, death (in children)*	Humans, cattle, swine, goats, sheep, poultry	Humans and livestock animals
Enteropathogenic *Escherichia coli*	10^8-10^{10} in adults, Unknown in infants	0.5-3 days	**Attaching and effacing *E. coli*, enteroadherant *E. coli*, infantile diarrheal disease** *Watery diarrhea, fever, cramps, vomiting, bloody stool in some cases, serious disease in infants*	Humans (esp. infants), cattle, swine, goats, sheep, poultry	Humans and livestock animals
***Leptospira* spp.**	Unknown, but may be as low as 3	4-19 days	**Leptospirosis, Weil's Disease, Canicola fever, Hemorrhagic jaundice, Mud fever, Swineherd's disease** *Fever, headache, chills, muscle aches, vomiting, meningitis, rash, jaundice death (rare)*	Humans, cattle, swine, horses, dogs, rats, wild animals	Farm and pet animals, rats and rodents (urine and abortion products)
Listeria monocytogenes	Unknown, but likely less than 10^3	3-70 days *(mean = 21)*	**Listeriosis, Listerella** *Fever, muscle aches, nausea, diarrhea, headache, stiff neck, confusion, loss of balance, convulsions miscarriage or stillbirth, premature delivery, death in about 20% of all cases*	Mammals, birds, fish, crustaceans, and insects	Domestic and wild mammals, fowl, and humans (aborted fetuses of livestock animals)
Mycobacterium bovis M. tuberculosis	10 *(by inhalation)*	4-12 weeks	**Tuberculosis, TB** *Fatigue, fever, cough, chest pain, hemoptysis fibrosis, irreversible damage to lungs*	Humans, cattle, swine, other animals	Humans, diseased cattle, swine, and other mammals
***Salmonella* spp.** (non-*typhi* or *paratyphi*)	100-1000 *(by ingestion)*	0.25-3 days	**Salmonellosis, Acute Gatroenteritis** *Abdominal pain, diarrhea, nausea, vomiting, dehydration, septicemia, reactive arthritis*	Humans, cattle, swine, poultry, horses, rodents, household pets	Humans, cattle, swine, poultry, horses, rodents, domestic pets
Yersinia enterocolitica	10^6	3-7 days	**Yersiniosis, enterocolitis, pseudotuberculosis** *Diarrhea, acute mesenteric lymphadenitis mimicking appendicitis, fever, headache, anorexia, vomiting, pharyngitis, reactive arthritis*	Humans, swine, household pets	Primarily swine

Table 1. Selected pathogenic zoonoses that may be of concern for water quality near CAFOs (*Continued*)

Infectious Agent	Infectious dose	Incubation Period	Disease *Symptoms*	Host Range	Reservoir
Protozoans					
Balantidium coli	Unknown, may be as low as 10-100	4-5	**Balantidiasis, Balantidiosis, Balantidial dysentery** *Diarrhea, dysentery, abdominal colic, tenesmus, nausea, vomiting, bloody and mucoid stools*	Humans, swine	Primarily swine, also rodents
Cryptosporidium parvum	132	1-12	**Cryptosporidiosis** *Diarrhea, cramping, abdominal pain, weight loss, nausea, vomiting, fever* *Prolonged symptoms and in some instances death in immunocompromised host*	Humans, small and large mammals, poultry, fish, reptiles	Humans, cattle, and other domestic animals
Giardia lamblia	1-10 *(by ingestion)*	3-25	**Giardiasis, Lambliasis, "Beaver Fever"** *Diarrhea, abdominal cramps, bloating, fatigue, weight loss, severe hypothyroidism, lactose intolerance, chronic joint pain*	Humans, wild and domestic animals, household pets	Humans, wild and domestic animals
Toxoplasma gondii	Unknown	10-23 *(by ingestion)*	**Toxoplasmosis** *Mild cases – diarrhea, localized lymphadenopathy, fever, sore throat, and rash* *Severe cases – stillbirths, abortion, newborn syndrome, hearing and visual loss, mental retardation, dementia and/or seizures*	Humans, felines, most warm blooded animals and birds	Cats, cattle, swine, chicken, sheep, goats, rodents, and birds

Table 1. Selected pathogenic zoonoses that may be of concern for water quality near CAFOs (*Continued*)

Infectious Agent	Infectious dose	Incubation Period	Disease *Symptoms*	Host Range	Reservoir
Helminthes					
***Schistosoma* spp.**	Unknown	14-42	**Schistosomiasis, Bilharziasis, Snail Fever, Swimmer's Itch** *S. mansoni and S. japonicum –diarrhea, abdominal pain, and hepatosplenomegaly* *S. haematobium – urinary manifestation including dysuria and hematuria* *Chronic infections may lead to liver fibrosis, portal hypertension, or colorectal malignancy*	Humans, cattle, swine, water buffalo, horses, rodents, and household pets	Humans, cattle, swine, water buffalo, horses, rodents, household pets
Trichinella spiralis	Unknown	1-2 days for gastrointestinal symptoms 2-4 weeks for systemic symptoms	**Trichinelosis, Trichinosis, Trichiniasis** *Malaise, nausea, diarrhea, abdominal cramping, muscular soreness, edema of upper eyelids, eosinophila, ocular pain, photophobi, pneumonitis, remittent fever, cardiac and neurologic complications or death*	Humans, swine, household pets, rodents, wild mammals, and marine mammals	Swine, household pets, rodents, wild animals

Table 1. Selected pathogenic zoonoses that may be of concern for water quality near CAFOs (*Continued*)

Infectious Agent	Infectious dose	Incubation Period *days*	Disease *Symptoms*	Host Range	Reservoir
Viruses					
Hepatitis E Virus	Unknown	14-63	**HEV** *Jaundice, anorexia, hepatomegaly, abdominal pain, nausea, vomiting, fever, Liver Failure; most severe hepatitis during pregnancy of all hepatitis viruses*	Humans, swine, rodents, chicken	Unknown – possibly in swine
Influenza A virus	2-790	1-4	**Flu** *Acute fever, chills, headache, myalgia, weakness, runny nose, sore throat, cough*	Humans, swine, horses, domestic and wild avian species	Humans, animal reservoirs (particularly swine) are suspected as sources of new human subtypes
Lymphocytic choriomeningitis virus	Unknown	8-21	**LCM, Lymphocytic meningitis** *Mild influenza-like illness or maningeal or meningoencephalomyelitic symptoms, Guillain-Barré type syndrome, orchitis or parotitis.* *In more severe cases, temporary or permanent neurological damage, abortion, congenital hydrocephalus, and mental retardation*	Humans, swine, household pets, rodents	Rodents, swine, household pets
SARS Coronavirus	Unknown	6.4 (mean)	**SARS** *High fever, dry cough, dyspnoea, myalgia, diarrhea, vomiting, death (13.2% for infected individuals under 60, 43.3% for those over 60)*	Humans, swine chickens, ferrets, cats, macaques	Unknown – but animal reservoir is suspected
West Nile Virus	Unknown	3-14	**West Nile Encephalitis, Viral Encephalitis** *Sudden onset of flu-like illness, malaise, anorexia, nausea, vomiting, rash, and lymphadenopathy.* *More severe infections can result in aseptic meningitis or encephalitis, mental status changes, seizures, coma, severe neurologic disease, and death (4-11%)*	Mammal, reptilian, and avian hosts. Mammals generally considered dead-end hosts	Birds are the amplifying host

3. Antimicrobial Resistance

Antimicrobial agents include all types of natural or synthetic substances capable of killing or inhibiting the growth of microorganisms. Antimicrobials include antibiotics, antivirals, antifungals, probiotics, disinfectants, sanitizers, food preservatives, antimicrobial pesticides/biocides, and wood preservatives among others (Health Canada, 2002). The proper use of antimicrobial agents is an integral component of good animal agriculture practices. However, their use may be exacerbated in large confinement facilities where animals are raised in close quarters and infection in one animal can rapidly spread through hundreds or even thousands of animals. Many times, infection of one animal leads to the treatment of many animals within the facility prophylactically (Shea, 2004). Additionally, antimicrobial agents have long been administered in sub-therapeutic (non-lethal) doses to livestock animals in their feed, with the ultimate goal of increased animal growth rates. Table 2 lists the antimicrobials used therapeutically and non-therapeutically (prophylaxis and growth promotion) in livestock animals in the United States.

The use of antimicrobial compounds in animal feed has increased more than 10-fold since the 1950s, as total U.S. production of antimicrobials increased from approximately 1 million pounds in 1950 to as much as 44 million pounds in 1986 (Levy, 1992; U.S. Congress, OTA, 1995; McEwen and Fedorka-Cray, 2002). The rise in agricultural use of antimicrobial agents is certainly related to changes in their production and availability, improvements in animal health practices, increasing need for therapeutic use as animals are confined into smaller and more densely packed housing units, a perceived need for prophylactic use due to close confinement and increased risk of the spread of disease, and realization of the financial benefits of shortening the time to reach market weight. According to Dewet *et al.*, (1997) farmers with large operations are much more likely than those with small farms to use antibiotics in feed supplements for growth promotion and prophylaxis. Of the large confinement operations, those working with veterinary consultants were twice as likely to use such feed additives. In a recent survey of antimicrobial treatment practices, approximately 83% of feedlots administered at least one antimicrobial to cattle in feed or water for prophylaxis or growth promotion (Animal and Plant Health Inspection Service, 1999). Precise figures on the use of antibiotics in animal agriculture are not available, but Table 3 shows some recent estimates by various sources. Although estimates shown in Table 3 vary, three facts remain: the use of antimicrobials in animal agriculture has increased substantially since the 1950s, copious amounts of antibiotics are used every year in livestock animals, and most of the antimicrobials used are for growth promotion and prophylaxis, not for the treatment of sickened animals.

3.1 Mechanisms of bacterial resistance

Each class of antimicrobial compound operates at a specific site within the bacterial cell. Bacitracin, cephalosporins, penicillins, ionophores, and polymyxins attack cell walls and membranes. Aminoglycosides, chloramphenicols, and tetracyclines act on cellular components responsible for protein synthesis. Rifamycins, nalidixic acid, and quinolones act upon nucleic acids, and methotrezate and sulfonamides interrupt important biochemical pathways within the cell (Khachatourians, 1998). To combat the action of antimicrobial compounds, bacterial cells have adapted three primary mechanisms including reducing the accumulation of antimicrobial

Table 2. Selected Antimicrobial Agents Approved for Use in Animal Agriculture*

Antimicrobial Class and Drug	Use in Animal Agriculture			Analogs Used for Human Therapy ‡
	Animal Species	Therapeutic	Non-therapeutic†	
<u>Aminoglycosides</u>				
Gentamicin	Cattle (Beef and Dairy), Horses, Swine, Poultry[§]		X	Amikacin, Gentamicin,

Table 3. Estimates of the use of antimicrobial agents in livestock animal production

Total Mass Used	Specific Use	Source
20 million pounds used annually	20% for treating disease 80% for growth promotion and prophylaxis	Swartz, 1989
18 million pounds used in 1985	12.2% for treating disease 63.2% for prophylaxis 24.6% for growth promotion	U.S. Congress, OTA, 1995
17.8 million pounds used in 1998	83% for prophylaxis and treating disease 17% for growth promotion	Animal Health Institute, 2000
29.5 million pounds used annually	7% for treating disease 93% for growth promotion and prophylaxis	Mellon *et al.*, 2001
14.4 million pounds used in 1997	Not Reported	Silbergeld, 2004

agents within the cell, attacking and inactivating the antimicrobial compounds enzymatically, or altering, protecting, or replacing target cellular structures. Bacteria may gain these resistance mechanisms in three ways: (1) acquire resistance genes from the DNA of antibiotic producers and modify them such that they are optimized for resistance to the antimicrobial agent (2) mutate genes whose products play a role in physiological cell metabolism such that they attack or inactivate the antimicrobial agent, and/or (3) mutate genes whose products are the target structures of the antimicrobial compounds such that the target structures become resistant to the inhibitory effects of the respective antimicrobials (Schwartz and Chaslus-Dancla, 2001).

The initial development of antimicrobial resistance may be relatively slow as single point mutations that give rise to resistance genes are rare events (10^{-9} to 10^{-8} per cell per generation) (Kelly et al, 1986; Freifelder, 1987; Smith et al, 1999). Once acquired, antimicrobial resistance traits can be rapidly transferred vertically through division of the host cell, and/or horizontally between different bacteria (both commensal and pathogenic) via transduction (a bacteriophage-mediated process), conjugation/mobilization (requiring contact between donor and recipient cell), or transformation (transfer of free DNA into competent recipient cells). In the mixed bacterial populations of animal and human skin and mucosa, conjugation and mobilization are considered to be of primary importance for the spread of resistance genes (Schwartz and Chaslus-Dancla, 2001) and may occur on the order of 10^{-5} to 10^{-4} per cell per generation (Summers, 2002). Transduction only occurs between bacteria of very similar species and genera as it is limited by host-specificity of bacteriophages, and therefore plays a lesser role in the spread of resistance traits in these milieus. Spread of resistance traits via transformation is considered to be very limited (Bennett, 1995).

The primary genetic elements involved in horizontal gene transfer include plasmids, transposons, and integrons/gene cassettes. Aside from the antimicrobial-resistance traits, plasmids and transposons may also carry genes (such as the *tra* gene complex) which allow them to move from one bacterial cell to another via conjugation or mobilization. Plasmids may serve as vectors for transposons and integrons/gene cassettes facilitating their horizontal transfer to competent cells. Transposons and integrons/gene cassettes can be transferred via transduction when resistance genes are co-located with prophage genes that are not excised precisely from chromosomal DNA prior to packing into phage heads. Small plasmids may also be transferred via transduction if they are packed into bacteriophage heads instead of phage DNA during phage assembly (pseudophages), however this process is limited compared to conjugation and mobilization (Schwartz and Chaslus-Dancla, 2001). Once established, resistance genes may persist in commensal bacteria serving as a reservoir for rapid acquisition of antimicrobial resistance for any new pathogen that may inhabit the intestinal tract (Barza, 2002). Of particular interest are enterococci and *E. coli* that can play a major role in the transmission of mobile resistance genes (Salyers, 1995).

Antimicrobial-resistance in bacteria may be conferred by tandem arrays of genetically linked resistance genes borne by integrons or other transposons that can reside in the chromosome and on conjugative or mobilizable plasmids (O'Brien et al, 1985; Zhao *et al.*, 2001; Roe *et al.*, 2003). Adaptation of a bacterial cell to any given antimicrobial via gene transfer can thus result in selection for resistance to not only that specific agent, but also, by genetic linkage of resistance genes, to other antimicrobials (Summers, 2002). Antimicrobial resistance determinants are also often co-located with virulence determinants on mobile genetic elements. Treatment with antimicrobials for which resistance is conferred may result in the enrichment of more virulent bacterial strains in the selective environment. Epidemiological evidence from reported *Salmonella* and *Campylobacter* infections suggest that resistant strains are somewhat more virulent than susceptible strains, exhibiting prolonged or more severe illness (Travers and Barza, 2002). In a study of 67 individuals not treated with antimicrobials, diarrhea lasted longer when the isolates were ciprofloxacin-resistant (12 days) than when they were ciprofloxacin susceptible (6 days) ($P=0.02$) (Marano *et al.*, 2000). The likelihood of hospitalization and average length of hospital stay are significantly higher in those infected with antimicrobial-resistant organisms than those with susceptible stains (Lee *et al.*, 1994).

Resistance to one antimicrobial compound may also confer resistance to other antimicrobial compounds through similarity of the antimicrobial agents (Khachatourians, 1998). Cases of multi-drug resistance in bacterial zoonoses caused by structural similarity of human-use antimicrobials to those used in animal agriculture have been documented. Virginiamycin-resistant bacterial isolates from turkeys were found to be resistant to the structurally similar and clinically important human-use drugs quinipristin and dalfopristin (Feinman, 1998; Chadwick and Goode, 1997). Tylosin-resistant streptococci and staphylococci-resistant animal isolates were determined to be resistant to the structurally similar and clinically important human-use drug erythromycin, and were found not only in the livestock animals, but in their caretakers as well (Feinman, 1998; Chadwick and Goode, 1997). Virginiamycin and Tylosin are both used prophylactically and/or for growth promotion in beef and dairy cattle, swine, broilers, and turkeys. Table 2 lists human-use drugs that are structurally similar to several antimicrobial compounds used in animal agriculture.

3.2 Antimicrobial resistance in livestock animals

The occurrence of antimicrobial-resistant bacteria tends to be rapid following introduction of antimicrobial agents into clinical or agricultural use. For instance, occurrence of tetracycline resistant bacteria was reported in 1956, four years following its introduction to clinical use and only eight years following its initial discovery. The time lag between introduction to clinical use and occurrence of antimicrobial resistant bacteria was 15 years for vancomycin, 4 years for nalidixic acid, 3 years for gentamicin, 3 years for fluoroquinolones, one year for erythromycin, and less than one year for streptomycin (Schwartz and Chaslus-Dancla, 2001). Although the latent period between the introduction of an antimicrobial and the emergence of resistance may vary, once the prevalence of resistance in a population reaches a certain level, reversal of the problem may be extremely difficult (Swartz, 2002). For example, fluoroquinolone-resistant Campylobacter were detected in 43-96% of market chickens from two producers more than one year after fluoroquinolones were no longer used in their poultry production (Price *et al.*, 2005).

Repeated exposure of bacteria to antimicrobial agents and access of bacteria to increasingly large pools of antimicrobial resistance genes in mixed bacterial populations are the primary driving forces for emerging antimicrobial resistance (Schwartz and Chaslus-Dancla, 2001). Resistance of both commensal and pathogenic bacteria in livestock animals to antimicrobials of clinical importance is now commonplace and is related to their increased use for growth promotion and prophylaxis over the last 50 years (Shere et al, 1998; Maynard *et al.*, 2003). Hayes et al (2004) surveyed 541 *Enterococcus faecium* isolates from 82 farms within a poultry production region in the eastern United States. Sixty-three percent were resistant to quinipristin-dalfopristin and 52.7% were resistant to four or more antimicrobials. In a study of several swine farms in the United States, Jackson *et al.*, (2004) determined that Tylosin use for growth promotion resulted in erythromycin-resistance in 59% of enterococci isolates, compared to 28% at a farm where Tylosin was used for treatment of disease only, and 2% at a farm that did not use Tylosin. National surveillance of Salmonella in swine in the U.S. has revealed resistance to several important antimicrobials including tetracycline (50%), ampicillin (12%), sulfamethoxazole (23%), and streptomycin (23%) (NARMS, 1998). Hoyle *et al.*, (2004) studied ampicillin-resistant *E. coli* in calves in the United Kingdom and determined that ampicillin resistance peaked over 80% within 4 months, steadily declining to less than 10% as the calves aged to 8 months. Schroeder *et al.*, (2002) tested 752 *E. coli* isolates from humans and animals for resistance to several antimicrobials of clinical importance. Approximately half of the isolates displayed resistance to one or more antimicrobials including penicillins, sulfonamides, cephalosporins, tetracyclines, and Aminoglycosides, with the highest frequencies of antimicrobial resistance in humans and turkeys and the lowest in non-food animals. Sayah *et al.*, (2005) studied antimicrobial resistance patterns in livestock, companion animals, human septage, wildlife, farm environments (manure storage facilities, lagoons, and livestock holding areas) and surface water in the Red Cedar Watershed in Michigan. *E. coli* isolates from livestock showed resistance to the largest number of antimicrobials and multidrug resistance was most common in swine fecal samples. Resistance was demonstrated most frequently to tetracycline, cephalothin, sulfisoxazole, and streptomycin. Similarities in patterns of resistance in *E. coli* were observed in livestock animals and environmental samples taken from their respective farms. These authors suggest that farm environment samples may best describe potential contamination of nearby waters with antimicrobial-resistant bacteria.

3.3 Risk to public health

Much concern surrounds the elevated use of antimicrobial agents in confinement facilities and, in particular, the use of antimicrobial agents at non-therapeutic doses in animal agriculture (American Academy of Microbiology, 1999, Mellon *et al.*, 2001). The use of antimicrobial agents inevitably selects for resistance of both commensal and pathogenic microorganisms exposed to the agents (Linton et al, 1975; Dawson *et al.*, 1984; Levy et al, 1976; Dunlop et al, 1998; Endtz *et al.*, 1991; Jacob-Rietsma *et al.*, 1994; Bager *et al.*, 1997; Low *et al.*, 1997; Tauxe, 1997; Gynn *et al.*, 1998; McEwen and Fadorka-Cray, 2002; Vasil' *et al.*, 2002). The conditions of widespread, prolonged exposure to antimicrobial compounds at sublethal doses with little dose control in CAFOs may exacerbate their development. Once established, the movement of antimicrobial-resistant microorganisms from animal to animal or animal to animal care worker may be facilitated by the crowding of animals into confinements, often with suboptimal hygiene. The co-colonization of animal gastrointestinal tracts by antimicrobial-resistant commensal bacteria and bacterial pathogens may lead to further development of antimicrobial-resistant bacterial zoonoses (Kruse *et al.*, 1999). As much as 75-80% of an antibiotic may pass undigested through an animal, thus its waste may not only harbor high concentrations of antimicrobial-resistant bacteria, but also their resistance genes and raw (undigested) antimicrobial compounds (Campagnolo and Rubin, 1998). This waste is often stored in open air lagoons and/or spread on fields where these compounds, resistant organisms, and antimicrobial-resistance gene reservoirs may move into the environment via aerosolization, infiltration into the groundwater, or runoff into surface water resources.

Antimicrobial resistance in zoonotic pathogens is a serious threat to human health (Ghidán *et al.*, 2000; Cheng *et al.*, 2002; Travers and Barza, 2002). Many of the drugs are used in animal agriculture and human medicine are the same or very similar including, but not limited to, beta-lactams (penicillin, ampicillin, cloxacillin), tetracyclines, sulfonamides and potentiated sulfonamides, cephalosporins, and fluoroquinolones (McEwen and Fadorka-Cray, 2002). Exposure to zoonotic pathogens harboring resistance to antimicrobials of clinical importance may lead to diseases with few or no treatment options in humans. In cases where pathogens are resistant to administered antimicrobial compounds, vulnerability to infection can increase up to three-fold, primarily resulting from a transient decrease in an individual's resistance to colonization by the pathogen (Barza and Travers, 2002). Antimicrobial-resistant pathogens tend to be more virulent than their susceptible counterparts, causing more prolonged or severe illnesses (Marano *et al.*, 2000; Travers and Barza, 2002; Swartz *et al.*, 2002). There is circumstantial evidence that increased prevalence of antimicrobial resistance in human isolates may be linked to the use of antimicrobial agents in animal agriculture (Levy *et al.*, 1976; Jensen *et al.*, 1998; Swartz *et al.*, 2002; Silbergeld, 2004). Many cases of severe human disease caused by acquisition of antimicrobial-resistant zoonotic pathogens from animal agriculture have been documented (Levy *et al.*, 1978; Schlech *et al.*, 1983; Holmberg *et al.*, 1984; Morgan *et al.*, 1988; Besser *et al.*, 1993; Cieslak et al, 1993; Isaacson *et al.*, 1993; Lee *et al.*, 1994; MacKenzie *et al.*, 1994; Millard et al, 1994; Tschape *et al.*, 1995; Centers for Disease Control and Prevention, 1998; Jackson *et al.*, 1998; Crampin *et al.*, 1999; Huovinen, 1999; Wegner *et al.*, 1999; Franklin, 1999; Kruse, 1999; Health Canada, 2000; License *et al.*, 2001; Clark *et al.*, 2003).

4. Survival of Pathogens in the Environment

Pathogens at concentrated animal feeding operations may be present in animal wastes, water used for maintenance of livestock and animal housing units, soils where animal manures and wastewaters are spread, on crops grown in soils where manures were applied or where contaminated irrigation waters are used, and groundwater and surface waters contaminated by manure runoff. The survival of pathogenic organisms in the environment varies widely depending on the pathogen, environmental conditions, and the chemical, physical, and biological composition of milieu of interest. Enteric bacterial, viral, and protozoan pathogen inactivation in soil, water, crops, or manure may be affected by predation, competition, water stress/osmotic potential, temperature, UV radiation, pH, inorganic ammonia, and organic nutrients (Geldreich *et al.*, 1968; Davenport *et al.*, 1976; Crane and Moore,1986; Hurst *et al.*, 1989; Davies and Evison, 1991; Olson *et al.*, 1999; Sattar *et al.*, 1999; Burkhardt *et al.*, 2000; Davies-Colley *et al.*, 2000; Wait and Sobsey, 2001; Jamieson *et al.*, 2002; Ferguson *et al.*, 2003). The importance of each factor is strongly related to the milieu of interest. In general, the survival of pathogens is inversely related to predation, competition, temperature, UV radiation, water stress, and inorganic ammonia, except for *Cryptosporidium* oocysts and *Giardia* cysts, which have low survival at sub-zero (<-20ºC) temperatures (Van Donsel *et al.*, 1967; Zibilske and Weaver, 1978; Reddy *et al.*, 1981; Jamieson *et al.*, 2002; Ferguson *et al.*, 2003). The relationship of pathogen survival to pH and organic nutrients may be more complex. Under the right conditions, pathogens are capable of surviving in the environment for days to more than a year.

4.1 Manure and manure slurries

Table 4 summarizes the survival of bacterial and parasitic pathogens noted in literature in manures and manure slurries. These nutrient rich environments may offer protection from environmental insults such as solar UV radiation, desiccation, and temperature fluctuations, promoting survival or even regrowth of pathogenic zoonoses. For instance, Muirhead *et al.*, (2005) determined that within cowpats, *E. coli* grew for 6 to 14 days instead of following a traditional logarithmic die off curve and Olson (2003) noted that the eggs of *Ascaris suum*, a common parasite in swine, are highly resistant to inactivation in feces, potentially remaining infectious for years. However, these environments may also me hostile, as they may harbor predators and competitors, or produce toxic components that may reduce pathogen viability. For instance, inorganic ammonia, naturally produced by hydrolysis of urea and in decomposing manure, can be biocidal at high concentrations, and has been exhibited to be directly proportional to *Cryptosporidium* oocyst inactivation (Jenkins *et al.*, 1998; Jenkins et al, 1999). As seen in Table 4, animal manures and manure slurries may remain significant reservoirs for environmental contamination by zoonotic pathogens for many months.

Bacterial pathogens may persist for long periods in animal manures under typical environmental conditions. This may be exacerbated when the temperatures are low, moisture remains optimal, and aeration is not used. For instance, *Salmonella* and *E. coli* O157:H7 have been noted to survive for 4-6 months in animal manures and manure slurries kept at 1-9ºC, up to 49 times longer than at 40-60ºC. Nicholson *et al.*, (2002) studied the survival of *E. coli* O157:H7,

Table 4. Survival of pathogenic zoonoses in livestock manures and manure slurries

Environment	Temperature (ºC)	Survival[†] (days)						
		Bacterial Pathogens[‡]					Parasites[§]

[§] Cole *et al.*, (1999); Robertson *et al.*, (1992); Fayer *et al.*, (1998); Olson (2003); Olson *et al.*, (1999)

[*] Calculated as 7 times the reported decimal reduction time (time required for 1-log reduction in pathogen concentration) assuming logarithmic die-off and based on a reported initial inocula of 10^6-10^8 organisms per gram manure or milliliter slurry.

Salmonella, *Listeria,* and *Campylobacter* in dairy cattle, swine, and poultry manures stored at 40-60ºC and determined that aeration of the solid manures decreased survival times for *E. coli* O157:H7 and *Salmonella* by as much as 88%. These researchers noted a decrease in the survival of *E. coli* O157:H7 and *Salmonella* sp. when a higher dry matter content was maintained in the slurry. Kudva *et al.*, (1998) noted similar changes in *E. coli* O157:H7 in sheep manure, which survived for 630 days at temperatures below 23ºC when not aerated versus 120 days when aerated, the difference likely due to drying of the aerated manure.

Parasitic protozoan survival in animal manures may also be related to temperature, but the trends are not as strong as those reported for bacterial pathogens. This is likely due to their ability to form cysts and oocysts for protection from environmental pressures under the range of temperatures reported in Table 4. These parasites have been shown to be susceptible to temperature extremes, with reported survival of *Cryptosporidium* oocysts ranging from 1 hour at -70ºC, 1 day at -20ºC, one or more years at 4ºC, 3-4 months at 25ºC, 1-2 weeks at 35ºC, and just minutes at 64ºC (Fayer and Nerad, 1996; Finstein, 2004). *Cryptosporidium* oocysts in manures may also be susceptible to desiccation and bacterial degradation whereby warmer temperatures may accelerate the degradation process. A similar pattern exists for *Giardia* cysts, but they are inactivated more rapidly than *Cryptosporidium* oocysts and are less resistant to temperature extremes.

Information regarding the survival of zoonotic viruses in animal wastes is sparse. Although not shown in Table 4, zoonotic viruses in animal manures and manure slurries may exhibit long inactivation times that extend for weeks to months. Karetnyi *et al.*, (1999) determined that swine hepatitis E was detectable in positive stool samples for more than 2 weeks, regardless of whether the samples were maintained at -85ºC, 4ºC, or room temperature. Pesaro et al (1995) studied the survival of several viruses including picnoraviruses, rotaviruses, parvoviruses, adenoviruses, and herpes viruses as well as the coliphage f2 in nonaerated liquid and semisolid animal wastes. Ninety percent reduction in virus titer ranged from less than 1 week for herpes virus to more than 6 months for rotavirus, suggesting that a 4-$\log_{10}$ reduction in viruses may require storage for as much as two years for some pathogens. Although little information exists regarding the survival of viral pathogens in fecal environments, these studies show that under non-aerated conditions viruses may exhibit prolonged persistence in manure and manure slurries, suggesting a strong potential for viral pathogen contamination when manure is spread on land.

In general, pathogen survival in animal manures is dictated by the effects of aeration and temperature, whereby increased aeration and higher temperatures lead to more rapid die-off. Of the pathogens listed in Table 4, *E. coli* O157:H7, *Listeria* sp., and *Salmonella* sp. were the most persistent in manure and manure slurries regardless of the temperature. However, considering the work of Pesaro *et al.*, (1995), viral pathogens may persist much longer than the bacterial pathogens, and should be given more consideration in future studies.

Much of the work to date has concentrated on the survival of pathogens in cattle manures and manure slurries. However, based on the summary presented in Table 4, there seems to be dissimilarities in the survival of pathogens in different animal feces. This may be due to differences in the physical, chemical, or biological properties of the various animal manures, but could also be a result of the low numbers of studies on swine and poultry manures versus those of cattle. The lack of studies on pathogen survival in swine and poultry manures impedes the development of safe management practices.

The survival of pathogens in animal manures and manure slurries is typically studied under controlled laboratory conditions. Kudva *et al.*, (1998) noted that survival of pathogens in laboratory studies were generally lower than those observed in field studies. For instance, these researchers determined that *E. coli* O157:H7 survived in sheep manure for 100d under a controlled (4-10ºC) laboratory setting versus 630 days when exposed to environmental (ambient) conditions (<23ºC). Based on their observations, laboratory experiments may not provide a reasonable estimate of pathogen survival in on-farm conditions. Future efforts should concentrate on measuring the survival of pathogens *in-situ*.

4.2 Natural Waters

Manure runoff and wastewaters from concentrated animal feeding operations may contain pathogenic zoonoses and antimicrobial-resistant bacteria that can survive and proliferate in nearby natural waters. Runoff and wastewater discharges may also contribute both organic and inorganic nutrients that may encourage the growth and proliferation of indigenous or introduced pathogens (Grimes *et al.*, 1986). Table 5 summarizes the survival of bacterial and parasitic pathogens in dirty waters from livestock operations, natural waters, and drinking water as reported in literature. In these milieus, UV radiation, disinfectants, temperature, predators, and toxin producers generally challenge the survival of pathogenic zoonoses and antimicrobial-resistant bacteria (Chao *et al.*, 1988; Johnson *et al.*, 1997).

The survival of bacteria in natural waters may be longer than exhibited in manures or manure slurries. *Yersinia enterocolitica* exhibited the greatest survival among all bacterial pathogens considered in Table 5 whereas *Campylobacter* was the least. However, in a viable but not cultivable state, *Campylobacter* may survive for as much as 120 days at 4ºC. *E. coli* O157:H7 has also been noted to enter a viable but not cultivable state in water increasing the survival time over that reported in Table 5 (Wang and Doyle, 1998). Pathogens may also settle into streambed sediments, decreasing exposure to UV radiation and predators and increasing survival times over those reported in Table 5. For instance, Anderson *et al.*, (2005) determined that a 90% reduction in fecal coliforms in fresh waters required 4.2 days, whereas 50 days was required to achieve the same reduction in the underlying sediments. Although differences in the survival of *Enterococcus* spp. was observed, the trend was the same (1.4 days in water and 4.5 days in the underlying sediments), and held true for salt water environments.

Cryptosporidium oocysts may also be especially resistant in environmental waters, surviving for more than a year in optimal (low temperature) conditions. For instance, Robertson *et al.*, (1992) studied oocyst infectivity during incubation in cold river water and reported up to 66% viability at 33 days and 11% viability at 176 days. In another study, Medema *et al.*, (1997) determined that the time required for one-log reduction in *Cryptosporidium* oocyst infectivity in river water at 15ºC was 40-160d, whereas at 5ºC it was 100d. Even more extreme are viruses, which can persist for several years in the subsurface. Azadpour-Keeley *et al.*, (2003) reviewed the movement and longevity of viruses in the subsurface and suggested that soil environments may actually enhance viral survival. They report a wide variation in inactivation rates in different

soils at near-neutral pH suggesting it may take as little as 0.8 days to as many as 11 years to achieve 99.99% (4-$\log_{10}$) die off of some viruses in aquifers. Keswick *et al.*, (1982) report that survival of enteric bacteria and viruses were longer in groundwater than surface water, presumably due to lower temperatures and protection from sunlight and microbial antagonism.

Maintenance of antimicrobial-resistance in natural waters has not been studied extensively. In untreated seawater suspensions, Guardabassi and Dalsgaard (2002) noted that multiple antibiotic resistant *E. coli* and *Citrobacter freundii* survived and maintained their multiple resistance properties for more than 30 days, whereas a multi-antibiotic resistant *Acinetobacter johnsonii* survived and maintained its multiple resistance properties for 14 days. In untreated pond water suspensions, these authors noted survival times of 21 days (*E. coli* and *A. johnsonii*) and 28 days (*C. freundii*), while maintaining multiple resistance properties. This suggests that antimicrobial resistant microorganisms may survive for long periods upon discharge to aquatic environments and that stress and nutrient depletion may not affect the stability of their resistance phenotypes. The effect of low concentrations of antimicrobial compounds discharging to surface or ground waters via manure runoff, lagoon leakage, or wastewater discharge on the maintenance of antimicrobial-resistant phenotypes or genotypes has not been studied.

4.3 Manure-amended soil

Table 6 summarizes the survival of bacterial and protozoan pathogens in soils. The survival times reported in Table 6 are more similar to those of manures and manure slurries and less than those exhibited in water. In general, it has been reported that survival of pathogens in soil increases when manures are incorporated into soils rather than unincorporated. For instance, Hutchison et al (2004) studied the die off of *Salmonella*, *Listeria*, *Campylobacter*, and *E. coli* O157 following application of manure to soil and incorporation of the manure upon application, one week following application, or no incorporation. The authors noted that die-off was similar in summer and winter months, but more rapid when the manure was not incorporated into the soil. The increased survival of pathogens incorporated into soils may be related to decreased exposure to UV radiation, temperature extremes, and desiccation and increased availability of nutrients. However, soils may harbor competitor organisms and predators that can reduce pathogen survival. Survival of pathogenic bacteria in soils may also be limited by low soil pH (Jamieson *et al.*, 2002) or freeze-thaw cycling. Jenkins *et al.*, (1999) determined that *Cryptosporidium* oocyst infectivity decreased from greater than 50% to less than 1% when exposed to freeze-thaw cycles in a soil environment. Walker et al (2001) noted that inactivation of *Cryptosporidium* oocysts during freeze-thaw cycling or heating was enhanced by increased osmotic stress (decreased water potential).

The most important factor affecting the survival of enteric pathogens in soils systems may be the moisture status, which is influenced not only by precipitation, but also by moisture retaining properties such as particle size distribution and organic matter content (Gerba *et al.*, 1975; Tate *et al.*, 1978; Kibbey *et al.*, 1978; Chandler and Craven, 1980; Crane *et al.*, 1981; Reddy *et al.*, 1981; Faust, 1982; Mubiru *et al.*, 2000, Entry *et al.*, 2000b; Jamieson *et al.*, 2002). For instance, Nicholson *et al.*, (2002) studied the survival of bacterial pathogens following land spreading and determined that there are some indications that pathogen survival is longer in clay loam grassland soil than in sandy arable soil. Burton et al (1983) determined that *Salmonella newport*

survived longer in soils with higher clay content, potentially owing to a higher concentration of organic matter and nutrients. Mubiro *et al.*, (2000) suggested that survival of *E. coli* O157:H7 may also be enhanced in soils of higher matric potential not only due to enhanced water holding capabilities, but also because these soils better retained nutrients. The addition of manure to the soils may enhance survival of pathogens such as *Campylobacter* spp. or *E. coli* O157:H7, possibly due to increased organic and inorganic nutrient availability (Gagliardi and Karns, 2000).

The effects of water/osmotic potential on microbial stress in soil environments may be exacerbated by specific properties of the pathogen of interest. Bacteria and viruses with a hydrophobic envelope tend to accumulate at the air water interface leading to increased inactivation (Johnson and Gregory, 1993; Thompson *et al.*, 1998; Thompson and Yates, 1999). The lack of a hydrophobic envelope may reduce attraction to the air-water interface, and thus may afford some protection from viral inactivation due to osmotic stress (Ferguson *et al.*, 2003). In soils, osmotic stress typically increases near the soil surface, and may lead to reduced pathogen survival (Gerba, 1999).

Even when not incorporated into soils, the survival of pathogens following application of manures to land may be lengthy. Hutchinson *et al.*, (2005) determined decimal reduction times (the time required for 1-$\log_{10}$ reduction) for *E. coli* O157:H7, *Listeria monocytogenes*, *Salmonella* spp., and *C. jejuni* of 1.31 – 3.20 days (mean) and *Cryptosporidium parvum* oocysts of 8-31 days following the application of livestock waste onto fescue plots (no incorporation). Most zoonotic agents declined below detectible levels by 64 days, except for *L. monocytogenes*, which persisted for up to 128 days in some plots. Potential mechanisms for pathogen reduction may have included, among others, desiccation, UV radiation, and runoff from the grasslands to nearby receiving waters.

Where food crops are grown in manured soils or using contaminated irrigation waters, pathogens can contaminate produce surfaces. The level and persistence of contamination may be related to the irrigation method (spray irrigation or surface irrigation) and time of contact of produce with contaminated soils. For instance, Ingham *et al.*, (2004) identified *E. coli* contamination on carrots, lettuce, and radishes up to 120 days following application of non-composted bovine manure as a fertilizer in fields in Wisconsin. Following growth in *E. coli* O157:H7 contaminated manure-fertilized soil; Johannessen *et al.*, (2005) detected *E. coli* O157:H7 on the stems, but not on the edible parts of lettuce. Solomon *et al.*, (2002) noted that spray irrigation following a single exposure to *E. coli* O157:H7 resulted in 90% of the lettuce being contaminated with *E. coli* O157:H7 and the contamination persisted for more than 20 days in 82% of the plants. Where surface irrigation was used under the same circumstances, only 19% of the lettuce was contaminated. Immersion of harvested lettuce heads in 200ppm chlorine solution for 1 minute did not eliminate all *E. coli* O157:H7 cells from infected lettuce, regardless of irrigation method. Guo *et al.*, (2002) investigated water and soil as reservoirs of *Salmonella* for contaminating mature green tomatoes, and determined that the population of *Salmonella* on tomatoes in contact with contaminated soil increased over 4 days by 2.5 $\log_{10}$ CFU per tomato during storage at 20ºC, and remained constant for an additional 10 days. In contrast, where tomatoes were not in contact with soil, but *Salmonella* were inoculated onto the fruit surface, the number of cells declined over 14 days by 4 $\log_{10}$ CFU per tomato when held at 20ºC. At day one, *Salmonella* was associated with the skin surface. As time of storage increased, more *Salmonella* cells were associated with less accessible stem scar and subsurface areas of the tomatoes, which may render the fruits more resistant to disinfection with sanitizing agents.

4.4 Discussion

Relatively few studies are available describing the survival of pathogenic zoonoses in environmental milieu, especially considering the broad range of properties of soils, manures, and waters that may potentially be contaminated. Much of the emphasis has been placed on cattle manures, manure-amended soils, and surface waters, with less emphasis on ground waters and manures from other livestock animals such as swine and poultry. In general, pathogenic zoonoses tend to survive longer cooler rather than warmer temperatures and in water rather than in manures or soils. This may be problematic as manures and soils are stationary whereas water is a significant transport medium for pathogens. Further, very few studies have been reported on the survival of viruses which is troubling because the relatively few studies that are available suggest that viruses are more persistent than bacteria and parasitic protozoa and can travel vast distances in both surface and ground waters. A significant limitation is the lack of information regarding the survival of antimicrobial-resistant bacteria in various milieus including the persistence of phenotypic and genotypic antimicrobial-resistance traits. Most studies reported in Tables 4-6 were carried out in the laboratory instead of *in-situ*, and only a few examined more than one environmental stressor simultaneously. The combined effects of multiple stressors in the natural environment or presence of additional growth and maintenance factors may limit or enhance pathogen survival in reference to lab-scale studies of single stressors (Crane and Moore, 1986; Robertson et al, 1992; Kudva *et al.*, 1998; Jenkins *et al.*, 1999; Friere-Santos *et al.*, 2000; Walker *et al.*, 2001).

Current methods for detecting pathogens in environmental systems may limit the ability to determine accurate survival times in difficult milieu. Specific soil or manure properties or survival strategies of the various pathogens may limit their detection with cultivation techniques. For instance, upon being stressed, bacteria may die or adapt using a number of mechanisms including formation of spores, formation of ultramicrobacteria, or entering viable but not cultivable (VBNC) states. Many of the bacterial pathogens can survive for much longer periods of time than indicated in Tables 4-6 in VBNC states (Wang and Doyle, 1998; Santo Domingo *et al.*, 2000; Rollins and Colwell, 1986). Better and more sensitive methods for pathogen detection in different media need to be developed to determine more accurately pathogen survival. Accurate information regarding the survival of pathogenic zoonoses and antimicrobial resistant bacteria is necessary for modeling their fate and transport from confined animal feeding operations. Based on available information, ensuring the safety of food crops and water resources may require management practices that eliminate pathogens in manures and other CAFO wastes prior to land application or discharge to natural waters.

5. Pathogen Movement – An Ecological Perspective

Figure 2 provides a partial picture of the potential routes of transmission of zoonotic pathogens from confined livestock animals to humans and the environment. The movement of pathogens onto, within, and off farms is a complex ecological issue owing to the continuous exchange of microbes between human and animal hosts and environmental reservoirs (Sobsey *et al.*, 2002; Summers, 2002). For instance, Herriott *et al.*, (1996) tested twelve herds and their feeds and water troughs as well as co-located (non-bovine) livestock, companion animals, wild birds, rodents and flies at dairies and feedlots in Idaho, Oregon, and Washington for the presence of *E. coli* O157:H7. *E. coli* O157:H7-positive cattle were identified in all 12 herds with a prevalence of 1.1-4.4% in dairies and 1.5-6.1% in feedlots. It was also detected in 1.3% of trough water samples, 2.0% of trough water biofilm samples, in a nearby horse, two dogs, pooled bird droppings, and composite fly samples. Considering antimicrobial resistance, the issue becomes more complicated as mobile genetic elements conferring resistance provide a distinct selective advantage in stressed environments such as the colonic tract of humans and animals being treated with antimicrobials. In these environments, proliferation of resistance traits among bacteria can be rapid and have lasting effects (O'Brien, 2002; Summers, 2002). Addressing the movement of pathogens between intensive livestock operations and the environment will require understanding of the ecological principle that everything is connected to everything else. The following is a discussion of some of the potential pathways for movement of zoonotic pathogens from livestock animals raised in confinement to humans and the environment.

5.1 CAFOs and Abattoirs

The presence of zoonotic pathogens in CAFO environments may begin with the stocking of infected animals or with the use of selected feed products on the farm. Animal feeds and drinking water containing antimicrobial compounds may lead to the development and persistence of resistant bacterial zoonoses in livestock animals which may proliferate through the farm environment. Animal feeds can also be a direct source of zoonotic pathogens and antimicrobial-resistant bacteria for livestock animals (Curtain, 1984; Durand *et al.*, 1990; Izat and Waldroup, 1990; Gabis, 1991; Veldman *et al.*, 1995; Davies and Wray, 1997; Primm, 1998; Shirota *et al.*, 2001a,b). For instance, of ten feed ingredient piles at 12 commodity dairy feeding farms, Kidd *et al.*, (1999) identified two feeds contaminated with *Salmonella enteritidis*. Sixty two percent of Enterobacteriaceae isolates from the ten piles were ampicillin-resistant and 10% were tetracycline-resistant. Although feed can be contaminated on-farm, it may also arrive contaminated, as shown in a recent survey of 629 feed samples from 3 feed mills where 8.8% of feed mash samples and 4.2% of pelleted feed samples were positive for Salmonella (Jones and Richardson, 2004). Antimicrobial-resistant bacteria and other pathogens can also be present in trough waters (Marshall *et al.*, 1990; Herriott *et al.*, 2002; Kemp *et al.*, 2005) potentially resulting from either stocking troughs with contaminated water or through deposition of contaminated material into the water from an animal harboring the disease (via the saliva, mucosa, or feces). Antimicrobial compounds in the water and the presence of biofilms in which bacteria are in close contact may lead to proliferation of antimicrobial resistance within these microbial communities. The confinement of animals into dense units where trough waters are shared and where animals have increased contact with each other and their fecal matter may exacerbate the spread of pathogens from animal to animal.

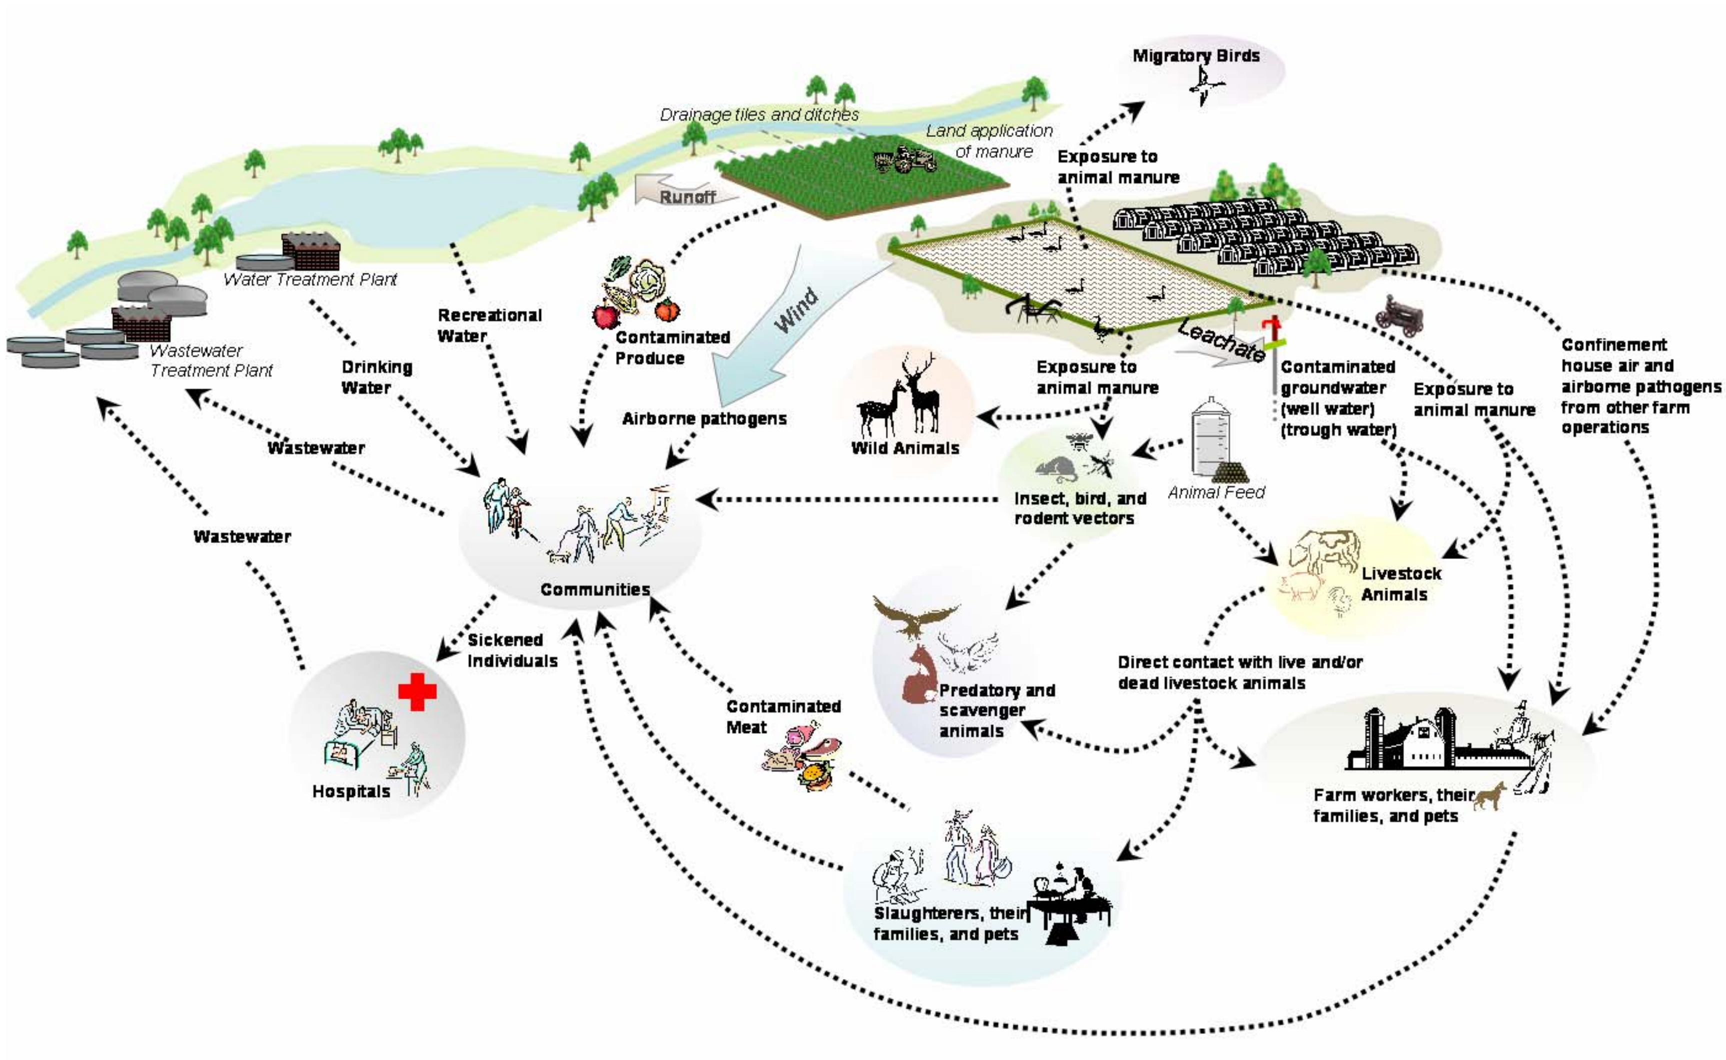

Figure 2. Movement of pathogens - an ecological perspective

Standing trough waters and animal feeds laden with antimicrobial compounds and pathogenic zoonoses as well as unsanitary conditions and poor manure management practices pose other problems for controlling the spread of disease. Animal and insect vectors may be attracted to feed piles, trough waters, fecal matter, manure treatment lagoons, treatment wetlands, or the dense animal populations present in CAFOs resulting in movement of pathogens on and between farms as well as off of farms and into human populations. Several studies have supported the movement of pathogens and antimicrobial resistant bacteria through animal vectoring. In a longitudinal study on Wisconsin farms, Shere *et al.*, (1998) reported that the use of antimicrobials subtherapeutically in animal feeds or trough waters and therapeutically for treatment of diarrhea correlated well to the emergence of antimicrobial-resistant *E. coli* O157:H7, which may have been transmitted through birds eating the animal feed and drinking contaminated trough waters. Nielsen et al (2004) screened 446 fecal samples at eight Danish cattle and swine farms and detected stx1 and stx2 genes in production animals, wild birds, and rodents suggesting transmission between the livestock animals and vectors. Halos *et al.*, (2004) detected the *Bartonella* citrate synthase gene in Hippoboscidae flies on wild roe deer, cattle, horses, and sheep in France suggesting that these flies may act as a vector for transmission of *Bartonella* between wild and domestic ruminants. Waldenström et al (2005) observed antimicrobial resistant *Campylobacter jejuni* in wild thrushes, shorebirds, and raptors in Sweden suggesting the spread of antimicrobial-resistant pathogens to wild birds. Raptors had the highest prevalence of antimicrobial-resistant strains, potentially from predation on infected animal vectors. On 12 diary and beef feedlots in Idaho, Oregon, and Washington, Herriott *et al.*, (2002) identified *E. coli* O157:H7 in composite fly samples and pooled bird droppings. Marshall *et al.*, (1990) inoculated pigs with an antimicrobial-resistant strain of *E. coli* and within a four month period was able to isolate the same strain from trough water, bedding materials, mice, flies, and a human caretaker.

Other studies may point to broader ecological implications of animal vectoring in the environment. Cole et al (2005) compared free-living Canadian geese in Craven county, Georgia that were using swine waste lagoons and surface waters adjacent to farm fields to Canadian geese in Griffin, Georgia, where there were crop fields, but no nearby animal production facilities. The proportion of *E. coli* isolates resistant to antimicrobial agents was significantly greater ($p=0.0004$) among Craven county geese (72%), where interaction with swine waste lagoons was observed, than in Griffin geese (19%). These researchers proposed that Canadian Geese may be acting as vectors for antimicrobial-resistance and resistance genes in agricultural animal-production environments. Their findings suggest the spread of pathogens and antimicrobial resistant bacteria from livestock operations may be vast considering potential migration of Canadian geese over hundreds of kilometers.

Other factors unique to concentrated animal feeding operations may encourage the spread of disease on farms. Several researchers have detected high levels of airborne bacteria ($2x10^3$ – $8x10^5$ CFU/m^3) in confinement house air including antimicrobial-resistant bacteria and other zoonotic pathogens such as *Enterococcus*, *Staphylococcus*, *Pseudomonas*, *Bacillus*, *Listeria*, *Salmonella*, *Campylobacter*, and *E. coli* (Cormier *et al.*, 1990; Cazwala *et al.*, 1990; Crook *et al.*, 1991; Heederick *et al.*, 1991; Predicala *et al.*, 2002). In houses of experimentally infected broiler chickens, Gast et al (2004) were able to detect *Salmonella* spp. in the air for four weeks post-infection, even when the litter was cleaned from the floors weekly. In a study of three mechanically ventilated swine CAFOs, Zahn *et al.*, (2001) detected tylosin resistance in 80% of cultivable airborne bacteria. Chapin *et al.*, (2005) isolated 137 *Enterococcus* and staphylococci from the air within a concentrated swine feeding operation and screened them for resistance to erythromycin, clindamycin, virginiamycin, tetracycline, and vancomycin. 88% of the isolates expressed high-level resistance to at least two antibiotics and 84% to at least three antibiotics commonly used in swine production, but none were resistant to vancomycin, an antibiotic that has never been approved for use in livestock in the United States. Thirty seven percent of the isolates were resistant to virginiamycin, an analog to quinipristin-dalfopristin which is a drug of last resort for multidrug-resistant gram-positive infections characterized by glycopeptide-resistant *E. facium* and coagulase-negative staphylococci.

These findings have significant implications for the health of livestock animals, animal care workers, their families, and casual farm visitors, and to a lesser extent to nearby communities that may be susceptible to secondary infections via exposure to sickened animal care workers and their families. Chapin *et al.*, (2005) proposed a scenario by which airborne pathogenic zoonoses resistant to clinically important antimicrobials may spread from confined livestock animals to the public through exposure to sickened animal care workers and their families.

> *"Bacteria resistant to virginiamycin are often cross-resistant to quinipristin-dalfopristin, and a previous study has shown that transfer of streptogramin-resistant Enterococcus can occur between animals and humans in the livestock environment (Jensen et al., 1998)… Inhalation of air contaminated with multidrug resistant Enterococcus or streptococci could lead to colonization of both the nasal passages (Aubry-Damon, 2004) and the lungs of swine CAFO workers, potentially making the workers themselves reservoirs of antibiotic-resistant organisms. Co-exposures to other aerosols and gases in the swine environment such as organic dusts, molds, and ammonia have been shown to induce symptoms associated with chronic bronchitis, including a persistent cough characterized by expectoration (Mackiewicz, 1998). The presence of this type of cough can increase the potential for secondary spread of antibiotic-resistant organisms into the community, where additional individuals could serve as reservoirs of multidrug-resistant bacteria… Thus, the inhalation of virginiamycin-resistant gram-positive bacteria in the swine environment could contribute to the appearance of quinipristin-dalfopristin-resistant gram-positive infections in humans, leaving few or no treatment options for the affected individual(s)"* – Chapin *et al.,* (2005)

The more recent work of Armand-LeFevre *et al.*, (2005), who determined that a number of *Staphylococcus aureus* strains that caused infections in swine populations (including four methicillin-resistant strains) were also present in healthy swine farmer nasal cavities, but not in the nasal cavities of healthy non-farmer controls, further supports their hypothesis.

Many other pathways for infection of animal care workers with pathogenic zoonoses and antimicrobial-resistant bacteria exist including, but not limited to direct contact with infected animals, increased exposure to insect and wild animal vectors on the farm, exposure to animal excreta, handling animal carcasses, exposure to contaminated air from manure spreading, and drinking water from fecally-contaminated wells (Skilbeck and Miller, 1986; Everard *et al.*, 1989; Seuri and Granfors, 1992;Thomas *et al.*, 1994; Hogue *et al.*, 1997; Cole *et al.*, 2000; Barkocy-

Gallagher et al, 2001; Chomel, 2004). These exposures have manifested in increased illness in animal care workers, their families and pets, and casual farm visitors (Levy *et al.*, 1976; CDC, 2000), and have potentially spread into nearby communities based on empirical evidence reported in literature. For instance, McDonald *et al.*, (1997) genotyped vancomycin-resistant fecal bacterial isolates from swine, poultry, farm workers and their pets in Denmark and concluded that transmission had occurred between livestock animals, humans, and household pets. Hummel *et al.*, (1986) detected nourseothricin-resistance traits in 33% of fecal isolates of swine exhibiting diarrhea, 18% of fecal isolates from swine farmers and their families, and 16% fecal isolates from outpatients exhibiting diarrhea in communities adjacent to the swine farms. Nourseothricin was not used for treatment of human disease in the region, but was used for two years for promoting growth of swine on the farms.

> The presence of antimicrobial-resistant bacteria may occur rapidly following the introduction of antimicrobials as growth promoters in feed animals. Levy et al (1976) determined that tetracycline-resistance in fecal isolates from chickens increased rapidly from 10% of animals excreting less than 0.1% of organisms resistant to tetracycline (baseline) to 90% of animals excreting 100% of organisms resistant to tetracycline within 2 weeks of introducing tetracycline to chicken feed, whereas no increase was observed in the control group. Further, multidrug resistance developed, even though only tetracycline was being supplemented in the feed. By 12 weeks, more than 60% of the animals from the experimental group excreted bacteria resistant to tetracycline plus one or more other antimicrobial compounds. More then 25% were resistant to 4 or more antimicrobials. After 4 months, antimicrobial resistance had spread from the experimental group to the control group, where a third of the chickens excreted bacteria of which more than 50% of isolates were tetracycline resistant. Within 6 months, antimicrobial resistance had also spread to the farm workers and their immediate families. More than 30% of fecal samples form farm workers and their families contained more than 80% tetracycline-resistant organisms, versus 6.8% from their neighbors. A 4-drug resistance pattern similar to that observed in the experimental chickens was observed in the farm workers and their families. Stopping the feed additives eventually reduced the incidence of tetracycline-resistant bacteria in the farm dwellers.

Livestock animals can also be a source of antimicrobial-resistant bacteria and pathogenic zoonoses such as *E. coli* O157:H7, *Salmonella* sp., and *Staphylococcus aureus* in abattoirs, which may slowly die off or in some instances regrow in the waste products (Hepburn *et al.*, 2002). When improperly handled, these wastes may potentially contaminate adjacent land and nearby watercourses or infect slaughters, and through secondary infections, their families and pets (Crawford *et al.*, 1969; Nesbakken, 1988; Molin *et al.*, 1989; Reboli and Farrar, 1989; Merilahti *et al.*, 1991; Seuri and Granfors, 1992; Huys *et al.*, 2005). In fact, as with animal care workers, epidemiological evidence supports transmission of these pathogens from livestock animals to humans in the abattoir environment, but suggests the infection rate is lower than that observed in farmers and their families. For instance, van den Bogaard *et al.*, (1997) phenotyped fecal *Enterococcus* spp. isolates from turkeys, turkey farmers, turkey slaughterers, and nearby residents of the turkey farms in Europe. Vancomycin-resistant *Enterococcus* (VRE) was detected in half of turkey samples, 39% of turkey farmers, 20% of turkey slaughterers, and 14%

In a recent study, van den Bogaard *et al.*, (2001) surveyed three poultry operations (broilers, turkeys, and laying hens) and five human populations (turkey farmers, broiler farmers, laying-hen farmers, broilers slaughterers, and turkey slaughterers) in the Netherlands for antimicrobial-resistant fecal *E. coli*. These researchers determined that 35% of isolates from laying hens were antimicrobial-resistant, as compared to 84% of the isolates from turkeys and 80% of the isolates from broilers. Similarly, 66% of *E. coli* isolates from turkey farmers, 60% from broiler farmers, 67% from turkey slaughterers, and 59% from poultry slaughterers were antimicrobial-resistant whereas only 45% of isolates from laying hen farmers were antimicrobial-resistant. Antimicrobial resistance patterns of the isolates were similar between turkeys, turkey farmers and turkey slaughterers, and in broilers, broiler farmers, and broiler slaughterers. Pulsed-field gel electrophoresis (PFGE) "fingerprinting" patterns of an *E. coli* isolate from a turkey was identical to one from a turkey farmer. Similarly, one isolate from a broiler chicken was identical to an isolate found in a broiler chicken farmer. Their results strongly indicate transmission of antimicrobial resistant bacteria between humans and poultry commonly occurs.

of area residents. VRE is one of the leading causes of nosocomial infections in the hospital environment. Nijsten *et al.*, (1994) determined that the resistance of fecal isolates to antimicrobial compounds was more prevalent in swine farmers than slaughterhouse workers and suburban residents in the same geographic region. In Japan, antimicrobial resistance of fecal microbes was also noted to be highest in swine farmers and elevated in slaughterhouse workers when compared to urban control cohorts (Saida *et al.*, 1981). Others have realized similar trends supporting the movement of antimicrobial-resistant bacteria from farm animal to farmer or slaughterer (Ozanne *et al.*, 1987; Levy, 1978; Marshall *et al.*, 1990).

5.2 Food

It is well established that pathogenic zoonoses can cause human disease via consumption of contaminated meat products (Corpet, 1993; U.S. Congress, Office of Technology and Assessment, 1995; Milleman *et al.*, 2000). The amplified use of antimicrobial compounds in confinement animals for growth promotion and prophylaxis may exacerbate disease by reducing treatment options and potentially increasing the virulence of bacterial pathogens in meats. For instance, in 1995 fluoroquinolone antibiotics were approved for use in poultry for growth promotion and prophylaxis. In 1997, Smith *et al.*, (1999) screened chicken obtained from Minnesota shopping markets that originated from 15 abattoirs in nine states for *Campylobacter jejuni* and resistance to ciprofloxacin, an important human-use fluoroquinolone antibiotic of choice for presumptively treating severe bacterial food poisoning. Fourteen percent of the samples were contaminated with ciprofloxacin-resistant *C. jejuni*. During a similar period, statewide-surveillance indicated that fluoroquinolone-resistance increased from 1.3% of all human *C. jejuni* infections in 1992 to 10.2% in 1998 (Smith et al, 1999). In a more recent study, Wallinga *et al.*, (2002) surveyed 200 fresh whole market chickens and 200 packages of ground turkey from stores in Iowa and Minnesota and determined that 95% of whole chickens were contaminated with *Campylobacter* and 18% with *Salmonella*. Two percent of ground turkey samples and were contaminated with *Campylobacter* and 45% with *Salmonella*. Six percent of the *Salmonella* isolates were resistant to 4 or more antimicrobials, while 62% of the *Campylobacter* isolates were resistant to 1 or more antimicrobial compound including an 8%

prevalence of resistance to ciprofloxacin. Greater than ninety percent of enterococci isolated from the chicken or turkey were resistant to quinipristin-dalfopristin, an important antibiotic for the control of VRE infections in hospitals. In a similar study, Hayes *et al.*, (2003) screened 981 samples of raw retail meats including chicken, turkey, pork, and beef from 263 grocery stores in Iowa and found high levels of resistance to several antimicrobials in *Enterococcus* isolates. Their results indicate that antimicrobial-resistant *Enterococcus* spp. commonly contaminate retail meat products and that the antimicrobial resistance pattern of isolates from each meat product (poultry, pork, and beef) reflected well the use of approved agents in each food animal production class (broilers, swine, and beef cattle).

Dairy products may also be contaminated with pathogenic zoonoses and antimicrobial-resistant bacteria following direct contact of dairy cattle to contaminated sources in the farm environment and subsequent excretion from the udders of infected animals (Oliver *et al.*, 2005). For instance, Van Kessel *et al.*, (2004) surveyed 861 bulk tank milks on farms in 21 states and detected *Listeria monocytogenes* (6.5%) and several *Salmonella* serotypes (2.6%) including Montevideo, Newport, Muentster, Meleagris, Cerro, Dublin, and Anatum. Kim *et al.*, (2005) tested 316 bulk milk tank samples across the U.S. between January 2001 and December 2003 for *Coxiella burnetii*, the causative agent for Q-fever. These researchers detected *C. burnetii* in greater than 94% of bulk tank milk. Jayarao and Henning (2001) surveyed bulk tank milks from 131 dairy herds in South Dakota and Minnesota and detected *Campylobacter jejuni* (9.2%), shiga-toxin producing *Escherichia coli* (3.8%), *Listeria monocytogenes* (4.6%), *Salmonella* spp. (6.1%), and *Yersinia enterocolitica* (6.1%), with one or more species of pathogenic bacteria in 26.7% of the samples. Although pasteurization may reduce the incidence of disease in humans attributable to contaminated milk, Oliver *et al.*, (2005) argue that outbreaks of disease have been traced back to both unpasteurized and pasteurized milk, and that unpasteurized milk is often consumed directly by dairy producers, farm employees, and their families, as well as by their neighbors and raw milk advocates. In their bulk tank-milk study, Jayarao and Henning (2001) observed that 60% of the dairy producers drank unpasteurized milk, 27% of which contained one or more types of pathogenic bacteria. According to the model presented in Figure 1, disease contracted via this route may be spread to nearby communities via contact with infected individuals. It has also been noted that an even larger segment of the population may be directly exposed to contaminated dairy products via consumption of cheeses made from unpasteurized milk (Oliver *et al.*, 2005).

CAFOs produce massive quantities of manure, much of which is spread onto agricultural fields as fertilizer. Fecally-contaminted water, potentially resulting from runoff from manure-treated fields or discharge of wastes from agricultural operations, may be used to irrigate crops in arid regions of the United States. Direct contact with soils on which manure was applied and/or irrigation with fecally-contaminated water may result in contamination of produce such as lettuce, radishes, apples, and sprouts with pathogenic zoonoses including antimicrobial-resistant bacteria, especially where the edible parts are exposed to the soil or water (Besser *et al.*, 1993; Tschäpe *et al.*, 1995; Nelson, 1997; Taormina *et al.*, 1999). In a recent study, Ingham *et al.*, (2004) identified *E. coli* contamination on carrots, lettuce, and radishes up to 120 days following application of non-composted bovine manure as a fertilizer in fields in Wisconsin. In contrast, Johannessen *et al.*, (2005) did not detect *E. coli* O157:H7 on the edible parts of lettuce after growth in *E. coli* O157:H7-contaminated manure fertilized soil. Solomon *et al.*, (2002) noted that spray irrigation following a single exposure to *E. coli* O157:H7 resulted in 90% of the lettuce being contaminated, persisting for more than 20 days in 82% of the plants. Where surface irrigation was used under the same circumstances, only 19% contamination was observed on the lettuce. Immersion of harvested lettuce heads in 200ppm chlorine solution for 1 minute did not eliminate all *E. coli* O157:H7 cells from infected lettuce, regardless of irrigation method. It has been suggested that some produce may absorb pathogens into their internal tissues through the root system, protecting them from cleaning procedures such as washing or irradiation. In a survey of fresh domestic produce conducted in the spring of 2000, the US Food and Drug Administration detected Salmonella on 2.6% of cantaloupe, 1.6% of cilantro, and 1.8% of lettuce originating from U.S. farms (US FDA, 2001).

5.3 Air

Vast quantities of manure produced at CAFOs containing high levels of pathogenic microorganisms and antimicrobial-resistant bacteria are applied to agricultural lands each year. Viable bacteria and viruses become airborne from agricultural sprayers, pasturelands, and farm fields treated with manure, ultimately decreasing the quality of air near CAFOs. The upward flux of viable bacteria may be strongly related to plant cover and soil moisture condition. For instance, upward flux of viable bacteria from bare soil and various crops has been reported to increase an order of magnitude in dry soil over young corn in wet soil, another order of magnitude in a closed wheat canopy over dry soil, and four orders of magnitude between bare soil and an alfalfa field (Lindemann *et al.*, 1982). Although plants have been found to be a stronger source of bacteria than soil (Lindemann and Upper, 1985), specific agricultural practices that increase particle emissions may significantly impact bacterial loading to an airshed. Strong vertical temperature gradients, low relative humidity and low soil moisture may lead to increased emission of PM10 from agricultural fields during tilling (Holmen *et al.*, 2000; Clausnitzer and Singer, 2000). As dust may harbor viable bacteria, these factors may increase pathogen loading to an airshed. If pathogens survive in soils until harvest, it is possible that significant airborne spread may occur. It has been estimated that during harvest, up to 42% of bacterial loading in an airshed can be attributed to harvesting activities (Lighthart, 1984; Tong and Lighthart, 2000).

Upward flux of viable bacteria may also be related to temperature, exposure to solar radiation, protection from associated soil particles, and wind speed. Lindeman and Upper (1985) report that upward flux of bacteria over bean plants in Wisconsin occurred during the warmest parts of the day with a maximum around noon, especially on windy days, and was observed to cease when wind speeds were less than 1m/s. Tong and Lighthart (1999) suggest that peak concentrations of viable bacteria over agricultural lands in Oregon may occur in late afternoon, presumably due to less exposure to solar radiation or association with larger particles protective from the effects of the sun. Upward flux of viable bacteria over a high desert chaparral have been observed to peak late in the evening, with minimum viable bacterial concentrations at 13:20 hours and a maximum at 22:00 hours, presumably due to the strong effects of solar radiation (Lighthart and Schaffer, 1994). The effects of temperature on upward flux of bacteria may overcome the effects of solar radiation. Summer months have been associated with higher incidence of airborne viable bacteria, even though increased solar radiation may negatively influence bacterial viability due to UV damage or desiccation of bacterial cells (Tong and Lighthart, 1997; Tong and Lighthart, 2000).

Several studies have documented increased airborne pathogens directly attributable to the spread of human or animal manure on agricultural lands through spray irrigation with contaminated waters or deposition of animal placental and fecal wastes and subsequent distribution to downwind animal or human receptors (Boutin *et al.*, 1988; Hughes, 2003; Donnison *et al.*, 2005; Brooks *et al.,* 2005). Boutin *et al.*, (1988) identified bacterial counts as high as 2000 viable particles per cubic meter at the edge of applied areas following land spreading of cattle and pig slurry. Donnison *et al.*, (2005) studied the survival of *Bacillus subtilis* and *Serratia entomophila* in irrigation aerosols in spring and summer in New Zealand. Viable *B. subtilis* and *S. entomophila* corresponding to the respirable fraction of inhaled air were recovered at 100 m from a low pressure sprayer and 200 m from a high pressure sprayer. Brooks et al (2005) studied the aerosolization of *E. coli* and coliphage MS-2 from liquid biosolids applied from a spray tanker under hot (22-37.5C) and arid (5-15% relative humidity) conditions. At wind speeds between 0.7-6 m/s, these researchers could not detect aerosolized *E. coli* at distances as low as 2 m, but detected coliphage MS-2 at distances as far as 60 m. Paez-Rubio et al (2005) identified aerosolization as a potential mechanism for the dissemination of wastewater bacteria and other microorganisms at flood irrigation wastewater reuse sites. These researchers identified more than 1 billion enteric bacteria per cubic meter in downwind air samples. Airborne *Coxiella burnetii* associated with sheep operations and Picnoravirus from swine operations have been estimated to travel several kilometers in the air in concentrations sufficient to cause infectious disease in humans and animals (Henderson, 1969; Hugh-Jones and Wright, 1970; Smith *et al.*, 1993; Hawker *et al.*, 1998; Lyytikainen *et al.*, 1998).

5.4 Recreational and Drinking Water

The USEPA's 1998 National Water Quality Inventory indicates that agricultural operations, including animal feeding operations, are the most common polluters of rivers and streams, contributing to the impairment of 59% of those surveyed. Agricultural operations also have significant impacts on lakes, ponds, reservoirs, and estuaries, contributing to the impairment of more than 3,590,000 acres of these valuable water resources (USEPA-NACAC, 2005). Figure 3 illustrates the relationship between confined livestock animals in the U.S. in 1997 and impairment of surface waters indicated in the 1998 National Water Quality Inventory. In 1998, pathogens (microbial indicators, not overt pathogens) were the most common water pollutant contributing to 7,742 impairments (14.24% of surveyed waters). Sources of these microorganisms may have included wastewater and storm water outflows, the spreading of biosolids and animal manures on agricultural lands, and wild animals. However, the sheer quantities of animal wastes generated and spread onto land compared to those of other sources suggests animal agriculture may be the dominant contributor. Pathogenic microorganisms continue to pose a major challenge to the quality of U.S. waters, contributing to a total of 7,894 impairments (13.16% of surveyed waters) on the USEPA's 2002 National Water Quality Inventory.

A survey of literature regarding overt pathogens in agricultural waters and drinking water sources suggest that the National Section 303(d) listings may underscore the actual extent of microbial contamination in agricultural watersheds resulting from livestock activities. For instance, two surveys of source waters for surface water treatment plants in 29 states resulted in detection of *Cryptosporidium* oocysts in 55% and 87% of the waters tested. Similarly, *Giardia*

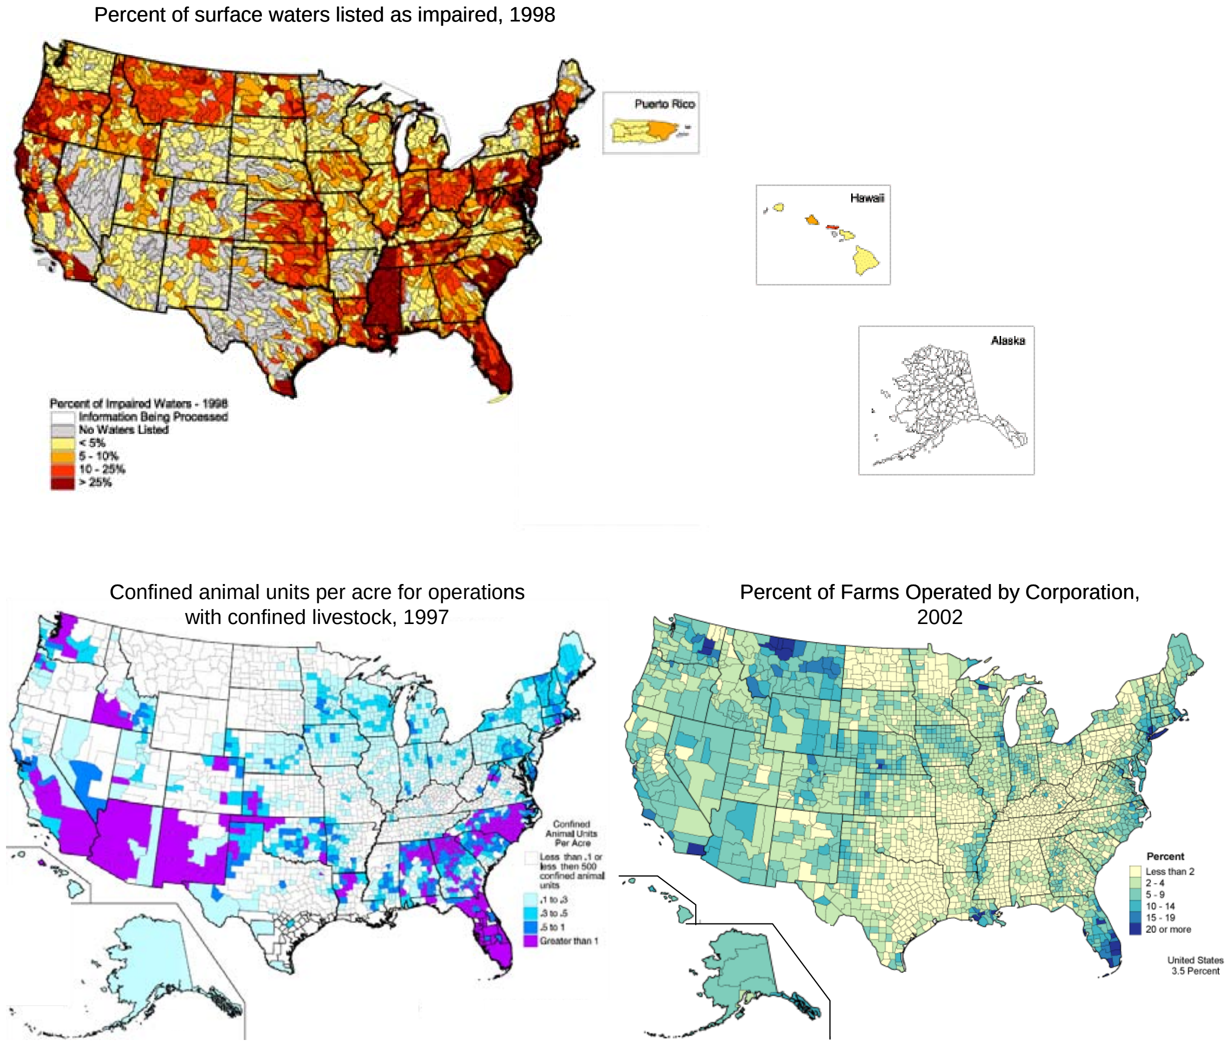

Figure 3. The impact of confined animal feeding operations on agricultural watersheds (adapted from USDA-NRCS, 2002; USEPA, 1998)

cysts were detected in 16% and 81% of the waters tested (LeChevallier *et al.*, 1991; Rose *et al.*,1991). *Mycobacterium avium*, potentially from cattle, swine, and broiler operations, have been detected in several marine waters, rivers, lakes, streams, ponds, and spring waters (AWWARF, 1997; Ichiyama *et al.*, 1988; Falkinham *et al.*, 2001; LeChevallier, 1999). A high prevalence of *Campylobacter* spp. in environmental water samples in a dairy farming area in the United Kingdom including 56.7 % of running waters (streams and ditches) and 45.9% of standing waters (ponds) was recently noted (Kemp *et al.*, 2005). Swine farming activities have been implicated in the contamination of at least one major Canadian river by enteroviruses (Payment, 1989), and have also been correlated to the presence of *Cryptosporidium parvum* oocysts, *Yersinia enterocolitica*, and *Salmonella* spp. in nearby drainage canals, groundwater wells, and surface waters where lagoon and spray systems are used (CDC, 1998). Groundwater surveys in Ontario Canada indicated that wells located near manure application areas were at higher risk for fecal bacterial contamination, and the level of contamination was inversely correlated to the distance the wells were from animal feedlots or exercise yards (Conboy and Goss, 2002).

The delivery of zoonotic pathogens to environmental waters following manure application is dependent on several factors including, but not limited to, the initial and persisting pathogen load, properties of the pathogen of interest, the soil and vegetation type, travel distance/time to the receiving water, pathogen inactivation by various environmental stressors, and potential engineered or natural barriers to pathogen transport. When manure is spread onto land, overland flow of pathogens to water bodies may occur via attachment to applied waste products, attachment to soil particles, or movement in the free form (Tyrrel and Quinton, 2003, Muirhead et al, 2005). Leachate from manure-amended fields and poorly designed manure holding lagoons may inundate natural soil barriers resulting in contamination of underlying groundwater (Jones, 1980; Kowel, 1982; Natsch *et al.*, 1996; Jogbloed and Lenis, 1998). Within the soil profile, movement of pathogenic zoonoses may be limited by soil moisture and solid-phase interactions (adsorption-desorption) or facilitated by the presence of macropores from burrowing animals, fractured media, or plant roots (Ferguson *et al.*, 2003). Contaminated groundwater may be captured by drainage tiles that discharge to surface waters, bypassing overland treatment in natural or engineered vegetative or riparian buffers. Alternatively, pathogens may enter groundwater where they may potentially migrate towards wells or natural springs that may be used for drinking water. The delivery of an infective dose to a susceptible individual will depend not only on the transport properties of pathogens, but also on the time required for pathogen inactivation due to environmental stressors or predation in surface and groundwater resources.

The concentration of pathogens reaching subsurface tile drains that discharge to nearby streams often exceeds drinking water supply and recreational use standards (Warnemuende and Kanwar 2000). Tile drainage has been noted to be a significant pathway for pathogens to enter surface waters from manure-treated fields, especially during periods of wet weather (Dean and Foran, 1992; Joy *et al.*, 1998; Geohring *et al.*, 1999; Hunter *et al.*, 2000; Monaghan and Smith, 2005). Evans and Owens (1972) noted that approximately 0.05% if *E. coli* applied with swine manure applications to a sandy clay loam pasture could be recovered in the tile drainage water. In a study of swine operations in Iowa and Missouri, Karetnyi *et al.*, (1999) identified swine hepatitis E in a tile outlet draining a field to which manure had been applied. Evans and Owens (1972) determined that fecal bacteria present in swine waste slurries could be detected in the tiles draining the pasture to which the waste was applied within a few hours of application.

Where pathogens bypass tile drainage systems or tile drainage is non-existent, significant contamination of groundwater resources may occur. The transport of pathogens that have infiltrated the soil profile depends strongly on adsorption-desorption interactions. Key characteristics of pathogenic zoonoses related to adsorption-desorption phenomena include size, surface electrostatic properties, cell wall hydrophobicity, and the presence of flagella (Gerba, 1984; Dowd *et al.*, 1998; Heise and Gust, 1999). For viruses, attachment to soil particles is rapid, and may be increased by low pH or high ionic strength groundwater or by high soil organic carbon content (Gerba, 1981; Gerba *et al.*, 1978; Goyal and Gerba, 1979; Taylor *et al.*, 1980; Moore *et al.*, 1981; Taylor et al, 1981; Moore, 1982; Singh *et al.*, 1986; Bales *et al.*, 1991; Bales *et al.*, 1993; Sakoda *et al.*, 1997). At the neutral pH of most groundwater, organic carbon content of the soil may dominate retardation of viral particles. Retardation of bacterial particles in saturated porous media may also be dominated by organic-carbon partitioning, but can also be a product of straining or simple filtration (Heise and Gust, 1999). Straining and filtration may be

In a collaborative study performed at 9 Swine CAFOs in Iowa employing lagoon and spray systems, the CDC tested the swine waste lagoons and several selected points near the agricultural facilities for pathogenic zoonoses. They identified elevated concentrations of *E. coli* (≤380,000 per 100mL), *Enterococcus* sp. (≤1,900,000 per 100 mL), *Salmonella* sp. (≤9,300 per 100 mL), and *Cryptosporidium parvum* oocysts (≤2250 per liter) in the swine waste lagoons. *C. parvum* oocysts were detected in monitoring wells nears the swine waste lagoons of three CAFOs (9-15 oocysts per L) and in the river adjacent one CAFO (6 oocysts per L). A single *Yersinia* sp. was detected in an agricultural drainage ditch draining the spray field at one facility. Elevated *E. coli* were detected in the agricultural drainage wells (300-740/100mL), drainage ditches (520-3,700/100mL), monitoring wells (10-390/100mL), and drainage tile inlet/outlets (10-2,900/100mL). Similarly, *Enterococcus* sp. were detected in the agricultural drainage wells (4,500/100mL), drainage ditches (610-13,000/100mL), monitoring wells (80-910/100mL), and drainage tile inlet/outlets (30-2,400/100mL). *Campylobacter* sp. were not detected at any of the sampling points. Of the 18 *E. coli*, 3 *Salmonella* sp., and 20 *Enterococcus* sp. isolates tested for antimicrobial resistance, 16 *E. coli*, and all 3 *Salmonella* and 20 *Enterococcus* sp. were resistant to one or more antimicrobials commonly used in swine management practice as feed supplements and therapeutics (16 total including fluorfenicol, tetracycline, sulfamethoxazole, ampicillin, streptomycin, apramycin, bacitracin, lincomycin, penicillin, synercid, kanamycin, cephalothin, amoxicillin-clavulanic acid, ceftiofur, chloramphenicol, and gentamicin). Eight *E. coli* and all 3 *Salmonella* sp. and 20 *Enterococcus* sp. were multi-drug resistant (2-11 antimicrobials) (CDC, 1998).

even more significant for the larger protozoan parasites such as Cryptosporidium oocysts and Giardia cysts. Once contaminated, restoration of water quality in contaminated aquifers is very slow (Olson, 2003).

In packed sand columns, it has been demonstrated that Cryptosporidium oocysts, although initially filtered, may exhibit time-dependent detachment leading to a constant low-level elution from porous media (Harter *et al.*, 2000). Free oocysts have been observed to move in pore water without retardation suggesting potential for considerable transport in aquifers considering their long survival times (Brush *et al.*, 1999; Harter *et al.*, 2000). Similarly, viruses become attached to sediments near the source of contamination and leach slowly into the groundwater. Therefore, even single contamination events may provide a lingering source of viral contamination to groundwater (de Borde *et al.*, 1998b). Viruses have been shown to be able to travel considerable distances through the subsurface depending on their size, adsorption characteristics, and degree of inactivation (Keswick and Gerba, 1980; Dowd *et al.*, 1998). For instance, enteric viruses, some of which may remain infective for more than 9 months, have been observed to move up to 1000-1600 m per year in channelized limestones and several hundred meters per year in glacial silt-sand aquifers with travel times similar to bromide tracers (Skilton and Wheeler, 1988; Bales et al, 1995; Bosch, 1998; de Borde et al; 1998a; de Borde et al; 1999). Bacterial pathogens may similarly move considerable distances as indicated in a study by Withers *et al.*, (1997), who identified groundwater contamination by *E. coli* from an unlined cattle waste lagoon 76 m below ground surface and 80 m downstream the lagoon in the United Kingdom.

A significant limitation of the National 303(d) listings is the lack of monitoring for antimicrobial-resistant bacteria. Antimicrobial-resistant bacteria are generally shed in animal feces, but may also be present in the mucosa of livestock animals. The massive use of antibiotics in animal agriculture pose a great risk as antimicrobial-resistant bacteria shed in animal wastes and stored in lagoons or spread onto land may eventually find their way to the aquatic environment (CDC, 1998; Levy, 1998; Chee-sanford *et al.*, 2001). For instance, Chee-Sanford *et al.*, (2001) detected all eight classes of tetracycline-resistance genes in two swine waste lagoons and the underlying groundwater up to 250 meters down-gradient the lagoons. Tetracycline resistant bacterial isolates from groundwater harbored a *tet*(M) gene identical to that detected in the swine waste lagoons. Resistance genes from antimicrobial-resistant bacteria in contaminated discharge waters can be transferred to otherwise susceptible bacteria living in unpolluted aquatic habitats, encouraging the spread of antimicrobial resistance in environmental waters (Guardabassi and Dalsgaard, 2002; Gurdin *et al.*, 2002). The extent of proliferation may be limited by the distance from the discharge point.

Antimicrobials in livestock animals are primarily removed in the urine and bile, either unchanged or in metabolite form, and therefore can directly contaminate environmental waters. Once in the environment, antimicrobial compounds and their metabolites may degrade rapidly (tetracyclines, penicillins, and fluoroquinolones) or persist (macrolides and sulfonamides), resulting in long-term contamination near animal confinement operations. For instance, Campagnolo *et al.*, (2002) detected several antimicrobials used in animal agriculture in animal waste lagoons (2.5-1000 µg/L) and in monitoring wells, field drainage tiles, springs, streams, and rivers (0.06-7.6 µg/L) proximal to confined animal feeding operations in Iowa and Ohio. The use of antimicrobials in animal agriculture most certainly contributed to the frequent detection of antimicrobials in a recent U.S.G.S. survey of rivers and streams of the United States (Kolpin *et al.*, 2002). Although the presence of a pharmaceutical residues and their metabolites in potable water sources present their own ecological challenges (Goni-Urriza *et al.*, 2000; Zuccato *et al.*, 2000; Hirsch *et al.*, 1999; Halling-Sorensen *et al.*, 1998; Daughton *et al.*, 1999), their typical concentrations in environmental waters are usually far below (approximately 1000-fold) those that would selectively enrich for resistant bacteria. Resistant bacteria found in surface waters are likely to have originated from wastewater or manure runoff from antimicrobial-rich settings such as animal feeding operations or wastewater treatment plants or subsequently contaminated animal vectors (Levetin, 1997; Stetzenbach, 1997; Summers, 2002).

Although low environmental concentrations of antimicrobials may not be adequate to enrich for resistant strains of bacteria, their role in the proliferation and maintenance of antimicrobial-resistance genes in these complex milieus is uncertain. For example, Gurdin et al (2002) screened isolates of *E. coli* and enterococci from swine farm wastes, and environmental isolates of *E. coli*, enterococci, *Kleibsiella*, and *Aeromonas* in surface waters upstream and downstream of study farms for antimicrobial resistance. These researchers observed that the diverse resistance patterns exhibited by rural background surface water isolates likely reflected human and animal impacts. In contrast, bacteria isolated downstream from swine farms exhibited increased antimicrobial-resistance that reflected the swine waste isolates. Sixty seven percent of Aeromonas and 12% of enterococci isolates upstream the study farms were resistant to erythromycin, whereas 91% of Aeromonas and 30% of enterococci isolates down-stream the study farms were resistant. Antimicrobial residues were also more likely to be detected downstream rather than upstream swine farms. However, antimicrobial resistance did not always correlate to detection of residues. Swine farms were shown to be capable of contributing resistant enteric bacteria that act as reservoirs for the spread of resistance traits to susceptible bacteria, and antimicrobial residues which may encourage the maintenance and spread of the resistance traits. More work is needed to clearly identify threshold concentrations of antimicrobial residues in environmental waters that encourage the spread of antimicrobial resistance.

5.5 Hydrologic events

Once in natural water bodies, viral particles, bacteria, and protozoan cysts and oocysts may attach to larger particles such as organic matter or soils and settle into the sediments of streams or reservoirs. Due to their size, settling of free particles may be limited. Their association with sediments may offer some protection from environmental stressors such as solar and UV radiation, pH extremes, desiccation, antibiotics, and predators leading to increased survival (Gerba and McLeod, 1976; Smith *et al.*, 1978; Roper and Marshall, 1979; Bitton and Marshall, 1980; LaBelle and Gerba, 1980; Schaiberger *et al.*, 1982; Metcalf *et al.*, 1984; Rao *et al.*, 1984; Long and Davies, 1993). .As such, the sediments of natural water bodies may act as reservoirs for pathogenic zoonoses and antimicrobial-resistant bacteria discharged from CAFOs (Hendricks, 1971; Grimes, 1975; Gerba *et al.*, 1977; Davies *et al.*, 1995). For instance, in estuary waters, Metcalf *et al.*, (1984) detected enteroviruses and rotaviruses in 14 and 50% of two water samples but 72 and 78% of their respective sediments contained these viruses. In 20-70% of surface waters, it has been observed that viruses occur as solid-associated particles, and may be present in high concentrations in bed sediments when compared to overlying water even at vast distances from the original source of contamination (Ferguson *et al.*, 2003).

The movement of pathogens from CAFO operations can be exacerbated by rainfall, which may stimulate the release of pathogens from otherwise stable manure-treated fields or fecal pats leading to increased overland transport, discharge to surface waters by drainage tiles, or infiltration into groundwater resources (Kress and Gifford, 1984; Mawdsley *et al.*, 1996a,b; Hunter *et al.*, 2000; Ogden *et al.*, 2001; Davies *et al.*, 2004; Monaghan and Smith, 2005). Often, stream flow increases significantly during hydrologic events, stirring up bedded sediments and further increasing pathogen concentrations, especially in shallow surface waters (Ferguson *et al.*, 2003). For example, Ferguson (1994) determined that an increase of 1-cm in rainfall increased *Cryptosporidium* oocysts in the Georges River by 24%. Atherholt *et al.*, (1998) demonstrated a positive correlation between parasitic protozoan concentrations in the Delaware River Watershed and precipitation events. Kistemann *et al.*, (2002) measured *E. coli*, fecal streptococci, *Clostridium perfringens*, *Cryptosporidium*, and *Giardia* in the tributaries of 3 drinking water reservoirs during normal and wet weather events and noted a 1-2 $\log_{10}$ increase in bacterial and parasitic microbial concentrations during runoff compared to normal conditions. Crowther *et al.*, (2002) observed highly significant positive correlations between concentrations of coliforms, *E. coli*, and enterococci in two watersheds in the United Kingdom during hydrologic (high flow) events and land use/management variables associated with intensive livestock farming. High flow conditions were associated with a greater than 10-fold increase in geometric mean fecal indicator concentrations (coliforms, *E. coli*, and enterococci) potentially due to storage and resuspension of viable organisms in channel bed sediments. Kunkle (1972) noted a marked dependence of bacterial concentrations on stream flow in the Sleepers River Basin near St. Johnsbury, Vermont, and emphasized the importance of stream surveillance that accounts for the hydrology involved. Joy *et al.*, (1998) reported bacterial contamination of surface water due to the application of liquid manure by accepted practices over a two year period. Drainage tiles were determined to deliver significant amounts of bacteria to surface waters, which was exacerbated by rainfall shortly following manure application.

Extreme precipitation may pose more significant problems for CAFO operators as lagoons and other engineered manure management systems such as vegetative buffers, infiltration basins, and constructed wetlands may be challenged by the level of flooding associated with these events. Passive manure management systems are typically designed for 20-50 year flood events, and may be overtopped during more rigorous flooding. Flood waters may engulf vegetative buffers allowing direct contact with animal wastes applied to fields. Flooding may also engulf animal confinement houses drowning animals and transporting raw fecal material and animal carcasses downstream. Waste management systems that do not fail will experience elevated discharge, reducing their efficacy as a barrier to pathogens. Because of the potential liability associated with overtopping or failing waste lagoons during flooding, many CAFO operators opt to spray down their lagoons during heavy rainfall in lieu of violating freeboard limits (Wing *et al.*, 2000). Significant environmental damage associated with intentional and accidental release of manures and other potentially infectious materials from CAFO operations during flooding events has been documented and the danger still persists (Taylor, 1999; Mallin, 2000; Scmidt, 2000; Wing *et al.*, 2002). In 1999, Hurricane Floyd flooded several CAFOs and caused extensive environmental damage to river and coastal waters in North Carolina. During this event, it was estimated that dozens of animal waste lagoons were breached and more than 100,000 hogs, 2.4 million chickens, and 500,000 turkeys drown in the flood waters. Wing *et al.*, (2002) estimate that greater than 240 CAFOs still operate within the region flooded by this category 3 hurricane.

6. Public Health Outcomes

Pathogens may enter and proliferate in a farm environment through the stocking of new animals, exposure to airborne pathogens from an upwind source, contaminated trough water or feed, insect or rodent vectors, human-to-animal and animal-to-animal transmission, to name a few. Concentrating animals in confinement with suboptimal hygiene may encourage the spread of disease within farms. As discussed eariler (Section 4: Survival of Pathogens in the Environment), the survival of zoonotic pathogens in animal manures and the environment can range from days to years depending on the pathogen, the medium, and environmental conditions. Where animal wastes are improperly managed, there exists potential for the movement of pathogens off farms and into nearby water, land, and air. Uncontrolled releases of pathogens may occur via runoff, aerosolization, or infiltration into soils and groundwater, especially when manure is spread onto land. Stored animal feeds and manure can attract animal vectors that can spread disease within a farm, to nearby farms or communities, or, in the case of migratory birds, over large distances spanning hundreds of kilometers. Animal care workers are exposed to elevated levels of pathogens in confinement house air and through direct contact with livestock and animal manures, leading to an increased incidence of illness and spread of disease to their families and communities. A similar trend is seen in abattoir workers and their families due to the proliferation of pathogens within slaughterhouse environments. Contamination of produce or meat products with zoonotic pathogens may further spread disease within human populations. Even where extensive management practices are in place, exposures can and do occur. The outcomes of these exposures are animal and human disease, sometimes with serious consequences.

6.1 Waterborne and Foodborne Outbreaks

The impacts animal feeding operations may have on public health are evident in surveillance of waterborne and foodborne outbreaks in the U.S. reported by the Centers for Disease Control and Prevention (CDC). Table 7 summarizes the CDC outbreak data between 1991 and 1997. During this period, there were more than 3,900 reported outbreaks infecting more than 500,000 individuals. Based on reported data, foodborne outbreaks were 8.3 times more likely to be reported than waterborne outbreaks. However, waterborne outbreaks tend to affect larger numbers of individuals per incident, most likely because communities share drinking water resources and recreational waters. Between 1991 and 1997, the number of infected individuals per waterborne outbreak was 35 times larger than for foodborne outbreaks (2-3 times larger discounting the *Cryptosporidium* outbreak in Milwaukee in 1993 that infected more than 400,000 individuals). Of the outbreaks of known etiology reported from 1991-1997, slightly less than half (48%) of the recreational water outbreaks and nearly two thirds (66%) of the outbreaks associated with untreated drinking water were caused by zoonotic pathogens. During the same period, 82% of the foodborne outbreaks of known etiology were caused by zoonotic pathogens. The pathogens most often

Of the outbreaks of known etiology reported from 1991-1997, slightly less than half (48%) of the recreational water outbreaks and nearly two thirds (66%) of the outbreaks associated with untreated drinking water were caused by zoonotic pathogens. During the same period, 82% of the foodborne outbreaks of known etiology were caused by zoonotic pathogens.

associated with outbreaks include *Giardia*, *Cryptosporidium*, *Campylobacter*, *Salmonella*, and toxigenic *E. coli* (including *E. coli* O157:H7, *E. coli* O126:NM, and *E. coli* O121:H19). As noted above, all of these microbial agents are endemic in cattle, swine, and poultry flocks, and all are characterized by a low infectious dose.

Although the number of outbreaks and cases of illness reported to the CDC due to recreational and drinking water exposure, as well as foodborne sources, are massive, they greatly underscore the true incidence of disease caused by these sources. A complex chain of events must occur in order for a foodborne or waterborne disease outbreak to be reported to the CDC's foodborne and waterborne outbreak surveillance systems. A break at any point in the chain results in an unreported incident. Significant limitations to the reporting system begin at infection, as there is a continuum of disease from asymptomatic infection and mild illness to death. Illness can be sporadic in the population following exposure, and most sickened individuals seek medical attention only in severe cases. Outbreaks that are most likely to be brought to the attention of public health authorities include those that are large, such as interstate or restaurant-associated outbreaks, or those that can cause serious illness, hospitalization, or death. The identification of the source of infection in many cases is difficult and may be compounded by the long incubation periods of some agents, as noted in Table 1 (Section 2: Pathogens). For instance, the illness following exposure to *Brucella* spp. may manifest in as little as five days or as much as 60 days, a time in which the number of potential vehicles of transmission may be massive. Even where cases may be simple, reporting may be limited. Reporting of outbreak data is at the discretion of the states, many of which do not have adequate monitoring and reporting systems in place, primarily due to lack of financial resources to implement such systems. Outbreaks reported in the foodborne and waterborne outbreak surveillance summaries are a small and variable fraction of all outbreaks and cases that occur in the U.S. every year. They do not include those caused by secondary infections, animal contact infections, airborne infections, or many of the other pathways discussed above. As a result, the true incidence of illness that may be caused by zoonotic pathogens remains largely unknown. Table 8 shows the estimated total yearly incidence of disease caused by selected pathogens in the U.S. (Mead *et al.*, 1999). Based on these estimates, zoonotic pathogens may be responsible for as much as 90% of bacterial and parasitic infections of known etiology.

The actual incidence of waterborne and foodborne disease is certainly much higher than that reported in annual surveillance activities. For instance, Mead *et al.*, (1999) estimated that foodborne disease causes 76 million illnesses, 325,000 hospitalizations, and 5,000 deaths in the U.S. each year. The American Society for Microbiology (1998) reported that 900,000 illnesses and 900 deaths each year may be caused by waterborne microbial infections following recreational water contact. Morris and Levin (1996) estimated that disease-causing microbes in drinking water alone may cause 7.66 million illnesses and 1,200 deaths each year. Based on these estimates, acquiring infection by a foodborne organism may be 10-84 times more likely than for waterborne infections (either through recreation or drinking contaminated water). However, actual studies suggest that the risks associated with drinking water that meets federal standards are understated. The reasons for this are unclear, but may be related to the perception that water is "clean". There may be a tendency of individuals and medical practitioners to identify food as a source of contamination when the vehicle of transmission is unclear, especially when the etiological agent is not identified. In any case, evidence from studies of several water

Table 7. Water and foodborne outbreaks in the U.S. reported by the CDC (1991-1997).

Etiologic Agent	**Waterborne** Outbreaks (*Cases*)						**Foodborne** Outbreaks (*Cases*)	**Total** Outbreaks (*Cases*)

‡ AGI= Acute gastrointestinal illness of unknown etiology; also includes other illnesses of unknown etiology

Table 8. Estimated number of total cases, hospitalizations, and fatalities that may occur annually in the U.S. by selected etiological agent as reported by Mead *et al.*, (1999).

Etiologic Agent	Total Cases	Hospitalizations	Fatalities
Bacteria			
Brucella spp.	1,554	122	11
Campylobacter spp.	2,453,926	13,174	124
Escherichia coli O157:H7	73,480	2,168	61
Enterohemorrhagic *Escherichia coli* (non-O157:H7 STEC)	36,740	1,084	30
Listeria monocytogenes	2,518	2,322	504
Salmonella spp.	1,412,498	16,430	582
Yersinia enterocolitica	96,368	1,228	3
Protozoans and Helminthes			
Cryptosporidium parvum	300,000	1,989	66
Giardia lamblia	2,000,000	5,000	10
Toxoplasma gondii	225,000	5,000	750
Trichinella spiralis	52	4	0

systems meeting federal drinking water standards suggests that as much as 6-40% of gastrointestinal illness in the U.S. may be drinking water related (Payment *et al.*, 1991; Golstein *et al.*, 1996; Cottle *et al.*, 1999; Morris *et al.*, 1996; Schwartz *et al.*, 1997; Schwartz *et al.*, 2000; Levin *et al.*, 2002). For instance, in a study conducted in Contra Costa County, California, reverse osmosis drinking water treatment systems (half sham and half real) were installed on the taps of more than 400 participants (50% sham and 50% real). Participants with true systems had 20.4% less gastrointestinal illness episodes than those who used tap water meeting all federal and state drinking water treatment standards (Colford *et al.*, 2002). These results are similar to those of earlier Canadian studies (Payment *et al.*, 1991a,b; Payment, 1994; Payment *et al.*, 1994; Payment *et al.*, 1997), and indicate that infections acquired through contaminated drinking water may approach those acquired through consumption of tainted food.

6.2 Specific Cases

Although the scale of infections caused by zoonotic pathogens remains unclear, the transmission of pathogenic zoonoses from livestock animals to humans and other negative public health outcomes resulting from living in proximity to confinement animals has been clearly documented in reported literature. Both epidemiological studies (See sidelights.) and specific incidences reported in the U.S. and other high income countries, such as the United Kingdom (UK), Canada, The Netherlands, and Japan, have implicated livestock animals and their wastes as the source of illness and other health outcomes. Animal manures in particular have been implicated as the source of pathogens in several waterborne outbreaks (Jackson *et al.*, 1998; Crampin *et al.*, 1999; License *et al.*, 2001; Health Canada; 2001). When manure has been implicated as the source of outbreak, the consequences have been severe. For instance, manure runoff contaminating groundwater near a municipal well in Walkerton, Ontario, Canada resulted in an outbreak of *E. coli* O157:H7 and *Campylobacter* spp. in May, 2000 that caused 2,300 illnesses and 6 deaths (Valcour *et al.*, 2002; Clark *et al.*, 2003; Federal-Provincial-Territorial

Committee on Drinking Water, 2005). Solo-Gabriele and Neumeister (1996) describe a *Cryptosporidium* outbreak in Corrollton, GA in 1989 in which manure runoff was suspected to have been the cause of over 13,000 illnesses. Richardson *et al.*, (1991) and Atherton *et al.*, (1995) describe *Cryptosporidium* outbreaks in Swindon, Oxfordshire, and Bradford UK in 1989 and 1994, respectively, in which storm runoff from farm fields was suspected to have been the cause of 641 illnesses. MacKenzie *et al.*, (1994) describe a *Cryptosporidium* outbreak in Milwaukee, Wisconsin in 1994 in which 87 deaths and over 400,000 illnesses were attributed to animal manure and/or human excrement contaminating the water supply.

Merchant et al. (2005) studied the association between farm living and the prevalence of asthma outcomes. Children living on swine farms were more likely to have asthma outcomes, and the prevalence was more dramatic where antibiotics were added to feed. Nearly 43% of children on farms with less than 500 pigs had asthma or asthma indicators. This number climbed to 46% on farms with more than 500 pigs. However, 55.8% of children living on hog farms where antibiotics were added to feed experienced asthma or asthma indicators . This compared to 26.2% prevalence in children on farms that did not raise hogs. The study indicated that 33.6% of children not living on a farm and not around swine had at least one indicator of asthma. Although farms that use antibiotics tended to be larger, the research team concluded that antibiotic exposure may also have played a role in the development of childhood asthma.

Animal manure has also been implicated as the source of many foodborne outbreaks, mostly resulting from contaminated produce (Schlech *et al.*, 1983; Morgan *et al.*, 1988; Besser *et al.*, 1993; Cieslak et al, 1993; Millard et al, 1994; Tschape *et al.*, 1995). Manure-contaminated produce (fruit and vegetables, including juices and salads) tends to result in more illnesses per outbreak than those associated with contaminated meat. This is because fertilizing fields with manure or irrigating with fecally-contaminated water results in larger numbers of potentially infectious products that are eaten raw in most cases. For instance, Fukushima *et al.*, (1995) describe an outbreak of *E. coli* O157:H7 in Sakai City, Japan in which animal manure-contaminated alfalfa sprouts were suspected of causing 12,680 illnesses, 425 hospitalizations, and 3 deaths. Outbreaks of *E. coli* O157:H7 have also been associated with the consumption of manure-contaminated apple cider (Bresser *et al.*, 1993) and potatoes (Levy *et al.*, 1978). In contrast, contaminated meats, which may result from infected animals or contamination at the abattoir, are generally cooked, destroying pathogens and leading to more sporadic incidence of illness per outbreak. However, the number of outbreaks and total number of cases

Wing and Wolf (2000) surveyed residents of three rural communities, one in the vicinity of a 6000-head hog operation, one in the vicinity of two intensive cattle operations, and a third without livestock operations using liquid waste management systems. Residents in the vicinity of the hog operation were 7.6 times more likely to report occurrences of headaches, 5.2 times more likely to experience runny noses, 3.6 times more likely to have sore throats, 4.7 times more likely to excessively cough, 3.0 times more likely to have bouts of diarrhea, and 5.6 times more likely to have burning eyes than residents of the community without intensive livestock operations. All results were adjusted for sex, age, smoking, and work outside the home.

associated with contaminated meat are higher than produce. According to surveillance of outbreaks in the U.S. between 1990 and 1998, contaminated produce accounted for about 24% of the outbreaks and 41% of the cases (Griffiths, 2000).

Although proper cooking can eliminate most pathogens from meat products, contaminated meat remains a significant link between humans and pathogenic zoonoses. Outbreaks of enterohemmhorhagic *E. coli* in the U.S. between 1982 and 2002 can be attributed primarily to contaminated meat (41%), followed by produce (21%), person to person contact during illness (14%), contaminated drinking or recreational water (9%), and directly contacting infected animals or their wastes (3%) (Rangel *et al.*, 2005). The emergence of many antimicrobial-resistant zoonotic pathogens in human populations has been linked to the consumption of food animals and dairy products. For instance, Holmberg *et al.*, (1984) attributed a 6-state outbreak of multi-drug resistant *Salmonella newport* to consumption of beef from a feedlot that was using subtherapeutic doses of chlorotetracycline as a growth promoter. The emergence of multidrug-resistant *Salmonella typhimurium* DT 104 in 1988 in cattle in the UK was rapidly followed by its detection in meat (Threlfall *et al.*, 1997) and later in humans, presumably via the consumption of contaminated beef, pork sausages, and chickens. Between 1990 and 1995, human illnesses in UK attributed to *S. typhimurium* DT 104 increased from 259 to 3837 (Lee *et al.*, 1994). The emergence of fluoroquinolone-resistant pathogens in the Netherlands rapidly followed its introduction as veterinary drug in chickens and humans. Enrofloxacin-resistant *Campylobacter* in poultry increased from 0-14% between 1982 and 1989, while resistant *Campylobacter* causing human infections rose from 0-11% (Endtz, 1991). As poultry are a primary reservoir for *Campylobacter* spp., the use of fluoroquinolones in the poultry industry was implicated as the vehicle for human-acquired enrofloxacin-resistant *Campylobacter*.

Airborne zoonotic pathogens from animal feeding operations may also infect humans and other livestock animals. As noted above, pathogens and antimicrobial-resistant bacteria have been detected at elevated concentrations in confinement house air (Cormier *et al.*, 1990; Cazwala *et al.*, 1990; Crook *et al.*, 1991; Heederick *et al.*, 1991; Zahn *et al.*, 2001; Predicala *et al.*, 2002; Gast et al 2004; Chapin *et al.*, 2005). Farm workers exposed to confinement house air are much more likely than the general population to acquire infections of the lungs and sinuses (Mackiewicz, 1998; Aubry-Damon, 2004; Armand-LeFevre *et al.*, 2005), and the potential for secondary infection of nearby populations is high. Airborne zoonotic pathogens may also travel over vast distances downwind of an infected livestock source. Henderson (1969) and

Smith et al. (1993) and Hawker et al. (1998) describe an outbreak in the West Midlands, UK in which airborne transmission of *Coxiella burnetii* was identified as the causative agent of 147 illnesses. Outdoor lambing and calving was performed on farms south of the urban area. Strong gales blew towards the urban area on a single day approximately three weeks prior to the onset of illness. *Coxiella burnetii* is known to multiply to very high concentrations in the placenta of sheep which, following deposition on the ground during outdoor birthing, can dry out allowing bacterial release with airborne particulates (Welsh et al., 1958; Jones and Harrison, 2004). The mean incubation period for *Coxiella burnetii* in humans has been shown to be 20 days, consistent with the period of time between the day of strong gales and the peak onset of symptoms in the outbreak (Aitken et al., 1987).

Hughes and Wright (1970) describe a series of airborne picnoravirus outbreaks (foot and mouth disease) in pigs, cattle, and sheep in Worcester, UK in 1967, in which infected animals at three pig farms were suspected as the cause. Casal *et al.*, (1997) estimated that the airborne dispersion could have transported an infectious dose of this virus from the three source swine farms to cattle as far as 7 km away. However, secondary infection from cattle or sheep was unlikely to affect cattle or sheep more than 200 m away (Donaldson *et al.*, 2002). It has been estimated that picnoravirus can be transported in the air over distances as great as 60 km overland and 300 km over seas (Gloster *et al.*, 1982; OIE, 2005). Lyytikainen *et al.*, (1998) describe an outbreak of Q-fever in a small rural community in Germany in which airborne transmission of *Coxiella burnetii* from a nearby infected flock of 1,000-2,000 sheep may have caused 45 illnesses over a four month period. Outdoor calving was performed on the farm, and the wind blew from the farm towards the town 57% of the time during the course of the outbreak. Both picnoraviruses and *Coxiella burnetii* may be shed in animal feces suggesting that these organisms, among others, could be dispersed over vast distances following spray irrigation of animal manures onto croplands.

6.3 Antimicrobial Resistance

Antimicrobial-resistant bacteria and other zoonotic pathogens from CAFOs often infect humans, many times with serious consequences. Evidence in the reported literature overwhelmingly supports this conclusion and includes direct epidemiological studies, temporal evidence of the emergence of resistance in livestock animal populations prior to the emergence in human populations, trends in resistance among human isolates that mimic the use of antimicrobials in livestock animals, and studies that show farmers, slaughterers, and their family members are much more likely than the general population to acquire antimicrobial zoonoses. Antimicrobial resistance can limit treatment options in sickened individuals and increase the number, severity, and duration of infections (FAAIR Scientific Advisory Council, 2002). Varma *et al.*, (2005) evaluated *Salmonella* outbreaks in the U.S., and determined that among 32 reported outbreaks between 1984 and 2002, 22% of 13,286 people in ten *Salmonella*-resistant outbreaks were hospitalized compared with 8% of 2,194 people in 22 outbreaks caused by pansusceptible strains. These differences are not only the consequence of limited options for antimicrobials, but are also related to the increased virulence often associated with antimicrobial-resistant organisms. For instance, Lee *et al.*, (1994) determined that individuals infected with resistant organisms were ill 25% longer and were significantly more likely to be hospitalized than those infected with pansusceptible strains. Those

> Bezanson et al (1983) describe the infection of a newborn child with a multidrug-resistant strain of *Salmonella* ser. typhimurium resulting in septicemia and meningitis. The source of infection was the child's asymptomatic mother, who acquired the bacterium through ingestion of unpasteurized milk and passed it to her child during delivery in the hospital. Illness in the newborn child manifested within 24 hours, and within 72-96 hours had spread to several other infants in the hospital nursery. In another case described by Lyon et al. (1980), a multidrug-resistant strain of *Salmonella heidelberg* was spread from an asymptomatic mother to newborn child during delivery via cesarean section. The mother was a farmer who shortly before delivery had been working with calves from an infected herd. Three infants in the hospital nursery were infected with the organism and developed bloody diarrhea.

infected with resistant strains were hospitalized on average ten days versus eight days for those infected with susceptible strains, even though most subjects in both cases were treated with an antimicrobial to which the infectious agent was susceptible. The difference in hospitalization rates likely reflects the higher virulence of the resistant infectious organism, and, to a much lesser extent, an inappropriate first choice of antimicrobial for treatment. Resistance to antimicrobial agents, resulting from their extensive use in animal agriculture, may result in tens of thousands of additional infections by zoonotic pathogens compared to what would be experienced with pansusceptible strains. This may result in more than ten thousand additional days of hospitalization, and hundreds of thousands of excess days of diarrhea in the U.S. each year (Barza and Travers, 2002; Travers and Barza, 2002)

6.4 Hydrologic Events

Hydrologic events ranging from mild rainfall to flooding can increase the movement of pathogens from CAFOs or manure-amended fields to waters that are likely to come into contact with people. Serious public health consequences of the increased pathogen load, especially during flooding events, are common (Isaacson *et al.*, 1993; MacKenzie *et al.*, 1994; Health Canada, 2000; CDC, 1998). Several studies in low income countries have reported increases in morbidity and/or mortality following flood events due to cholera, cryptosporidiosis, nonspecific diarrhea, poliomyelitis, rotavirus, and typhoid and paratyphoid (Fun *et al.*, 1991; van Middelkoop *et al.*, 1992; Katsumata *et al.*, 1998; Biswas *et al.*, 1999; Sur *et al.*, 2000; Mondal *et al.*, 2001; Kunji *et al.*, 2002; Kondo *et al.*, 2002; Heller *et al.*, 2003; Vollard *et al.*, 2004). The increased relative risk (RR) or odds ratio (OR) of contracting disease during flooding in these cases ranged from 1.39 to 4.52. Significant increases in vector- and rodent-borne diseases were also observed (Trevejo *et al.*, 1998; Han *et al.*, 1999; Sanders *et al.*, 1999; Sarkar *et al.*, 2002; Leal-Castellanos *et al.*, 2003).

The increased risk of contracting disease post-flood in high income countries such as the U.S., UK, and Australia exist, but are less pronounced (Ahern *et al.*, 2005). Bennet *et al.*, (1976) observed hospital visits by the flooded to more than double in the year following an event in Bristol, UK, in 1968. These researchers also observed a 50% increase in mortality among the flooded, mostly in the elderly. Reacher *et al.*, (2004) interviewed 467 households following a flood in Lewes, UK, and observed a slight increase in gastrointestinal illness in those whose homes were flooded. In Brisbane, Australia (1974), a flood led to increased morbidity, but not mortality, in the flooded group (Price, 1978; Abrahams *et al.*, 1976). However, Handmer and Smith (1983) noticed no flood-related increase in hospital admissions during flooding in Lismore, Australia the same year. In a cohort study of 1,110 people in a U.S. Midwestern community, Wade *et al.*, (2004) reported an increase in the incidence of gastrointestinal illness during a flood event in April and May of 2001. The increase in gastrointestinal illness was pronounced in persons with potential sensitivity to infectious gastrointestinal agents and those who came into contact with the flood water, especially children. Heather *et al.*, (2004) noted the significance of heavy rainfall in the Walkerton, Canada outbreak of *E. coli* O157:H7 and *Campylobacter*. The rainfall was equivalent to a 60-year event, and it was suggested that this extreme precipitation may have mobilized animal wastes and led to the outbreak. Curriero *et al.*, (2001) studied the link between reported waterborne disease outbreaks in the U.S. between 1948 and 1994 and extreme precipitation events. These authors found a strong correlation between rainfall and disease. Disease due to surface water contamination primarily occurred during the month of the precipitation event, whereas disease associated with groundwater contamination occurred two months following extreme precipitation events.

Serious health outcomes from flooding events can and do occur in the U.S. and may be unfairly weighted against the underprivileged. The recent flooding of New Orleans, Louisiana following hurricane Katrina, a category 4 event, resulted in the exposure of tens of thousands of people to floodwaters laden not only with chemical wastes, but also decomposing bodies, animal carcasses, sewage, and animal wastes. *E. coli* concentrations in these waters reached as high as 42,000 per 100 mL, hundreds of times higher than levels associated with gastrointestinal illnesses that result from “recreational contact”. Those unable to escape the city prior to the hurricane were primarily the underprivileged, and illness was exacerbated by the lack of availability of medical provisions and personnel. The eye of the hurricane traveled through Mississippi, the fourth largest poultry-producing state in the U.S., with the highest rainfall amounts (ranging between 12.5-22.5 centimeters, falling at a rate of 1-2 cm per hour) tracking over the central and northeastern portions of the state. As can be seen in Figure 4, these regions are associated with the bulk of large concentrated swine feeding operations in the state of Mississippi. The pollution from these operations has been previously reported to disproportionately affect impoverished and African-American peoples (Wilson *et al.*, 2002). The full breadth of public health outcomes from this hurricane, as well as potential environmental injustice resulting from the flooding, have yet to be fully understood. These events, however, signify the need for water quality officials to seriously consider precipitation events during planning.

6.5 Economic considerations

Infection by zoonotic pathogens results not only in extensive human suffering, but also significant economic loss. For instance, the Milwaukee outbreak of Cryptosporidiosis in 1993 cost the community as much as 96.2 million; 31.7 million in medical costs and 64.6 million in lost productivity (ASM, 1998; Corso *et al.*, 2003; Water Health Connection, 2005). The Walkerton, Ontario outbreak of *E. coli* O157:H7 and Campylobacteriosis in 2002, with 2300 cases and 6 deaths, cost the community an estimated 40 million in lost productivity, medicine, and hospitalization costs. The American Society for Microbiology estimates that even a mild case of diarrhea may cost $330 in lost work productivity and over-the-counter medicines (adjusted to 2005 dollars). More severe cases were estimated to cost up to $9,500 per person for medical diagnosis and treatment. Considering the number of illnesses that may be experienced in the U.S. each year, foodborne illnesses may amount to three billion dollars per year due to hospitalization and more than 20 billion in lost work productivity and over-the-counter medicines, a significant portion of which may be due to transmission of disease from livestock animals. Similarly, waterborne illnesses may result in a total of two to twenty billion dollars in costs annually (Garthright *et al.*, 1988; Hardy *et al.*, 1994; Gerba, 1996; Liddle *et al.*, 1997; Fleisher *et al.*, 1998; Scott *et al.*, 2000; Dwight *et al.*, 2001; Fruhwirth *et al.*, 2001; Corso *et al.*, 2003). Considering the annual healthcare costs of managing antimicrobial resistance, which may be in the range of 4-30 billion dollars (Khachatourians, 1998; American Academy of Microbiology (AAM), 1999; Montague, 2000), the annual costs associated with illness caused by

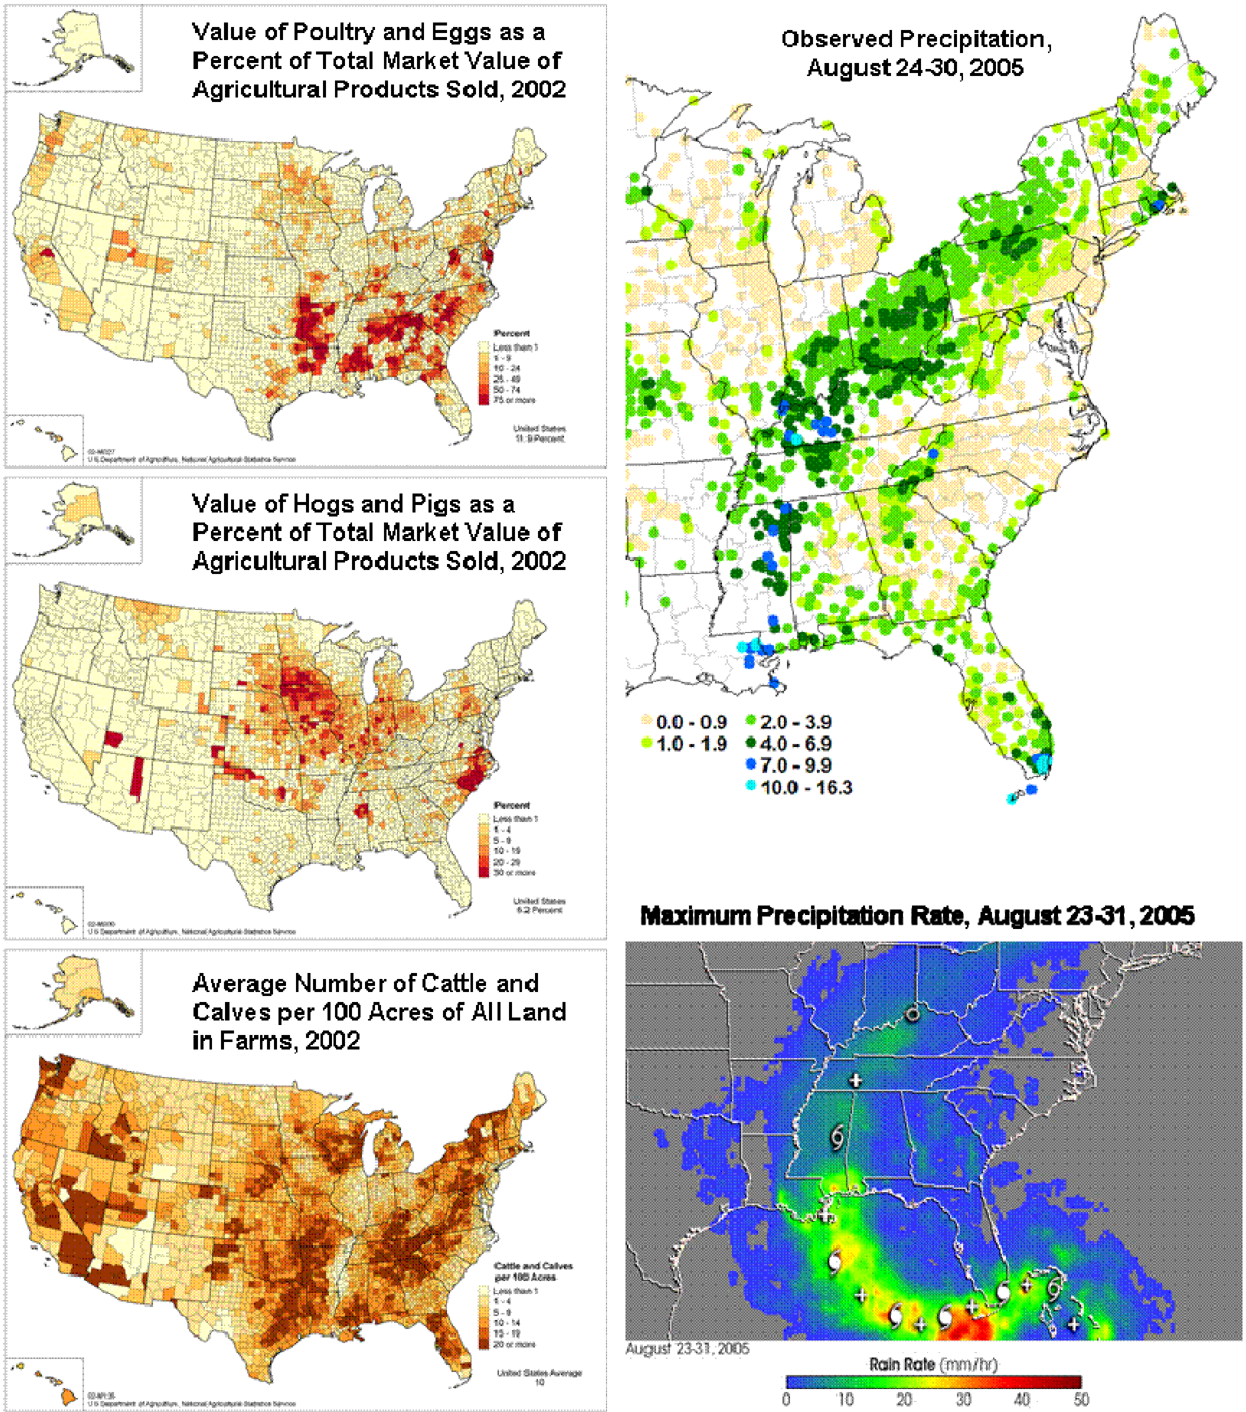

Figure 4. Distribution of livestock animals in regions impacted by Hurricane Katrina, August, 2005 (adapted from USDA, 2002; National Oceanic and Atmospheric Administration, 2005; National Aeronautics and Space Administration, 2005).

zoonotic pathogens and antimicrobial resistant bacteria from livestock operations may be staggering.

Significant economic losses may also be incurred by the closing of beaches when waters cannot meet USEPA recreational water guidelines. Of the thousands of beach closings every year, more than 80 percent are due to excessive levels of bacteria (ASM, 1998). A beach closing due to bacteria indicates that levels were excessive the day prior to the closing, during which time thousands of individuals may have been exposed to contaminated water. Dwight *et al.*, (2001) estimated the economic burden from illness associated with recreational coastal water pollution at Newport and Huntington Beaches, Orange County, California alone to be 3.3 million per year. Considering the thousands of beaches closed every year, economic losses may be in the billions of dollars.

6.6 Discussion

Both waterborne outbreaks and those associated with fresh produce have been on the rise in recent decades and will likely continue to increase as surveillance is improved. Although the source of contamination in many of these outbreaks remain unreported, poor manure management in livestock operations most assuredly plays a significant role as alternative sources of contamination are limited in scale compared to manure applications and typically much less infectious in character. The annual costs of infectious zoonotic diseases in the U.S. may reach into the tens of billions of dollars considering both food and waterborne illnesses. These estimates exclude such costs as death, pain and suffering, lost leisure time, financial losses to food establishments, legal expenses, and long-term health outcomes due to infections that may result in degenerative diseases or cancer. The economic burden of pathogenic zoonoses has been shifted from corporate farms who fail to use appropriate manure management at the source of disease to sickened individuals and businesses that experience decreased revenues due to beach closures and lost productivity. Economic burdens of CAFO pollution may be especially shouldered unfairly by minority groups and the poor, as evidenced by recent works describing environmental injustice surrounding the swine industries of North Carolina and Mississippi (Wing *et al.*, 2000; Wilson *et al.*, 2002). It is at present unclear how new molecular microbiological technologies such as microbial source tracking will affect litigation and potential liability of CAFO operators in future disease outbreaks.

7. Emerging Technologies: Monitoring Pathogens in the Environment

Concentrated animal feeding operations may release pathogens into the environment through a variety of mechanisms that may result in extensive human suffering and economic loss. Current surveillance activities may be inadequate to identify fully the scope of problems surrounding the release of overt pathogens from CAFOs to the environment. For instance, surface water quality surveillance in the U.S. relies on the quantitative detection of bacterial indicators of fecal pollution including *E. coli* and enterococci rather than direct identification of selected etiologic agents associated with disease in humans. Although related to gastrointestinal illness following recreational water contact, these indicators may not be reliable surrogates for all bacterial pathogens and most parasites and viruses. Human illness can occur even when the concentrations of *E. coli* and enterococci indicate that bathing waters are safe. The use of microbial indicators as surrogates for pathogens continues because infectious concentrations of pathogens in waters may be low and difficult to detect, and standard methods for analysis do not exist for many pathogens.

The February 28, 2005 ruling by the 2nd U.S. Circuit Court of Appeals required the USEPA to identify and characterize the performance of animal waste management practices and barrier technologies that specifically address contamination of the nation's waters by pathogens emanating from CAFOs. Transport properties and the virulence of various pathogens vary to a wide degree, and may be poorly represented by the bacterial indicators *E. coli* and enterococci (Ferguson *et al.*, 2003). Thus, this requirement signals the need for new and improved pathogen detection technologies. New approaches to water quality monitoring and emerging technologies enabling the identification of overtly pathogenic agents in natural waters and their source will greatly improve human health and welfare and increase the biosecurity of our natural resources.

Considering the many potential exposure routes following release of pathogenic zoonoses from CAFO facilities, identification of the risks associated with pathogens emanating from concentrated animal feeding operations may require technologies that enable the measurement of overt pathogens in air, drinking and recreational water, meat and produce, soil and sediments, and feces of various animals among others. For foods, standard methods for analysis for a small number of zoonotic pathogens already exist (FDA, 2005). For other matrices, such as soil and sediments, drinking water, and natural waters, methods are lacking or have not been standardized. Methods reported in literature include classical cultivation approaches, and more recently, identification and quantification of agents via the detection of surface antigens or nucleic acids. In either case, the detection of zoonotic pathogens with infectious doses as low as a few ingested or respired particles presents specific challenges including concentration of large environmental samples, removal of inhibitory compounds from sample concentrates, detection of viability, detection of multiple agents in a limited sample, and long analysis periods, especially for cultivation-based approaches. Considerable advances in emerging nucleic acids and sensor technologies are reducing analysis times from weeks to hours in some instances, but present trade-offs in terms of the costs and technical expertise required to apply the technologies. The intent of this review is not to provide a complete description of all of the emerging detection technologies and report their application, but rather to identify their strengths and limitations and discuss the challenges posed by their use.

7.1 Sample Processing

Appropriate sample processing is critical to detecting pathogenic agents at concentrations relevant to their infectious dose in environmental matrices. For some media that may contain high numbers of pathogens but are extremely heterogeneous such as animal manure, obtaining an appropriate sample may hinge on careful compositing procedures. For instance, Pearce *et al.*, (2004) examined the distribution of *E. coli* O157 in bovine fecal pats and determined that the density of O157 in the pats was highly variable, differing by as much as 76,800 CFU/g between samples of the same fecal pat. These researchers determined that most positive samples bordered the detection limit, and that testing of only 1 g per pat (as is commonly performed) may result in as much as 20-50% false-negatives. For other media such as air, sample processing may need to be particularly careful regarding stressing organisms in the sampling device.

The low infectious dose associated with many etiological agents leads to the need to concentrate copious quantities of air, food, or water into smaller volumes amenable to detection with classical cultivation or the newer molecular microbial methods. Several mechanisms have been used to concentrate these agents to detectable numbers including filtration, immunocapture, and enrichment. However, some of these methods may concentrate inhibitory and/or interfering compounds with the agent of interest, while others require additional analysis time or alter the sample from its initial state. Thus, the use of any of these mechanisms may present tradeoffs in downstream analysis, potentially affecting analytical detection limits, analysis times, or the number of agents that can be detected from a single sample. At present, standard methods for the concentration of viruses from water samples rely on electrostatic capture from 100 or more liters of water onto positively-charged filters followed by elution, precipitation, and resuspension in a small volume of sodium phosphate buffer (USEPA, 1993). Concentration of the protozoan parasites *Giardia* and *Cryptosporidium* require filtration of ten or more liters of water through a depth filter followed by elution, centrifugation, and immunomagnetic separation (USEPA, 2001). Concentration of bacterial pathogens is usually performed by membrane filtration, although turbidity of water can severely inhibit the volume of water that can be passed through the filter.

None of the accepted concentration techniques listed above is applicable to all of the various groups of etiologic agents (viruses, bacteria, protozoans). The detection of several agents may require the collection of multiple large volume samples from a single location and concentration by a number of techniques. To overcome these limitations, newer methods for sample concentration applicable to all classes of etiologic agents have been proposed. Most notably, hollow-fiber ultrafiltration has been used to simultaneously concentrate viruses, bacteria, and protozoan parasites from water samples as large as 100 L to volumes as low as 250 mL with recovery efficiencies on the order of 20-92% (Juliano and Sobsey, 1997; Kuhn and Oshima, 2001; Olsezewski *et al.*, 2001; Evans-Strickfaden *et al.*, 1996; Simmons *et al.*, 2001; Morales-Morales *et al.*, 2003; Ferguson *et al.*, 2004). Subsequent analyses with small portions of a single eluent can lead to detection of several pathogens at environmentally-relevant concentrations (Olsezewski *et al.*, 2001; Morales-Morales *et al.*, 2003). Hollow-fiber ultrafiltration may also have the added benefit of allowing small or water soluble inhibitors of nucleic acids techniques to pass into the permeate, rather than co-concentrate with the pathogens in the retentate, prior to sample analysis (Wilson, 1997).

7.2 Conventional Cultivation and Nucleic Acids Approaches

Conventional cultivation methods for the detection of bacterial pathogens usually require several steps including (1) sampling and release of bacteria from the environmental matrix, (2) pre-enrichment in non-selective broth to allow small numbers of stressed bacterial pathogens to recover and grow prior to applying further environmental stress in selective broths, (3) transfer to selective broth to enrich low numbers of pathogens and reduce competitor bacteria, (4) inoculation of a selective solid medium to identify presumptive positive colonies, and (5) biochemical and/or serological confirmation of presumptive-positive colonies. Most probable number (MPN) techniques can be used to arrive at a quantitative result (USEPA, 2005). Depending on the number of steps required; confirmation of the presence of specific pathogens by conventional methods may take as few as two days to two weeks or more.

Nucleic acid technologies follow the same framework for detection as cultivation methods, but detection or quantitation can occur prior to or following pre-enrichment in nonselective media or further enrichment in selective broths. Nucleic acid technologies are also commonly used in lieu of biochemical and/or serological confirmation for presumptive colonies, or to acquire more detailed genomic information on bacterial isolates, such as possession of antimicrobial-resistance or virulence traits. Enrichment broths (both selective and nonselective) for nucleic acids techniques are used not only to increase the numbers of pathogens, thereby improving detection, but also to dilute potential inhibitors of the polymerase chain reaction (PCR). Immunomagnetic separations have also been used to separate etiological agents from large volumes and/or samples with inhibitory agents prior to or following enrichment steps.

The detection limit of nucleic acid assays is usually dependent on the amount of time available for analysis. In general, if the etiological agent of interest is in high concentration or the medium is relatively clean (such as drinking water), short analysis times of less than 6-8 hours can be realized, as inhibitors may be in low concentration relative to pathogens in the original sample retentate. In more turbid samples with low numbers of infectious agents, such as stream waters, analysis times can extend from a day to as much as four days. Extensive sample processing and selective enrichments may be required to achieve detection limits relevant to the infectious dose. Tables 9 and 10 list several studies that have used nucleic acids techniques for the detection of etiological agents.

As can be seen in Table 9, nucleic acids techniques may provide very sensitive detection of selected etiological agents in clean samples, such as air or drinking water, even without enrichment. For turbid environmental samples, such as surface water, feces, or soils, nucleic acid technologies may have detection limits several orders of magnitude higher than cultivation techniques (See Table 9). This is because PCR inhibitors, such as humic substances associated with many environmental samples, are co-extracted with the etiological agent prior to detection. Even with inhibitors present, nucleic acid technologies may occasionally yield more sensitive results than cultivation-based techniques. For instance, Inglis and Kalischuk (2004) used nested real-time SYBR Green-PCR to quantify *Campylobacter lanienae* in cattle feces without enrichment. These researchers were able to detect *C. lanienae* at concentrations as low as 250 CFU/g feces in less than 4 hours, a level more sensitive than could be achieved with cultivation-based methods that required 2 days for presumptive results. However, in most instances,

improved sensitivity over cultivation-based techniques will not be realized without further sample processing.

Immunomagnetic separation methods (IMS) have been used successfully in several studies to concentrate etiological agents prior to or following sample concentration. These methods use paramagnetic particles coated with antibodies specific to the pathogen of interest to bind the agent and remove it from the sample matrix in a concentrated form via magnetic attraction of the pathogen-paramagnetic particle complex (Campbell and Smith, 1997; Bukhari *et al.*, 1998; Rochelle *et al.*, 1999). The separation of the agent of interest from the environmental sample reduces the presence of inhibitory substances improving detection by PCR. For instance, Abd El Galil *et al.*, (2004) developed a protocol for using combined Immunomagnetic Separation-Molecular Beacon-Reverse Transcription-PCR to detect Hepatitis A virus in groundwater samples. These authors concentrated 100 liters of groundwater using an electropositive microporous (1-MDS) filter followed by elution in beef extract, centrifugation, and resuspension of the pellet in 20 mL sodium phosphate buffer (final pH=7.4). Immunomagnetic separation with two-hour incubation was used to recover the virus followed by extraction of viral RNA, reverse transcription, and real-time PCR with a molecular beacon probe. As few as 20 plaque-forming units (PFU) per 20 mL groundwater concentrate were recovered by these methods. Immunomagnetic separation methods may be attractive where selective enrichment cannot be used effectively.

Selected amplification facilitators or specific DNA treatments may also be used to reduce (but not eliminate) the effects of inhibitory compounds on PCR (Satoh *et al.*, 1998; Abu Al-Soud and Rådström, 2000; Böddinghaus *et al.*, 2001). Common facilitators may include bovine serum albumin (BSA), the single-stranded DNA-binding T4 gene 32 protein (gp32), betaine, and several proteinase inhibitors, all of which work to a varying degree depending on sample type (Abu Al-Soud and Rådström, 2000). Of the facilitors used, BSA is the most common, and tends to work with samples from a wide variety of origins, including blood, human and animal feces, surface and ground waters, soils and sediments, and meat. For instance, Rudi *et al.*, (2004) applied integrated cell concentration and DNA purification using immunomagnetic beads with real-time (TaqMan) PCR to detect and quantify *Campylobacter jejuni* in chicken fecal samples. These researchers could detect as few as 1,000-10,000 CFU/g feces in untreated samples, but with 0.4% BSA in the reaction mix, could reduce PCR inhibition caused by the fecal extract, so that they could reduce their detection limit to as low as 230-2,300 CFU/g feces. Since the mode of action of many facilitators is similar (removal of inhibitors), their benefits are not additive (Abu Al-Soud and Rådström, 2000).

To improve detection of bacterial pathogens in difficult matrices, especially for particularly infectious agents that may be of interest at very low concentrations, enrichments can be used to revive stressed bacteria and increase their numbers prior to detection. Enrichments have the added benefit of diluting PCR inhibitors prior to detection by nucleic acid techniques, resulting in lower detection limits than can be realized by direct sampling (See Table 10). The enrichment of bacterial pathogens presents a trade-off: selective media may enrich one pathogen at the expense of other agents of concern. Several enrichment broths may be required to detect several agents. However, in some cases, nonselective broths may improve the detection of many bacterial pathogens following a single enrichment. For instance, Nam *et al.*, (2004) evaluated the use of universal pre-enrichment broth (UPB) versus selective enrichment broths [lactose broth, modified trypticase soy broth (plus novobiocin), and *Listeria* enrichment broth] for detection of *Salmonella* spp., *E. coli* O157:H7, and *Listeria monocytogenes* from dairy fecal slurry, lagoon water, drinking water, silage/feed, trapped rats, bird droppings, calf fecal swabs, milking parlor floor swabs, bulk tank milk, and in-line milk filters. These researchers observed no differences between growth in UPB and selective media using pure cultures of the three pathogens, either individually or mixed. However, slightly better recovery of pathogens from environmental samples was observed when UPB was used for the initial enrichment step, and transfers were made from the single pre-enriched sample to selective media. UPB supported the growth of all three pathogens to levels detectable by culture techniques within 24 hours from the different environmental matrices.

§ Nucleic acid techniques provided a result equivalent to or better than cultivation methods based on trials in actual samples

Several studies have documented improvements in detection of bacterial pathogens using nucleic acids techniques that can be realized using enrichments in both non-selective and selective broths. Ibekwe and Grieve (2003) used real-time TaqMan PCR to with a detection limit of 26,000 CFU *E. coli* O157:H7 per gram of soil without enrichment. Using a 16 hour pre-enrichment in modified Luria-Bertani broth (containing vancomycin, cefoxime, and cefsulodin); these researchers could reduce their detection limits to less than 10 CFU per gram soil. Burtscher and Wuertz (2003) evaluated the use of PCR for the detection of *Salmonella* spp. *Listeria monocytogenes*, *Yersinia enterocolitica*, and *Staphylococcus aureus* in biosolids from anaerobic digesters and aerobic composters following one- and two- step enrichment (24-48 hours) in selective broths. These researchers were able to detect less than 10 CFU per gram of waste for each organism following enrichment, versus 10^6-10^7 CFU per gram of waste without enrichment.

Nucleic acids techniques may also be useful as a surrogate for biochemical confirmation or for genotyping environmental isolates following detection with cultivation techniques, potentially saving days in analysis time. Müller *et al.*, (2003) tested sewage sludges and river waters for *E. coli* O157:H7 using combined cultivation and nucleic acids techniques. These researchers filtered 100 mL river water samples through 0.45 µm nitrocellulose membranes then enriched the retentate in peptone-saline water (PSW) supplemented with vancomycin-cefixime-cefsulodin solution for six hours. Similarly, 100 µL sewage sludge was enriched for six hours directly in the antibiotic-PSW solution. Immunomagnetic separation was used to isolate *E. coli* O157:H7 from a small portion of the enrichment media, and the paramagnetic bead-bacteria complexes were further enriched on selective media for 24 hours. Suspect colonies were investigated with PCR targeting genes associated with Shiga-like toxins 1 and 2, attachment and effacement, and enterohaemolysin. With these methods, the researchers could detect as few as 120 CFU/100 mL in sewage sludge and river samples in less than 48 hours.

Several researchers have also noted that PCR detection of antibiotic-resistance traits is more rapid and sensitive, and potentially more cost-effective, than culture or selective media. This is attractive for clinical diagnosis and surveillance (Lévesque *et al.*, 1995; Briggs *et al.*, 1999; Paule *et al.*, 2001; White *et al.*, 2001; Paule *et al.*, 2003; Blickwede and Schwartz, 2004; Sundsfjord *et al.*, 2004; Shamputa *et al.*, 2004; Jalava and Marttila, 2004). However, in some cases, resistance to antimicrobials can be phenotypically observed with the lack of detection of antimicrobial resistance determinants (Patel *et al.*, 1997). This may occur, as antimicrobial resistance may be conferred by several different genes, not all of which have been characterized. Because of the potential risks associated with misdiagnosis of disease, resistance screening by molecular methods in a clinical setting should be used as a compliment to classical phenotypic approaches.

Other problems may arise when using nucleic acids techniques if researchers are not careful with their methods. Of particular concern is establishing detection limits for nucleic acid techniques for pathogens in food, clinical diagnostic samples, and environmental matrices. Detection limits should be established with samples that closely mimic the matrix of interestenvironmental conditions. If detection limits are reported that over-estimate the efficacy of the method, their use for surveillance or diagnosis may put the public at risk. For instance, Lyon (2001) developed a real-time (TaqMan) PCR method to detect *Vibrio cholerae* O1 and O139 in raw oysters without enrichment. This researcher spiked 25 g oyster homogenates with a single inocula (approximately 6.2 x 10^6 *V. cholerae* O1 and 6.7 x 10^6 *V. cholerae* O139), then serially diluted with alkaline-peptone water to 6 $\log_{10}$ the original concentration. Because both organisms could be detected in the most dilute samples, a detection limit of 6-8 CFU/g oyster was reported. However, by diluting their samples up to six-fold in alkaline-peptone water instead of unspiked raw oyster homogenate, they may have diluted out a significant amount of PCR inhibitors for their most dilute samples. The true detection limits of this assay are unclear.

7.3 Pathogen Viability

For pathogenic zoonoses in different environmental matrices to pose a threat to human health, they must be in a viable state. The detection of viability by either cultivation-based techniques or nucleic acids approaches, however, may not be straight-forward. Cultivation techniques require the viability of microorganisms to yield a result. However, viable-but-nonculturable (VBNC) cells can remain undetected and may complicate interpretation of results. Aside from a clear definition of what constitutes a VBNC state (Barer and Harwood, 1999; Kell *et al.*, 1998; Keer and Birch, 2003; Besnard *et al.*, 2000; del Mar Lleó *et al.*, 2000; Grey and Steck, 2001b; Nilsson *et al.*, 1991; Turner *et al.*, 2000: Bogosian *et al.*, 2000), it still remains unclear as to whether cells in a VBNC state are pathogenic (Barer *et al.*, 2000; Grimes *et al.*, 1986; Steinert *et al.*, 1997; Grey and Steck, 2001a; Cappelier *et al.*, 1999). What is known, however, is that degradation of nucleic acids in VBNC cells may proceed at much slower rates than in killed cells. In fact, some studies have indicated that the pool of messenger RNA (mRNA) may stabilize within VBNC cells rather than continually degrade (Thorne Williams, 1997; Smuelders *et al.*, 1999). Indeed, VBNC bacterial pathogens may harbor genes encoding antimicrobial resistance and other virulence mechanisms for long periods of time after entering a VBNC state (Chaiyanan *et al.*, 2001), serving as a potential reservoir for virulence determinants in the environment. It is clear that molecular methods cannot differentiate between viable and VBNC pathogens when nucleic acids persist in the cells (Thorne and Williams, 1997; Smeulders *et al.*, 1999; Lázaro *et al.*, 1999; del Mar Lleó *et al.*, 2000; Weichart *et al.*, 1997).

Nucleic acid techniques may yield more rapid and sensitive results than cultivation-based techniques for detecting pathogens in different matrices, but there still remains a question as to what a positive PCR result means. Presence of DNA is not a reliable indicator of bacterial viability (McCarty and Atlas, 1993; Masters *et al.*, 1994; Deere *et al.*, 1996; Hellyer *et al.*, 1999). Ribosomal RNA has been shown to be a better indicator of bacterial viability due to a more rapid degradation than DNA upon cell death, but may not be reliable in all cases (McKillip *et al.*, 1999; Villarino *et al.*, 2000l McKillip *et al.*, 1998; Meijer *et al.*, 2000; Tolker-Nielsen *et al.*, 1997). Because of its extremely short half-life following cell death (seconds), mRNA may be the most reliable nucleic acid for indicating cell viability (Keer and Birch, 2003). However, it has been shown that mRNA may still persist. Therefore, care must be taken to design probes and primers that target regions of mRNA more susceptible to degradation (Cook, 2003).

Detecting mRNA requires a higher level of technical expertise than standard DNA-based methods, and does not lend to direct quantitation of pathogens in a sample as multiple and variable quantities of mRNA may be present in a single cell. Quantitative results may, however, be achieved using MPN techniques. Two methods commonly used for detecting ribonucleic acids are reverse-transcriptase PCR and nucleic acid sequence-based amplification (NASBA).

Enrichment of environmental or food samples prior to detection may enhance method sensitivity and aid in the detection of viable versus non-viable cells. Considering the potential of VBNC pathogens to act as environmental reservoirs for virulence determinants, as well as the ability of nucleic acids techniques to detect these cells, molecular methods may offer a distinct advantage over more classic cultivation-based assays for the protection of human health and the environment.

7.4 Emerging Surveillance Technologies

Considerable advances in nucleic acids and sensor technologies continue at a rapid pace (Walker, 2002; Dunbar *et al.*, 2003; Petrenko and Vodyanoy, 2003; Turnbough, 2003; Olsen *et al.*, 2003; Greene and Voordouw, 2003; Grow *et al.*, 2003; Unnevehr *et al.*, 2004; Panicker *et al.*, 2004; Raymond *et al.*, 2005). Of the emerging nucleic acids technologies, perhaps the most promising for surveillance and biosecurity are microarrays. Call *et al.*, (2003) and Ye *et al.*, (2001) describe the emerging use of microarrays and their potential for pathogen detection and genotyping. Microarrays are essentially a large set of very small southern blots, an array of many nucleic acid probes complimentary to discrete gene sequences, bound to a solid or semi-solid matrix, usually a modified glass surface. Because of the miniscule size of the blots (100-200 µm diameter "spots" separated from neighbors by typically 200-500 µm), thousands of sequences can be screened on a single array of less than four square centimeters. Target nucleic acids, which are typically, but not necessarily, PCR products, are challenged by the microarray under stringent hybridization conditions. Targets are usually prepared prior to hybridization with fluorescent labels or incorporating specific chemistries such as biotin-streptovidin that permit detection with a secondary fluorescent marker. Once post-hybridization steps are complete, arrays are catalogued using high resolution laser- or filter-based scanners and charged-coupled device (CCD) imaging. Based on hybridization patterns between the spotted arrays and the nucleic acids targets, the genotype of the original pathogen or the presence of specific pathogens in complex samples can be identified.

Microarrays are presently limited to endpoint detection, rather than quantification, of specific microbial targets. Although in some instances they can be used to detect nucleic acids isolated directly from complex matrices, the sensitivity of microarrays severely impedes their use for pathogen detection at the very low concentrations of interest in environmental samples without a specific nucleic acid amplification strategy (Call *et al.*, 2003). When coupled with nucleic acid amplification techniques, microarrays have been used successfully to detect enterohemorrhagic *E. coli* in chicken rinsate at concentrations as low as 55 CFU/mL. Perhaps more promising, microarrays can be used to rapidly genotype specific pathogens with greater sensitivity (Chizhikov *et al.*, 2001; Call *et al.*, 2001b; Johnson and Stell, 2000; Bekal *et al.*, 2003). Whole and partial genome microarrays for many pathogens are also commercially available, allowing for "fingerprinting" of microbial pathogens by establishing patterns unique to particular species that may further enable genotyping studies. By challenging these arrays with nucleic acids of a wide variety of sources, very small sets of unique markers for specific pathogens may be identifiable, better enabling environmental pathogen detection.

7.5 Discussion

Pathogen detection is performed routinely for meat, produce, seafood, milk, occasionally for biosolids from human municipal treatment facilities, but rarely for environmental matrices such as animal manure and their treated residuals, environmental waters, air, soils, and sediments. The recovery and detection of pathogens in environmental matrices are imperative to identify the extent to which these agents are removed, inactivated, or persist in livestock animal waste treatment processes and management systems at CAFOs. Conventional cultivation-based and newer nucleic acids-based approaches to detect or enumerate etiological agents in some environmental matrices are available. However, these methods are not amenable across different groups of pathogens or matrices and can complicate environmental sampling. Very limited standardization of pathogen detection methods exists, except for in the case of foods (Association of Analytical Communities (AOAC), 2005; FDA, 2005; USDA, 2005). The applicability of the standard methods for detecting pathogens in food to other matrices such as feces, water, and soil has not been established. Standard methods with the required sensitivity for detecting pathogens at relevant concentrations in environmental milieus are sorely lacking, especially for hyper endemic or emerging pathogens such as *E. coli* O157:H7, *Salmonella typhimurium*, *Yersinia enterocolitica*, *Campylobacter jejuni*, swine hepatitis E virus and the protozoan parasites *Giardia lamblia* and *Cryptosporidium parvum* (Sobsey *et al.*, 2002). The efficacy of animal waste management systems for removing zoonotic pathogens and antimicrobial-resistant bacteria from waste streams at CAFOs remains uncertain.

Aside from assessing the efficacy of livestock animal waste management systems, the recovery and detection of pathogens in water is imperative to protecting human health and the environment. The wise old adage of indicator organisms is becoming outmoded, as their reliability to predict all waterborne outbreaks is uncertain, their results come “a day late and a dollar short”, and newer technologies are becoming available that negate the need to rely solely on bacterial indicators of pathogenicity. Improving surveillance activities in recreational and drinking waters will require these new methods for detecting pathogens to be available in near real time. However, this may be hindered by specific physical or chemical properties of environmental waters that, combined with low concentrations of pathogens, may increase sample processing times. In general, the cleaner the sample, the more methods will be effective for rapid pathogen detection. For clean matrices such as drinking water, sample concentration methods alone may be sufficient to yield results directly usable by both cultivation and direct molecular detection. For more challenging matrices, such as ground and surface waters, significant sample clean-up may be required to remove inhibitors prior to processing with molecular methods.

As discussed above, the detection of etiologic agents in environmental waters is problematic, not only due to very low (but potentially significant) concentrations, but also due to a lack of methods with the required sensitivity and competing methods that are not amenable across different groups of pathogens. As such, there is a need to develop a unified and automated system for the detection of all waterborne pathogens (Straub and Chandler, 2003). It has been suggested that such technologies rely on nucleic acids analyses because they are amenable to automation and are at present the most promising for rapid and specific quantitation of viable microbial pathogens (Jothikumar *et al.*, 1998; Levin *et al.*, 2002; Straub and Chandler, 2003). Hollow-fiber ultrafiltration systems can concentrate all classes of pathogens in a single step and can be reused (Kuhn and Oshima, 2001; Olszewski *et al.*, 2001). Therefore, these filters may serve well as a basis for sample concentration in such a system. More recently, renewable surface technologies for automated sample processing coupled with microarray technologies have also shown promise as a basis of such a system (Chandler *et al.*, 2000a,b). Nucleic acids technologies, however, are still primarily in the hands of researchers and beyond the scope of all but the most highly trained staff and most affluent utility laboratories (Levin *et al.*, 2002). Significant investments need to be made in the development of simple and reliable technologies that are less technically-demanding.

Several pertinent issues need to be addressed before nucleic acids technologies are exclusively used as standard methods for surveillance activities, such as monitoring recreational and drinking water quality. First and foremost, there remains a need for regulatory establishment of acceptable concentrations in environmental matrices to determine the relevancy of detection limits established in these studies. Method development and standardization cannot proceed until target detection limits that reflect true risks of illness are established. These limits need to identify target concentrations based on epidemiological studies of health risk rather than indicate that pathogens should not be detected in a given sample volume. Regulatory guidelines should also clearly indicate standards regarding acceptable recoveries from environmental samples during concentration, analysis sensitivities, and standard errors. This is because sample concentration methods may present a wide variation in recovery of etiological agents from environmental waters, and regardless of the sample concentration methods used, PCR-based detection systems must confront a number of front-end challenges inherent to complex environmental waters that may reduce the sensitivity of the assay (Chandler, 1998; Loge *et al.*, 2002; Call *et al.*, 2003). As noted by others, a positive detection is relatively simple to interpret. However, knowledge of assay sensitivity, which varies from sample to sample, is critical to interpreting negative results (Loge *et al.*, 2002; Call *et al.*, 2003). It is possible that specific sample properties, such as the presence of PCR inhibitors, may affect the sensitivity of an assay thereby resulting in a false-negative result. The probability of false negative results will increase with lower numbers of pathogens per sample. Regulatory guidelines should consider these limitations in order to reduce the public health impacts of false-negative results. Good sampling designs need to consider how much sample is processed, the efficiency of pathogen isolation, the efficiency of nucleic acid extraction, and the effect of co-precipitating factors that inhibit PCR (Loge *et al.*, 2002; Call *et al.*, 2003).

Considering that acceptable regulatory concentrations of specific pathogens in environmental matrices will likely be very low, it is unlikely that current technology would be able to detect pathogens in real-time. Measurement of pathogens to satisfy what would be regulatory levels may still take 24-48 hours as they will require enrichment to increase pathogen numbers or reduce co-precipitating factors. This may also pose challenges as several different enrichment media may be necessary to detect several different pathogens. The only true method to alleviate the need for enrichment to detect low numbers of pathogens in environmental samples would be intensive sample concentration. Unless significant advances are made in sample concentration, nucleic acid extraction methods, and nucleic acid clean-up to remove inhibitory compounds, real-time pathogen detection will remain unrealistic. This will remain a critical issue for biodefense applications where near real-time identification of etiological agents may be imperative to protecting human health.

8. Microbial Source Tracking

Microbial source tracking (MST) is a set of methodologies by which the animal or human source of fecal pollution in a contaminated water body may be identified. MST technologies rely on phenotypic and genotypic differences in fecal microorganisms shed in the wastes of animals and humans that make them unique to a particular animal host (host-specific). These differences may arise due to variations in growth environments and the selective pressures of various animal guts such as differences in diet, antimicrobial treatments, temperatures, pH, and more. Upon release into the environment, it is assumed that these organisms remain unchanged and migrate with fecal pollution. Their detection in concert with indicators of fecal pollution or overt pathogens is thus assumed to be indicative of the animal source.

Knowledge of the source(s) of microbial contamination in water bodies and their relative load contribution helps to focus remedial efforts and resources in the right direction at an earlier time. Source identification may also enable investigation of best management practice (BMP) effectiveness leading to improvements in total maximum daily load (TMDL) development and implementation. There are many potential sources of bacteria extant in watersheds, and it is important to be able to sort out the source of observed contamination so that an evaluation of the effectiveness of control strategies can be made. MST may also improve enforcement activities when discharges exceed permitted levels.

In MST, the selection of the right indicator is important, since it is the single element which provides the measurable parameters to determine the origin of the pollution. Both phenotypic and genotypic technologies have been developed primarily using fecal coliforms, *E. coli*, fecal enterococci, fecal streptococci and viruses. Some of these technologies are library-dependent; they rely on comparing fingerprint databases, either phenotypic or genotypic, of microorganisms from known sources to the fingerprints of unknown samples. These may include antibiotic resistance analysis (ARA), carbon utilization profiles (CUP), repetitive extragenic palindromic PCR (rep-PCR) DNA fingerprinting, randomly amplified polymorphic DNA (RAPD) analysis, amplified fragment length polymorphism (AFLP) analysis, pulse field gel electrophoresis (PFGE), and ribotyping (Harwood, 2000; McClellan *et al.*, 2001; Hagedorn *et al.*, 2003; Carson *et al.*, 2003; Ting *et al.*, 2003; Leung *et al.*, 2004; Scott *et al.*, 2004; Webster *et al.*, 2004). Other MST technologies are library-independent; they rely on the conservation of unique genetic identifiers inherent to a specific fecal microorganism endemic to the members of a single animal species (the in-group) that are different from the genetic identifiers of the same or different fecal microorganisms in other animals or humans (the out-group). Examples of library-independent MST technologies include gene-specific PCR, 16S rRNA gene clone libraries, and target-specific PCR-based methods (Bernhard and Field, 2000; Khatib *et al.*, 2002; Khatib *et al.*, 2003; Field *et al.*, 2003; Simpson, *et al.*, 2003; Bonjoch *et al.*, 2004; Scott *et al.*, 2004; Simpson *et al.*, 2004; Suerinck *et al.*, 2005).

At present, MST studies have primarily employed library-dependent methods including ARA, AFLP, CUP, and ribotyping (EPA, 2005). Library-independent methods, especially gene-specific and target-specific PCR, have been the focus of recent literature as extensive libraries are not needed for their application, and they can be easily and rapidly applied to source identification studies. Potentially, phenotypic and genotypic methods could complement each other according to training, equipment, and funding available. This section highlights the more common methods of analysis that provide information about the source of microbial contamination and the methods used to analyze the data obtained by these methods. A full review of all available MST technologies is beyond the scope of this review. An excellent resource for further information regarding MST, its application, promises, and limitations is available in the USEPA Microbial Source Tracking Guide Document (2005).

8.1 Antibiotic Resistance Analysis (ARA)

The antibiotic-resistance analysis (ARA) method has gained popularity over the last decade because it is readily applicable and simple to use. However, the classification accuracy is usually lower than that of the molecular methods at the level of individual species. When animal species are grouped into larger animal categories like human, livestock, and wildlife, the accuracy improves notably to values of 95% or more. This method has been reported to provide sensible classifications of known and unknown fecal isolates and to resolve MST queries to satisfaction in various case studies (Parveen *et al.*, 1997; Hagedorn, 1999; Harwood *et al.*, 2000).

ARA is based on the following two premises (1) the use of antibiotics in humans and animals can result in antibiotic-resistant bacteria, and (2) differences in the selective pressures resulting from dosing with different types and concentrations of antimicrobials, as well as different growth environments in various animal intestines, result in unique patterns of antibiotic resistance specific to different animal types. The development and study of such specific patterns are the basis of this methodology, which uses fecal coliforms, *E. coli*, enterococci, or fecal streptococci as indicators. The laboratory procedure requires only conventional microbiology training and techniques. Therefore, it is cost-efficient and can be rapid when performed by an experienced research team. It begins with the recovery of the fecal bacteria from samples, mostly by membrane filtration and incubation in or on selective media. It continues with the inoculation of the isolated fecal bacteria onto agar or into broth medium containing a number of antibiotics at increasing concentrations. Lastly, the results are evaluated by comparing the antibiotic resistance profiles of the polluted water to the reference source library profiles.

The key to success of this method is having a representative source library with an acceptable *average of correct classification* (ARCC). Most important is to perform a cross-validation test before using the library to classify unknown isolates. The cross-validation test can be done with hold-out isolates or with new known isolates that are submitted as unknowns to the statistical software (Harwood *et al.*, 2000). The rate of correct classification from this test should not be significantly different from the original rates obtained when the library was initially classified. Similarly, it is important to use the antibiotics and the concentrations that provide the more accurate classification of the library isolates. For instance (as noted above), several antimicrobials used in animal agriculture have human-use analogs. Resistance that develops in livestock animals may therefore confer resistance to human antimicrobials and vice-versa. Therefore, preliminary tests are recommended prior to the analysis of the water isolates (Hagedorn *et al.*, 1999). While this method does not classify individual animal species very accurately, it has been used with satisfaction for human, poultry, livestock and wildlife categories (See examples below). In most cases, this is sufficient and supports the development of a restoration strategy.

Several examples of the use of ARA for MST exist. Parveen, *et al.*, (1997) used ARA methodology to differentiate point-source (PS) from nonpoint-source (NPS) *E. coli* from the Apalachicola Bay, Florida. They used 765 isolates and obtained average MAR indexes of 0.25 for PS and 0.13 for NPS. PS isolates showed higher resistance to single antibiotics and to combinations of antibiotics than NPS isolates. Sixty-five resistance patterns were observed for PS isolates, compared to only 32 patterns for NPS isolates, when cluster analysis was used. Wiggins (1996) developed a protocol to generate more extensive AR profiles by using various concentrations for each antibiotic tested. He also introduced the use of a reference source library and the multivariate analysis of variance discriminant function analysis to the studies of MST by ARA. He studied 193 water fecal streptococci, with a source library of 1,435 fecal streptococci isolates against a battery of five antibiotics at four concentrations each. An ARCC of 72% was obtained when the source categories were analyzed at the species level and 82% when some species were pooled into "poultry" and "beef" categories. In general, increasing the number of antibiotics used in an analysis increased the ARCC that could be achieved.

Others have further validated the ARA method by using additional statistical analysis. Hagedorn (1999) created separate source databases with 7,058 and 892 isolates with ARCCs of 87% and 88%, respectively, which increased to 97% and 95% after pooling species into poultry and beef. They used discriminant analysis to classify 4,615 water isolates from Page Brook River and obtained 82% beef, 7.3% deer, 5.6% waterfowl, and 0% human, and 5.3% unknown. Cluster analysis was also used, which generated very good separation between sources with high antibiotic resistance including chicken, dairy cattle and human clusters. Among beef cattle and deer, which had low levels of resistance, there was separation, but the deer tended to sub-cluster within the larger beef cow isolate cluster. Most of the unknown source isolates were grouped in beef cow, deer, and waterfowl clusters, whereas none grouped in the human cluster. Based on the results of this work, cattle access to the stream was reduced by fencing.

Harwood *et al.*, (2000) obtained ARCCs of 64% and 62 % with a source database of 6,144 fecal coliform and 4,619 fecal streptococci isolates. Similar to Wiggins (1996) and Hagedorn (1999), the ARCCs improved to 75% and 72%, respectively, after pooling the species into human and animal groups. Fecal coliforms from cattle were classified correctly at a higher rate than those of fecal streptococci. Conversely, fecal streptococci from humans were correctly classified at a higher rate than those from fecal coliform isolates. Overall, the fecal coliform database had a significantly greater ARCC than the fecal streptococci database. Spearman's ranked correlation using the percentage of correctly classified isolates versus the corresponding number of sampling events resulted in a significant negative-correlation between sampling events and the percentage of correctly classified isolates for the fecal coliform database, but not for the fecal streptococci database. They analyzed 91 fecal coliform isolates from surface water receiving effluent from faulty septic systems, 81 of which were classified into the human category. Similarly, 38 of 51 fecal streptococci from the same samples were categorized as human. After the septic systems were repaired, only 7.8% of fecal coliforms and 1.2% of fecal streptococci were classified as human.

Graves, *et al.*, (2002) constructed a library of 1,174 enterococci isolates, and with two categories (human and nonhuman) achieved an ARCC of 96%. By splitting nonhuman sources into livestock and wildlife, they were able to achieve an ARCC of 92%. They analyzed 2,012 enterococci isolates from a stream that drains a watershed with large populations of livestock and wildlife and that passes through a community of 82 homes served by individual septic systems. The yearly average classification was 10% human, 40% wildlife, and 50% livestock. Burnes (2003) analyzed 800 fecal coliform isolates from Big Creek, a mixed-use watershed, against a source library of 1,125 fecal coliform isolates (human and non-human categories, ARCC=94%). He found that human sources contributed greater than 50% of the base flow fecal coliforms in urbanized areas. Chicken and livestock appeared to be responsible for the base flow fecal coliforms found in rural reaches of the stream. Hydrologic events changed the contribution of each source to the stream such that fecal coliform pollution was 16% attributable to domestic sources, 21% attributable to wildlife, and up to 60% attributable to chickens and other livestock sources.

8.2 Ribotyping

Ribotyping is a DNA fingerprinting method that exploits small differences in 16S and 23S rRNA-coding regions of bacterial DNA to identify genetic relationships between unknown bacteria and a set of known index organisms (Grimont and Grimont, 1986; Stull *et al.*, 1988; Graves *et al.*, 1999). This method works on the premises that (1) multiple copies of the genes encoding 16S and 23S rRNA may appear within the bacterial genome with different flanking restriction site locations, (2) there is variability amongst 16S and 23S rRNA genes, and (3) there is variability in the intergenic spacer region between 16S and 23S rRNA genes. Ribotyping involves the culturing of a bacterium followed by DNA extraction and purification. Subsequently, the DNA is digested with one or more enzymes and the digestion products are separated by gel electrophoresis. DNA bands are typically transferred onto a nylon membrane and challenged by hybridization analysis with a chemically-labeled nucleic acid probe. The probes may be generated from an index bacterium, such as a particular strain of *E. coli*, by reverse transcribing the 16S and 23S rRNA and labeling the cDNA with a chemical labeling scheme. Because of small differences in the restriction sites of different bacteria, the resulting band patterns from the hybridization analysis will be distinct. This pattern is called a ribotype. By comparing ribotypes of unknown samples to a library of known samples challenged by probes from the same index organism, genetic and evolutionary relationships can be discerned. Ribotypes may be translated to a binary code facilitating a discriminant statistical analysis to aid in interpretation of results (Grimont and Grimont, 1986; Parveen, 1999; Carson *et al.*, 2001).

In early years, ribotyping was used in epidemiological studies to characterize bacteria such as *E. coli*, *Salmonella enterica* and *Vibrio cholerae* (Stull *et al.*, 1988; Olsen *et al.*, 1992; Popovic *et al.*, 1993). Gradually, ribotyping found application in multidisciplinary areas such as plant pathology, animal science, food technology, and MST (Nassar *et al.*, 1994; Nagai *et al.*, 1995; Kilic *et al.*, 2002; Scott *et al.*, 2004). By comparing libraries of ribotypes grouped by animal source, some researchers have noted that distinct bands unique to specific sources may emerge from non-distinct bands, thus facilitating the identification of the source of pollution in unknown samples. For instance, Parveen (1999) tested the applicability of this methodology to predict the source of *E. coli* pollution in the Apalachicola Bay, Florida. They analyzed a library of 238 *E. coli* isolates and found that discriminant analysis of the ribotype profiles showed an ARCC of 82%. A total of 97% of nonhuman and 67% of the human isolates were correctly classified. Carson *et al.*, (2001) extended the application of ribotyping to distinguish *E. coli* from humans and seven nonhuman hosts. When ribotypes from a library of 287 *E. coli* isolates obtained from humans, cattle, pigs, horses, chickens, turkeys, migratory geese, and dogs were used, the ARCC was 73%. By reducing the discrimination to human and nonhuman sources, these authors were able to achieve an ARCC of 97%. Using a library of 160 *E. coli* isolates, Scott *et al.*, (2004) was able to employ ribotyping to identify animals as the primary source of pollution in a water way near Charleston in South Carolina. Prior to this investigation, a significant human input was suspected. Kuntz *et al.*, (2003) successfully combined targeted sampling protocols with ribotyping to identify the source of fecal contamination of Sapelo River in Georgia. *E. faecalis* DNA fingerprints in the river were a 43% match to those in a nearby wastewater lagoon, suggesting that fecal contamination of the river originated from the wastewater treatment facility.

Other studies have used ribotyping successfully but have noted caveats in its application. For instance, Hartel (2002) studied 568 *E. coli* isolates from different locations in Georgia and Idaho to determine the geographic variability of *E. coli* from different animal species. They found that the percentage of ribotype sharing within an animal species increased with decreased distance between geographic locations for cattle and horses, but not for swine and chicken. The data suggested that the ability of libraries to classify unknown isolates is good provided both library and unknown isolates belong to the same geographic area. Wheeler *et al.*, (2002) explored the potential of *E. faecalis* as a human fecal indicator for MST using ribotyping. He analyzed fecal samples from humans and a variety of livestock, domestic, and wildlife and found that the host range of *E. faecalis* was limited to dogs, humans, and chickens and the ribotypes clearly distinguished between human and chicken hosts. The dog isolates were apparently eliminated when a protocol to quickly isolate *E. faecalis* was used. Hartel *et al.*, (2003) noted that ribotypes of *E. coli* isolates from wild deer was significantly affected by their diets. Wild deer exhibited 35 *E. coli* ribotypes, whereas penned deer generated only 11. Although issues of geographic stability, host range of target bacteria, and host stability of ribotypes may be of concern in some instances, ribotyping remains a preferred and well-accepted method for MST. From the results above, it appears to be a reliable tool to discriminate between pollution sources and provide valuable information for water management purposes.

8.3 Amplified Fragment Length Polymorphisms (AFLP)

AFLP is a DNA-fingerprinting method based on the detection of characteristic differences in the fingerprints of two genomes resulting from polymorphisms, insertions, and deletions that occur within or immediately adjacent to restriction sites. In this method, genomic DNA is extracted from the target cells and digested with a pair of restriction enzymes. Linkers specific to the restriction enzyme sites chosen are ligated to the DNA fragments providing the sequences for hybridization of PCR primers in the amplification steps. As large numbers of different fragments can be generated during digestion (more than 10^6 fragments per digestion of a genome of 10^9 base pairs (bp)), selective DNA amplification is used to limit the number of amplification products. Selective amplification can be achieved through a variety of mechanisms including 3’-extensions to one or both linkers, “pre-amplification” with only one primer complementary to one of the restriction enzyme sites, inclusion of 3’-extensions on the “pre-amplification” primer or one or both AFLP-PCR primers, and labeling only one of the AFLP-PCR primers. Amplified products are separated on a denaturing polyacrylamide gel in an automated DNA sequencer, and “fingerprints” are captured by specialized software which can scan the fingerprints for discriminatory bands. Evaluation of the results by various statistical analyses can be performed provided the DNA banding patterns are converted to binary form.

AFLP has proved to be highly discriminatory and reproducible when compared to other molecular typing techniques. During the last decade, it has become a reliable tool to classify bacteria to the strain level, as well as to perform genetic mapping of higher organisms (Janssen *et al.*, 1996; Desai *et al.*, 1998; Savelkoul *et al.*, 1999; Iyoda *et al.*, 1999; and Zhao *et al.*, 2000). Two reported evaluations of AFLP as a tool for MST stand out in literature. Both investigations compared AFLP to other fingerprinting techniques and utilized *E. coli* as the indicator organism. In the first of these studies, Guan *et al.*, (2002) studied a collection of 105 *E. coli* isolates from the feces of cattle, poultry, swine, deer, goose, moose, and human samples and compared AFLP to the ARA and the 16S rDNA methods. The results indicated that AFLP was significantly more effective than the other two methods. Ninety-four percent of the livestock isolates, 97% of the wildlife isolates, and 97% of the human isolates were correctly classified by AFLP. In comparison, 46% of livestock isolates, 95% of wildlife isolates, and 55% of human isolates were correctly classified by ARA, while 16S rDNA-based techniques resulted in 78%, 74%, and 80% correct classification, respectively. Although additional isolates in the source library may improve the ARCCs of the ARA and 16S rDNA methods, the resolution achieved by AFLP with a small library was impressive in this instance.

In another study, Leung *et al.*, (2004) used Shiga-toxin-producing *E. coli* (STEC), enterotoxigenic *E. coli* (ETEC), and non-pathogenic *E. coli* from cattle, swine, and human sources from very diverse geographic areas, including the U.S., Canada, Europe, and Australia, to construct source libraries. A multiple-response permutation procedure analysis of the data obtained with AFLP indicated that the seven groups defined by host-pathogenicity combinations (bovine STEC, bovine ETEC, bovine non-pathogenic *E. coli,* human STEC, human ETEC, human non-pathogenic *E. coli* and swine non-pathogenic *E. coli*) were significantly different. Subsequently, stepwise discriminant function analysis was used to select 39 discriminant DNA bands distinguishing the host specificity of the *E. coli* strains for the analysis. The overall cross-validation classification efficiency was 93.6% with 91.4% of human, 90.6% of bovine, and 97.7% of swine isolates being classified into their correct host types.

AFLP also distinguished the non-pathogenic *E. coli* from STEC and ETEC, and was able to classify the strains based on both host specificity and virulence (Leung *et al.*, 2004). Stepwise discriminant function analysis selected 41 DNA bands to classify the isolates based on pathogenicity with an overall cross-validation classification efficiency of 99.1% (100% of non-pathogenic *E. coli,* 100% of STEC, and 90.9% of ETEC correctly classified). Fifty DNA bands were selected by that same means to differentiate the seven host-pathogenicity combinations (bovine VTEC, bovine ETEC, bovine non-pathogenic *E. coli*, human VTEC, human ETEC, human non-pathogenic *E. coli* and swine non-pathogenic *E. coli*) with an average cross-validation classification efficiency of 86.4% (individual group classification efficiency ranging from 50 to 100%). Despite the wide geographic origin of the *E. coli* strains in this study, AFLP was capable of differentiating the *E. coli* strains with a high rate of correct classification from the various hosts.

Like most methods used in MST, AFLP needs the development of a reference source library of the indicator organism. Based on the reports above and the fact that AFLP screens the entire genome, this tool has great potential for MST. However, reports of case studies with successful application of AFLP are necessary to further MST using AFLP.

8.4 Host-specific molecular biomarkers

Host-specific molecular biomarkers for MST studies, target-specific PCR-based methods, are attractive because they offer rapid analysis (no source library or cultivation are needed) and greatly reduced cost. They are technically less demanding than most alternative MST techniques. Several bacterial targets have been proposed in the literature for MST applications including *Bacteroides*, *Bifidobacterium*, *Streptococcus* Lancefield Group D, and *Rhodococcus coprophilus* (Whitehead and Cotta, 2000; Vancanney *et al.*, 2002; Bernhard *et al.*, 2003; Bonjoch *et al.*, 2004; USEPA, 2005). However, since each marker is specific to a single animal host, a combination of markers may be required to fully identify potential sources of contamination. Because no cultivation is required, these methods are applicable to detection of several biomarkers in a single sample, which may strengthen the argument for source identification (USEPA, 2005). For instance, samples with positive results for several human-specific biomarkers, such as human-specific *Bacteroides* spp. (Bernhard *et al.*, 2003), both the human-specific primer pairs for *Bifidobacterium adolescentis* and *Bifidobacterium dentium* (Bonjoch *et al.*, 2004), and the human-specific *Enterococcus* spp. *esp* markers (Scott *et al.*, 2005), but negative for the cattle-specific *Bacteroides* (Bernhard *et al.*, 2003) or *E. coli* LTIIa toxin (Khatib *et al.*, 2002), would strongly implicate a human rather than cattle source. At present, *Bacteroides* markers are the most commonly used host-specific molecular biomarkers for MST (Bernhard *et al.*, 2003; Seurinck *et al.*, 2005; USEPA, 2005). However, the use of these markers for resolving watershed-scale microbial pollution is unknown.

The development of the human- and ruminant-specific *Bacteroides* biomarkers is described by Bernard and Field (2000a,b). These researchers created 16S rDNA clone libraries of members of the *Bacteroides-Prevotella* group from human and cow fecal samples. Individual and pooled clones were examined by length heterogeneity (LH)-PCR and terminal-restriction-fragment–length-polymorphism (T-RFLP) techniques. Sequencing and phylogenetic analysis demonstrated that the human-specific sequences clustered together and were closely related, but not identical, to sequences of *Bacteroides vulgatus*, which is commonly found in human feces. The cattle-specific sequences formed the new gene clusters CF123 and CF151. All human- and cattle-specific genetic markers were found in DNA extracted from river and estuary water contaminated with fecal pollution.

Primer sets were developed to amplify specific sequences within the *Bacteroides-Prevotella* host-specific gene clusters (Bernhard and Field, 2000a,b): one forward primer specific for the human-specific gene cluster HF8, two forward primers for the cattle-specific gene clusters CF123 and CF151, and a general *Bacteroides-Prevotella* reverse primer for use with all three forward primers. These primers were successfully used to amplify 16 human and 19 cow fecal 16S rDNAs (Bernard and Field, 2000b). In subsequent work, Bernhard *et al.*, (2003) used these primers to test 22 water samples from Tillamook Bay and the results were congruent with land use. For example, the human specific primer pair, HF183F/Bac708R, amplified only DNA from waters around urban areas and sewage treatment plants, demonstrating specificity for human *Bacteroides* DNA. The cattle specific primers, CF128F/Bac708R and CF193F/Bac708R, amplified DNA from waters primarily near rural areas. However, these primers amplified other ruminant DNA as well. Therefore, positive results with these primers should be scrutinized against land use and ruminant wild-life populations to prevent misinterpretation of results. Dick *et al.*, (2005) have also recently published host-specific primers for swine and horse.

Relatively few other host-specific molecular biomarkers have been reported in literature (Khatib *et al.*, 2002a,b; Nebra *et al.*, 2003; Bonjoch *et al.*, 2004; Scott *et al.*, 2005). Most of these markers target 16S rDNA, but some markers are emerging that detect alternative regions of the bacterial genome, such as virulence genes (Khatib *et al.*, 2002a,b; Scott *et al.*, 2005). The efficacy of these and other biomarkers have not been well established. Therefore, interpretation of the presence of these molecular markers in different *milieus* may be complicated. Because of the small number of environmental samples studied so far, host-specific molecular biomarker technology needs further exploration in case studies to show field-applicability.

8.5 Discussion

Several methodologies are available for MST studies. As shown by the publication evidence, ARA represents a good tool for MST validated by various applications in real-life case studies. However, specific considerations may limit its usefulness including human-livestock analogs, and transfer of resistance traits in different *milieus*. Ribotyping is probably the most field-tested method among the molecular methodologies used for MST. From the results above, it appears to be a reliable tool to discriminate between pollution sources and provides valuable information for water management purposes. Although ribotyping may generate high ARCCs, it has also been associated with a high cost and may be labor intensive, requiring long studies to achieve results (Hartel *et al.*, 2003). AFLP technologies are emerging as a promising tool for MST. These methods offer a high degree of specificity, as they can screen the entire genome instead of selected regions such as the 16S and 23S rDNA screened by ribotyping. However, considerable technical expertise and expense may be needed to fully utilize the technique. Other molecular methods, although sophisticated and capable of measuring parameters with high resolution, are in various stages of development. More research is needed for these methods to become accessible for a broader population of users. As of today, these techniques have mostly been used in feasibility studies with a small amount of isolates. Full-scale watershed studies are needed to assess the potential of these technologies for future use.

Several factors may complicate the use of MST technologies in contaminated watersheds. Poor survival of reference organisms in the environment may result in little or no detection, limiting the ability of the various methods to identify the source of fecal contamination (Simpson *et al.*, 2003; U.S.EPA, 2005). Even those reference organisms that are reasonably hearty may exhibit variable survival times for different phenotypes or genotypes dependent on the environmental milieu. This may lead to changes in genotypic and/or phenotypic signatures of the overall populations and divergence from fingerprints in source libraries established with the raw fecal material. For instance, Anderson *et al.*, (2005) studied decay rates for fecal bacterial indicator organisms (fecal coliforms and *Enterococcus* spp.) originating from dog feces, wastewaters, and soil in freshwater and sediment and saltwater and sediment. These researchers observed variable decay rates based on fecal bacterial source, environment, and even ribotype. These changes may complicate interpretation of environmental fingerprints and undermine source tracking efforts, potentially resulting in misinterpretation of environmental data.

Another serious complicating factor is that the transport properties of different bacteria may vary several-fold depending on the specific microbial agent and the *milieu* (Ferguson *et al.*, 2003). If transport and survival of the index organism(s) used to identify fecal pollution source(s) do not match that of pathogens emanating from potential sources, MST may yield questionable information. For instance, Simpson *et al.*, (2003) could not establish a relationship between the molecular fingerprints of 16S rDNA fecal *Bacteroides* clones in a large horse manure pile immediately adjacent to a receiving stream and downstream water as close as 5 m from the manure pile. In contrast, other researchers have noted significant overland and downstream transport of antibiotic-resistant bacteria and several bacterial, viral, and parasitic pathogens, such as *Cryptosporidium parvum*, *Salmonella* spp., swine hepatitis E, and *Yersinia enterocolitica*, for several hundred meters from concentrated animal feeding operations (CDC, 1998; Karetnyi *et al.*, 1999; Gurdin *et al.*, 2002). Further, if several different bacterial index organisms are used for source identification, as suggested by the USEPA (2005), the transport properties of the individual agents need to be clearly defined to interpret what differences in the level of detection for different animal sources mean. MST studies need to identify the distance at which selected biomarkers may be detectable from their pollution source(s) and whether or not this may be indicative of the fecal pathogens emanating from the same source.

9. Treatment Technologies and Management Practices

As animal agriculture has evolved to larger facilities with large numbers of animals in limited spaces, the problems associated with manure handling have grown. A single swine, beef, dairy, or poultry facility can produce waste equivalent to a small city. The waste is, for the most part, untreated and spread into the environment with little control on dissemination of microorganisms in the waste. All animal manures contain microorganisms, some of which are pathogenic to humans and other animals. Zhao *et al.*, 1995 surveyed dairy herds in 14 states to determine the prevalence of *E. coli* O157:H7. Their results indicated that *E. coli* O157:H7 was present in about 5% of each herd.

Prior sections of this report have enumerated the pathogenic organisms in manure and detailed the illnesses associated with them. Environmental problems originate when the manure containing pathogens is distributed into the open environment with no effort made to reduce the content of pathogens or limit their movement in the environment. Wind, surface flow, and subsurface flow can all carry enough pathogens to receiving waters to exceed water quality standards. In many cases, streams and lakes are used for recreation, and the people using them can be exposed to infection without knowing that they have been exposed. Knowledge of the survival and transport of potential pathogens in the environment is critical for implementing corrective actions on the landscape to limit people's exposure to pathogens.

Microorganisms can move in the environment in several ways. Organisms can move with any dust produced in animal housing, feedlots, or manure spreading. Other airborne transport can happen as liquid waste is spread by spraying as an irrigation process, spraying from an application vehicle, or agitation of lagoons prior to spraying. After manure has been applied to a field surface, microbes can move with water when rainfall exceeds the infiltration rate, thereby creating runoff. Rainfall impact dislodges the organisms from soil or manure particles, and flowing water transports them to receiving waters. Another path for movement of organisms is through subsurface drainage. Microorganisms can enter worm burrows or root channels and move downward in the soil profile as the water flows to groundwater or to drainage tile. If groundwater is shallow, it is possible for serious contamination to occur in wells situated too close to application sites or CAFO installations.

Tile drains can short circuit groundwater recharge by intercepting water and diverting it to streams before it can percolate through the soil. Water that infiltrates the soil down to tile depth is usually below the majority of the root zone and thus not available for plant uptake. Tile drains can accelerate the movement of nutrients and bacteria into receiving waters (Joy *et al.*, 1998, McLellan *et al.*, 1993). Hunter *et al.*, 2000 found that sheep grazing in pastures in England could adversely affect water quality even though the animal population was quite low, one animal per square kilometer basis. Tile drains and open ditches were conduits for microorganisms from pastures to streams. Janzen *et al.*, 1973 found that water quality in streams near dairy farms frequently exceeded coliform limits due to bacterial contamination. About 42 % of the farms were responsible for exceeding standards. Some research has shown that waste applied to the surface of a tiled field can enter the tile quickly after a rainfall. The width of the zone affected by tile at the soil surface is on the order of a meter. In fields that have tile drains, the spacing of tile lines is on the order of 25 or more yards depending on the soil type. Coarser grained soils will allow wider spacing of tile lines than fine grained soils. Each tile line will drain infiltrating water down to its level after a rain event. A portion of the infiltrating water will drain below the tile level and enter groundwater as recharge. There is a possibility that groundwater can be contaminated by manure spread on the surface.

As shown earlier in this report, beef, dairy, poultry and swine operations have become fewer in number and larger in animal populations. The result is to produce more manure in limited areas with little opportunity apply it to land at low enough levels to reduce pathogenic organisms to background levels. Microorganisms in manure produced in large CAFOs pose a serious risk to water quality for recreation, human health, and possibly to nearby farms by spreading disease. One of the most feared occurrences in the agricultural community is an outbreak of disease among farm animals. Recent outbreaks of hoof and mouth disease in the United Kingdom led to multiple billion dollar losses (Ferguson *et al.*, 2001). Reducing the presence of potential pathogens in wastes applied to land will go a long way to improving the safety of farms from disease. Reduction of the bacterial population in water can also improve downstream biosecurity of adjacent farm operations. Manure management practices and potential treatment technologies can be applied to reduce the number of microorganisms distributed into the open environment. There is a great need to implement microorganism reduction techniques to animal waste to prevent detrimental environmental effects.

9.1 Manure management: active and passive systems

Common practices used for managing manures in the U.S. include passive and active approaches. The passive systems include lagoons, storage prior to disposal, vegetated buffer strips, constructed wetlands, separation of different ages of animals, and land application. The passive systems do involve manipulation of manure to move it and eventually land apply the materials, but do not require more than minimal operator input. Active systems include composting, anaerobic digesters, aerobic digesters, and actively operated lagoons. Active systems require more operator attention, such as turning compost windrows, monitoring digesters, and mixing lagoons. In both cases, the key factor is operation with minimum input of labor and capital.

Lagoons are large excavations that may or may not be lined with plastic or clay that receive liquid wastes from animal confinement buildings. Lagoons can be single or multiple cell designs. A passive lagoon is effectively anaerobic due to the large load of organic matter flowing into the lagoon and limited aeration from diffusion and wind. Multiple cell designs can have anaerobic cells, followed by increasingly aerobic cells as the organic content of the waste stream decreases by settling and degradation by microorganisms. Lagoons can also be modified by adding covers to collect methane, or as a permeable cover to oxidize ammonia to nitrate that can be reduced to nitrogen gas in the microenvironment of the cover.

In some cases, usually dairy, beef, and poultry operations, manure is simply scraped into piles and held until a convenient time for disposal by land application. Separation of animals into age groups has also been shown to be effective in reducing specific pathogens, especially *C. parvum* (Atwill *et al.*, 1999). Young animals frequently shed large numbers of oocysts, and older animals do not. Manure from calves can be collected and treated separately from the larger quantities of manure from older animals (Hutchinson *et al.*, 2005). The costs of treatment are lower due to the much smaller mass to treat. In some cases, manure is periodically removed from the animal confinement buildings and directly land applied with no treatment. Simple holding of waste for greater than 90 days will achieve bacterial reductions of >90% (Thayer *et al.*, 1974).

Vegetated buffer strips (VBS) are placed along the downslope sides of fields where wastes are applied to intercept runoff water. As the water flows across the buffer strips contaminants are retained in the vegetated area. The vegetation slows water velocity, allowing settling of particles and infiltration of water into the soil. A well-designed VBS will reduce the quantity of microorganisms leaving a field during runoff events. Many studies have shown greater than 50% reduction of bacterial populations between water entering a VBS and water leaving a VBS. While this reduction may not fully achieve primary contact standards, it is a step in the right direction. Key factors in VBS success are the width of the VBS, slope of the soil, type of soil, and degree of vegetative cover. Good buffers are usually about ten meters wide, with slopes less than 8%, and have about 90% coverage with vegetation. Other management options can help lower the numbers of organisms being applied to the fields. Microorganisms can be retained in strips and wetlands to a significant degree; however, reduction of loads to meet water standards has proven elusive. Many VBS studies show reductions of organisms reaching streams by as much as 90+% (Coyne *et al.*, 1998). The difficulty arises in that reducing populations 90% (e.g., $1x10^6$ to $1x10^5$ per 100 mL) can still leave more organisms in the water than standards allow (Coyne *et al.*, 1995). Table 11 summarizes research done on the trapping of microorganisms in VBS systems and wetlands which primarily treat surface water flow and some shallow ground water.

Active manure management systems involve more operator participation to maintain functionality. Composting requires attention to carbon to nitrogen ratio, moisture, and periodic aeration. In composting, the degradable organic matter is consumed by microorganisms reducing the mass of material. During the process, the temperature of the compost pile will rise to over 50^o C. Under these conditions, pathogenic organisms cannot survive. Composting is very effective in reducing pathogenic organism content of wastes (Olson, 2003). Adequate disinfection requires that conditions of specified time at specified temperatures be met.

Anaerobic digesters can be either plug-flow or mixed reactors. In both cases, the easily degraded organic matter in the waste stream is consumed, reducing the oxygen content of the reactor to methanogenic conditions. Generation of methane can partially offset the costs of reactors and maintenance by providing electricity and / or hot water for the farm. Anaerobic digesters can be operated at ambient (20-30^{o}C), mesophilic (30-37^{o}C), or thermophilic (45-55^{o}C) temperatures. The efficiency of the reaction and reduction of pathogens is different under the different temperature conditions. The thermophilic reactors are more efficient in production of methane and in destruction of pathogenic organisms (Sobsey *et al.*, 2002). However, they are more susceptible to upsets. Aerobic reactors actively incorporate oxygen into the reactor fluid with the goal of maintaining aerobic metabolism by the microorganisms. Aerobic reactors can also operate at ambient, mesophilic, and thermophilic temperatures. The benefit of an aerobic reactor lies in odor reduction and greater carbon mass reduction. Pathogenic organisms are also reduced in aerobic reactors, with greater reductions occurring at higher temperatures (Hill, 2003). In an earlier study, Munch *et al.*, 1987 determined the decimation times for several pathogens in cattle and swine manure slurries from five herds in the temperature ranges 18-20^{o}C and 6-9^{o}C. The results are shown in Table 12. As can be seen in these results some organisms are relatively poor in survival. In general, colder environments favor survival, and aeration favors the reduction of microorganisms. Other organisms, especially fecal streptococci and *E. coli,* can have very long decimation times at cool temperatures. Management practices that address the resistant organisms should at the same time reduce the less-resistant organisms.

The pathogen reduction effectiveness of different manure management practices is shown in Table 13. In most cases, potential pathogens are reduced in common practices by 2 $\log_{10}$ orders or 99%. While this is important, it is not enough to achieve acceptable water quality standards in receiving waters. Lagoon effluent, surface runoff water, tile drain water, or digester effluent may need to have 4 to 6 $\log_{10}$ orders of organism reduction to meet water quality standards.

Olsen and Larsen, 1987, identified bacterial decimation times of several pathogenic organisms in meso and thermophilic anaerobic digesters. Their results are shown in Table 14. The important factors were the species of bacteria and temperature, but not the source of manure, reactor process (batch or continuous), gas produced, ammonia content, or pH.

Combining management practices has been shown to accomplish greater reductions of pathogenic organisms than single practices. Among the practices tested are multicell lagoons with constructed wetlands (Ibekwe *et al.*, 2002), multicell lagoons followed by constructed wetlands (Sobsey and Hill, 2002), solid separation prior to wetlands (Hill *et al.*,1999), lagoons followed by constructed wetlands followed by infiltration basins (Lorimor *et al.*, 2003), solids separation followed by composting of solids and treatment of the water, digesters followed by constructed wetlands (Bicudo and Goyal, 2003), animal diet manipulation to reduce pathogen

loads, and separation of animals into different buildings at susceptible life stages (Shaw *et al.*, 2004). North Carolina State University has compared conventional lagoons followed by sprayfields with solids separation followed by a constructed wetland. The second treatment system reduced coliforms and *E. coli* by 3 to 4 $\log_{10}$, while the first reduced coliforms and *E. coli* by 1 to 2 $\log_{10}$. Multicell lagoons have been shown to reduce potential pathogens in wastes by about 99 % in each cell. With two or three cells in series, microbial populations can be reduced to acceptable water quality levels. New York City has published a multiple barrier approach to protecting source water watersheds (New York City and the Watershed Agricultural Council, 1996). The approach starts with good animal husbandry, including herd health, separation of age groups, sanitation improvements, and crop system changes. Szostakowska *et al.*, 2004 reported on the presence of *C. parvum* and *G. lamblia* in cattle barn flies and landfill flies. The flies from the barn had a greater load of infective cysts than the flies from the landfill. These studies show the importance of controlling the spread of pathogenic organisms in the environment by nonagricultural vectors. The second stage is improving barnyards, manure handling, application timing, soil management, and composting. The third stage improves stream corridors, adds vegetated buffer strips, adds stream crossings for pastured animals, fences animals away from streams, and adds watering stations remote from streams. Milne (1976) showed that livestock in proximity to a stream increased the nutrient and organism load in the stream. Fecal coliforms and fecal streptococci were found in the stream above water quality standards. Jellison *et al.*, 2002 found major sources of *Cryptosporidium* spp. in a watershed to be from wildlife and cattle. *C. parvum* was found in cattle and deer. One example of a method of runoff control is simply fencing livestock away from streams (Line *et al.*, 2000; Owens *et al.*, 1996). In both cases, fencing cattle away from streams led to significant reductions of nutrients and sediments entering the streams. Owens *et al.*, 1996 also showed that 1% of storm flow accounted for 27% of the sediment losses. Peak losses were in May and June.

9.2 Disussion

Conventional manure management techniques do reduce the populations of pathogenic microorganisms. The extent of the reduction for most techniques is on the order of 90-99%. The pathogenic organisms originate in the digestive tracts of warm blooded animals, so it is not surprising that conditions in the open environment are inimical to their survival. Important factors in organism survival are nutrient content of the waste, organic content of the waste, temperature, and the species of microorganism. Organic acids, ammonia, and pH changes can also act to reduce the survival of microbial populations. Competition and predation can also affect the population of pathogens in waste materials. Once the manures are spread on fields, microbes can move with air, surface and subsurface flow. VBSs will retain large fractions of microbial populations, but not enough to allow discharge into receiving streams. Solar radiation and timing of manure application with regard to rainfall have a significant effect on microorganism survival. Soil management techniques are also important in planning for reduction of pathogen reduction. Surface application of manure will take advantage of solar radiation as a disinfection technique, but ammonia losses to the atmosphere may be increased. Injection of liquid waste will retain ammonia as a fertilizer, but pathogen survival is enhanced when organisms are protected from drying and the effects of sunlight. The most effective methods for manure management that also control pathogenic organisms are composting and thermophilic digestion. In both cases, the temperature of the process is adequate to destroy many pathogenic organisms. Composting is probably the least costly process to use. It does require attention to solids content, moisture content, and C: N ratios. Properly done, composting can yield a value-added product that can be marketed to the public. This does require development of a marketing plan. High temperature digestion will also destroy pathogens. Under anaerobic conditions, methane can be recovered and used to offset the cost of building and running the digester. High temperature aerobic digesters destroy pathogens and reduce the carbon mass that must be handled, but operational costs are likely to be high and are hard to justify.

The best methods for reducing pathogen loads in manures will combine more than one management tool to achieve reduction of microbial populations to levels that will meet water quality standards. One example of a combined management process is separation of solids from the waste stream, composting of the solids, and digestion of the liquid portion followed by a constructed wetland. This process would reduce pathogen loads in the waste so that land application of either the solid or liquid phase would pose little or no risk to receiving waters. Another example of a combined treatment system is an anaerobic digester, followed by solids separation and constructed wetlands for treatment of the liquid phase of the waste. Multicell lagoons, followed by constructed wetlands, are another form of combined systems. Wastes should not be applied to land unless two or three management/treatment steps are used before land application. VBS should also be present at the edges of the fields used for application of the wastes. Waste management will include management of the animals in terms of diet and housing sanitation. Animal producers will need to work with agricultural researchers and planners to reduce the dissemination of pathogenic microorganisms from their facilities. Achieving these reductions need not require high cost technologies. In some cases, the reductions can be achieved by modifying existing facilities and perhaps adding additional processes, such as wetlands. Adding baffles to lagoons to increase the length of the flow path is one such modest cost option.

Changing the manure management process at CAFOs will require that each facility examine its manure handling process and look for ways to incorporate more steps that reduce pathogen loads. The USDA Natural Resources Conservation Service publishes conservation standard practices that can be applied to manure management problems (http://www.nrcs.usda.gov/technical/Standards/). Collaboration between producers, conservation officers, and environmental advisors can lead to great improvements in the handling of animal manures in the U.S.

10. Ongoing research at the EPA and Other Federal Agencies

The presence of CAFOs and the associated wastes are a topic of interest for several agencies of the U.S. government. Natural resources in the U.S. that are potentially affected by the presence of CAFOs and the attendant manure include, but are not limited to the air, water, and soils. In particular, the United States Department of Agriculture (USDA) has a significant interest and commitment to animal issues, both from a production and an environmental perspective. Within the USDA, two organizations have a dominant interest in manure-related research including the Agricultural Research Service (ARS) and the Cooperative State Research, Education, and Extension Service (CSREES). ARS has a formal research area known as National Program 206 (NP206) that is tasked with manure related research with a wide array of topics of interest to the EPA. CSREES sponsors research by funding of universities and other organizations. Research goals encompass atmospheric emissions, nutrient management, pathogens, and pharmaceutically active chemicals, and byproducts. All phases of animal production will enter into aspects of manure management from feed formulas to field application of manure. In addition, the Natural Resources Conservation Service (NRCS) funds implementation of conservation practices through a variety of programs. NRCS does not conduct research directly. In the conservation activities of NRCS, there are several different programs established to help livestock producers improve the environmental performance of their operations. These programs are either cost-sharing or outright grants to help producers mitigate environmental impacts of livestock operations. One of the larger programs is the Environmental Quality Incentive Program (EQIP) that provides low interest loans and cost sharing to producers that install conservation practices on their property. The EQIP funding level was about $1.5 billion in Fiscal Year 2005 (http://www.nrcs.usda.gov/programs/2005_allocations/2005_allocations.html).

Another agency that conducts research into microbial problems related to CAFOs is the United States Geological Survey (USGS). The USGS conducts water quality research across the U.S. and complements USDA research in several ways. USGS emphasizes assessment of water bodies and the impacts of animal waste in karst terrain and ground and surface waters. USGS tends to place its research in a watershed context while USDA tends to place its research into a location specific context. Both approaches are needed to fully address the impact of animal waste on water resources in the U.S. See Table 15 for a listing of some current microbiological research carried out by USGS.

The Centers for Disease Control (CDC) has conducted research on the public health effects of animal waste in the environment. The areas of interest to CDC include antibiotic resistance, bacterial populations, and nitrates in water. The research conducted by CDC has been severely limited due to budget cutbacks. There is an important need for epidemiological analysis of microorganisms originating from animal waste to determine if human health is at significant risk. Waterborne disease is believed to be greatly under-reported (Morris and Levin, 1996; American Society for Microbiology, 1998). Many cases of gastroenteric illness that could be attributed to contaminated water are likely to go unreported by people because they simply do not associate swimming in streams, lakes, and ponds with the onset of symptoms. It is more likely for people to assume that a gastroenteric illness was associated with foods consumed during recreational activities.

Table 15. Studies carried out or in progress in the United States Geological Survey

Location	Media [†]	Analytes	Waste Type	Observations
Missouri	GW	Nutrients, Fecal Bacteria	Poultry	Wells showed contamination with no history of manure in the area
Delaware	SW		Poultry	
Arkansas, California, Missouri, Colorado, Virginia	SW	Bacteria, Viruses, Protozoa, Nutrients	Various	Presence in streams, fate and transport, methods, isotopes
Arkansas	GW	Nitrate, Bacteria		Effects in karst terrain, spring resurgences, nitrate from septic systems, highest bacteria in initial flow
Not identified	Feed	*E. coli*, *Salmonella*	Cattle	Resistance development, cost analysis
Not identified	GW, SW	Viruses	Swine	Survey of waste from hog to stream, survival
Iowa	GW, SW	Nutrients, Bacteria	Swine	Effect of CAFO on GW,SW
Missouri	SW	Bacteria	Poultry	Coliforms in Shoal creek watershed
Not identified	GW, SW	Antibiotics		Methods, presence of antibiotics in water
Iowa	SW	Antibiotics		Survey of streams for antibiotics
Florida	GW	Nutrients, Bacteria	Dairy	Survey of wells for bacteria and nitrate, downstream had elevated levels of both.
Central Appalachia	GW	Bacteria	Dairy	Land use effects, seasonal variation, soil-water effects, BMP effects
New Mexico	GW	Nitrate	Dairy	94 dairies surveyed, high nitrate found at many
Missouri	GW	Viruses, Bacteria	Various	Survey of wells, few had contaminants, positives in areas of high agriculture
Michigan	GW, SW	Bacteria	Various	Models currently inadequate to describe transport, no well contamination
Five States, eastern US	GW	Nitrate, Phosphorus		Permeability versus runoff
Not identified	GW, SW	Nutrients, Bacteria	Various	
Michigan	SW	Bacteria	Wild Birds	Birds were dominant sources, antibiotic resistance patterns, rainfall increased counts in 48-72 hours depending on wind, collection time affected counts.
Nebraska	SW, wetlands	Bacteria, Nutrients	Swine	Decline of contaminants through wetlands before a wildlife refuge.

[†] GW = Groundwater; SW = Surface water

The various agencies with interests in microorganisms associated with animal waste have a broad range of topics that they are pursuing. A key topic for all agencies is development and validation of methods for the identification and enumeration of potential pathogens in the different media associated with manure in the environment. The methods for total and fecal coliforms and enterococci are mature, but largely limited to water. There are few methods suitable for a broad range of media such as soil, sediment, lagoons, manure, and water. New methods need to be developed especially to identify overt pathogens in different media. Assuming that a given method is credible, the survival and transport of microorganisms in the environment becomes the next major topic of research. Currently, there is limited research on the movement of microorganisms in the environment. Do they move with soil particulates? What affects movement of organisms in the environment? Are they independent of soil? How long do different organisms survive in the environment? What are safe limits of the different organisms in recreational waters? Beyond the questions raised here are larger questions of how to control the content of microorganisms in animal waste. What effect do animal diets have on microbial populations in the manure? What effect does manure storage have on pathogen populations? Is pathogen regrowth a significant problem?

In addition to development of methods for enumerating pathogenic organisms in environmental samples, there are several other common topics of interest to USDA, USGS, CDC, and EPA. These topics include survival and transport of organisms in the environment, source identification and tracking, and antibiotic resistance characteristics of the microorganisms. Do tile drain lines enable transport of bacteria into receiving waters? What effects do different soil types have on microorganism survival? What effect does timing of manure application to soil have on microbial populations? What is the effect of solar radiation on bacterial survival? What effect does rainfall have on transport of microorganisms from application sites to nearby streams? What effects do different Best Management Practices (BMPs) have on the movement of microorganisms in the environment? BMPs commonly include vegetated buffer strips, constructed wetlands, runoff retention basins, infiltration basins, terracing, injection of waste into the soil rather than broadcast application, and more. The development of models of microbial behavior in the environment is a topic of interest to the different Agencies because good models can help to conserve resources and assist in planning for Total Daily Maximum Load (TMDL) implementation and assessing plans for placement of new animal operations on the landscape.

Research carried out by the different agencies is performed on many different scales. Laboratory scale studies are performed to develop new detection and enumeration methods, measure movement of microorganisms through small soil columns under controlled conditions, develop source-tracking techniques, and evaluate small model digester performance. The work done to develop new methods for detecting and estimating microbial populations uses several approaches: 1) Culture-based methods are being refined to be more selective and to reduce the number of steps or time required to provide data for analysis; 2) antimicrobial compound resistance patterns are used as one approach to identify organisms originating either from humans or animals; 3) genetic analysis techniques are also being developed to discriminate human from nonhuman isolates to help identify sources of organisms in water. Another goal is to develop robust methods that can detect and estimate the population of specific organisms in the environment and track them to their source. The benefit of source identification is that corrective actions can be focused more effectively on specific problems rather than being applied to a broad area. Laboratory-scale work is also done to conduct analyses of samples from different environments using legally standard methods. Beyond the laboratory, field experiments are conducted at plot-scale, field-scale and watershed-scale. The plot and field-scale experiments usually evaluate the effects of application rate, application timing, rainfall effects on transport, and survival of microorganisms in the field. Also included at this scale are effects of vegetated buffers, wetlands, and other field management practices that can impact the transport and fate of microorganisms. Watershed-scale examination of effects of CAFOs on microbial populations in waters is perhaps the most difficult to carry out. Examination of waters for populations of total or fecal coliforms only reveals if the waters meet standards or not. The current methods simply do not allow for estimation of the contribution of human versus other animal inputs. Similarly, the inputs of wildlife cannot be separated from domestic animals or humans using total or fecal coliform methods. Consequently, installation of management practices at one CAFO may reduce that facility's input to the stream, but have little effect on the total load of microorganisms. Much work needs to be done to adequately model microorganism behavior in the environment and to identify critical control points. A means for separating the total microbial load into its important components needs to be developed and validated to enable estimation of the maximum load for individual water bodies. Associated with this work is a need to estimate or identify the health risk of fecal organisms in water.

The majority of the research conducted by USDA has dealt with the control and retention of plant nutrients in manures. The nitrogen and phosphorus content of manure represents a valuable resource for fertilization of agricultural land. Similarly, the organic matter content of manure is a valuable soil conditioner. In recent years, the ARS has added a significant amount of research on the microbial content of manures with regard to the presence of pathogenic microorganisms, the transport of organisms in the environment, and the survival of organisms in the environment (Table 16). When farms were smaller and had small numbers of livestock present, the manure produced was largely used as a soil amendment and fertilizer. In most cases, the small farm manure load would have been indistinguishable from the background of wildlife sources. The advent of large animal production units has altered the quantity of manure generated in small land areas. It is common now to have poultry houses with over 100,000 birds and swine houses with more than 1,000 animals in a building. Beef feedlots and dairy facilities can also have very large numbers of animals present. The amount of land available within economical transport distances for application of manure is also limited. The result is that too much manure is applied to too little land, leading to the possibility for serious runoff losses of nutrients and potential pathogens.

The importance of understanding microbial behavior in the environment cannot be overestimated. The health of humans and animals can be seriously affected by microorganisms that are commonly present in manures. If one farm has animals that are shedding pathogens in their manure, that manure can be a source of infection for other farms, recreational water users, and possibly municipal water supplies downstream of the farm. The true risks remain largely unknown because there is little information on the presence and survival of pathogens in animal waste after it enters the environment. USDA research on the microorganisms in manure is addressing this concern in studies from laboratory to entire watershed studies. The indicator organisms (coliforms and Enterococci) are useful for screening of waters for the presence of fecal contamination, but are limited in revealing the presence of pathogens.

Table 16. Studies carried out or in progress by the United States Department of Agriculture, National Program 206 †

Location	Media §	Analytes	Waste Type	Observations
Georgia	SW, Soil	Bacteria	Poultry	Survival and transport of pathogens
North Carolina	SW	Nutrients, Bacteria	Swine	Advanced waste treatment system evaluation
	SW	Bacteria	Cattle	Runoff content of bacteria, vegetative treatment system
Virginia	SW	Viruses	Dairy	
Maryland	SW	*Cryptosporidium parvum*		Modeling, runoff, transport
Chesapeake	SW	Bacteria, Protozoa		
Illinois	SW	Nutrients, Bacteria		Integrated waste systems
Wisconsin	SW	Bacteria	Dairy	
California	GW	Nitrate, Bacteria	Dairy	Dairy lagoon water site
Idaho	SW	Nutrients, Bacteria	Swine, Poultry, Fish	Gases, PM2.5, management effects, percolation
Texas	SW	Bacteria, Protozoa	Cattle	Best Management Practice effects, method recovery efficiency

§ GW = Groundwater; SW = Surface water

Considering that microorganisms originating in animal waste represent a significant risk to people and animals, methods to reduce the microbial load of waste are important. There is a great need to develop manure management procedures that will reduce the load of microorganisms before waste is allowed to enter the open environment. Anaerobic digestion is one technique with promise to be cost neutral or beneficial due to the use of generated methane as a fuel source. Aerobic digestion is a net cost, but reduces odors and microorganisms. Composting reduces odors and microorganisms and produces a potentially salable product. Composting may be practical if markets can be developed. There are other approaches that generate activated carbon, pelletized fertilizers and other products. Combinations of waste management methods may also be used to reduce microorganism loads before waste disposal. Storage of wastes for six months has shown reduction of bacterial populations. Storage in concert with another management practice may be able to reduce loads of organisms to the point where application to land would pose little fecal load runoff potential. The important factor is that any treatment approach has to be economically feasible in comparison to existing manure management practices.

A key task to be completed is integration of the various government agency research activities. The benefit of integration will be to maximize efficiency of planned research by expanding the scope of work, avoiding duplication of effort, and sharing of information across interest groups. EPA is establishing a scientist to scientist level series of workgroups with the goal of integrating work across agencies. Other goals include enabling scientists to participate in larger projects than any individual could manage alone and prepare documents that are useful to producers at the farm level for implementation of environmentally sound practices. Collaboration with the USDA and Extension services will facilitate these goals.

11. Summary and Outstanding Issues

Bacteria, viruses, and parasites that can cause disease in humans are endemic in livestock animals. The confinement of animals into densely-populated feeding operations exacerbates the spread of disease and encourages the use of antimicrobial agents for both prophylaxis and to increase animal growth rates, resulting in the emergence of antimicrobial-resistant bacteria. These zoonotic pathogens may proliferate in confinement houses and are shed in animal wastes that, in most cases, are stored and eventually spread onto land. Exposure to antimicrobial-resistant bacteria and other zoonotic pathogens may occur through direct contact with livestock animals, breathing confinement house air, contact with insect and animal vectors, recreational or drinking waters contaminated with manure runoff or leaking manure storage pits, eating produce from manure fertilized fields, and secondary infection from exposed individuals. Several mechanisms are in place to prevent the spread of disease from livestock animals to humans and may include animal stocking techniques, animal waste treatment practices to destroy pathogens (such as composting and thermophilic anaerobic digestion), storage of animal manure to reduce pathogen concentrations prior to spreading, barriers (such as wetlands and buffer strips) to control runoff from manured fields, and surveillance of our nation's food and waters for pathogenic organisms. However, from reported literature, it is clear that exposure to zoonotic pathogens cause significant human suffering and economic losses in the billions of dollars annually due to lost productivity, treatment of disease, and beach closures. Because of the continuing human disease caused by zoonoses contaminating food and water resources in the U.S., we believe that the current environmental regulations and conventional animal manure management practices are inadequate for protection of human health and the environment.

The USEPA and other governmental entities including the USDA, USGS, and the CDC are actively working towards resolving the threat to human health and welfare posed by antimicrobial-resistant bacteria and other zoonotic pathogens that may be released into the environment from CAFOs. As can be seen in this review, the outstanding issues regarding the fate and transport of zoonotic pathogens are vast; addressing these issues will require the expertise of all of these agencies and the many disciplines they represent. Of particular concern is the synthesis of information generated in these studies into a comprehensive and usable package, so that resources can be pooled to arrive at a more complete and usable plan.

Much work is still needed to fully address issues surrounding the contamination of our environment and with antimicrobial-resistant bacteria and zoonotic pathogens originating from livestock animals. Based on our review, we recommend that the pathway forward involve not only value-added research, but also policy changes that are consistent with current limitations on the use of human waste biosolids as fertilizers.

11.1 General recommendations

Animal agriculture produces copious amounts of manure, most of which is stored untreated and spread onto land. Based on available manure management technologies, ensuring the safety of food crops and water resources will require active treatment practices that greatly reduce or eliminate pathogens in manures and other CAFO wastes prior to land application or discharge to natural waters. At present, animal manures applied to land as a fertilizer are not regulated in terms of pathogen reduction. This lack of regulation is at odds with requirements for the application of biosolids originating from human septage (USEPA, 2003). Consider:

- Even moderately-sized concentrated animal feed operations, such as a 2,500 dairy cattle operation, may produce as much manure as a city of 61,000 people. Serious fines for environmental pollution and lawsuits would result if a city of that size spread all of its sewage onto land without treatment.
- Animal manures and other animal wastes may contain high concentrations of pathogens, hormones, antimicrobials and other pharmaceutically active compounds, metals, nutrients, and other chemicals, similar to human sewage.
- Animal manures can be as much as 100 times more concentrated than human sewage, as human wastes are diluted with other domestic wastewaters prior to treatment.
- Because of their concentrated form, animal manures have a higher demand for oxygen, higher nutrient content, and higher concentration of pathogens than human septage on a per weight basis.
- Every year animals raised in CAFOs produce three times as much manure as humans in the U.S.

Regulatory bodies should carefully weigh the full costs associated with zoonotic disease, which are estimated to reach into the billions annually, when considering difficult decisions regarding the regulation of livestock animal wastes. Several cost effective options for animal waste treatment can be implemented at CAFO facilities that would reduce pathogens to safe levels prior to application as a fertilizer. The most effective and cost-efficient methods for achieving these ends may be composting or thermophilic anaerobic digestion with recovery of methane that can be used as a fuel. However, circumstances specific to each animal confinement facility would need to be considered when choosing appropriate manure treatment systems. These active treatment systems should be used in concert with management practices to reduce pollution of water bodies by treated manure fertilizers, such as vegetative filter strips, terraced landscapes, and constructed wetlands.

Of great concern is the continued use of antimicrobials in animal agriculture for growth promotion and prophylaxis. Many of the drugs used to promote growth in animal agriculture are the same as or very similar to human medicines, and result in the shedding of high concentrations of antimicrobial resistant bacteria that may infect humans and other animals. Antimicrobial resistant zoonotic pathogens are a serious threat to human health (Ghidán *et al.*, 2000; Cheng *et al.*, 2002; Travers and Barza, 2002), and billions of dollars are spent in the U.S. every year treating diseases resistant to antimicrobials and managing the spread of resistance in hospital environments. The benefits of growth promotion in livestock animals are certain, and at present, difficult to offset completely with market alternatives (Harper, 2004; Gill, 2005). However, a combination of education of owner/operators, alternative feed additives, and improved and more sanitary animal husbandry practices are promising for achieving this end (Gill, 2005). Regulatory agencies should fully weigh the costs and benefits of continued use of antimicrobial compounds in animal agriculture for growth promotion and consider the phased removal of these feed additives from the market in favor of alternative technologies. Tighter regulation of the use of antimicrobial compounds for prophylaxis should also be considered.

11.2 Recommendations for Future Research

Significant progress has been made to date to address the release and movement of microorganisms from CAFOs and fields fertilized with their manure byproducts. Research has ranged from bench studies on pathogen survival to investigations of specific management practices for impeding the movement of fecal indicator bacteria to receiving waters and specific surveys of pathogens and antimicrobial-resistant bacteria near CAFO facilities. Current research is exploring new and innovative ways to detect and quantify pathogens in soils, manures, and natural waters that are enabling more specific characterization of animal waste management practices and technologies performance. These techniques have also opened the door for development of improved monitoring and surveillance systems that may revolutionize the way we look at water quality. Some of these new technologies are progressing rapidly towards the end of being able to identify with great accuracy the source of pathogenic agents in recreational and drinking water resources that may cause disease. Other advances are being made in the development of cost efficient and reliable livestock animal waste treatment technologies that may ultimately reduce the burden of zoonotic disease in the U.S.

Although advances are being made, significant amounts of work are still required to fully address the issues surrounding antimicrobial resistant bacteria and other zoonotic pathogens from CAFO facilities. There is a need for fundamental information on specific etiological agents pertinent to their movement and inactivation in manures, soils and sediments, and natural waters. There remain questions as to what levels of these agents are acceptable in natural systems such that the risk of contracting disease upon accidental exposure is low. New models that can predict with accuracy the fate and transport of pathogens in the environment following the application of manure fertilizers to land are needed to identify potential control points to locate new operations safely and in a sustainable manner. In addition, integrated systems that can monitor our nation's water resources in real-time for threats that may be posed by zoonoses and other biological agents are needed to improve biosecurity. All of these research needs are integral to improving human health and welfare in the U.S., especially in areas of intensive livestock farming. The following is a top ten list of research needs to address the pathogen issue and reach this goal.

1. *There is a need for standardized methods of analysis for zoonotic pathogens in animal manure, soil and sediments, wastewater, recreational water, and drinking water.*

    Standard methods with the required sensitivity for recovering and enumerating pathogens at environmentally relevant concentrations in animal manures, soils, wastewaters, recreational water, and drinking water are sorely lacking, especially for hyper-endemic or emerging pathogens. These methods are needed to (a) identify the extent to which these agents are removed, inactivated, or persist in animal waste treatment processes and management systems at livestock operations, (b) determine the survival of these agents in manures, soils, sediments, and natural waters to improve our ability to predict their fate and transport in the environment, and (c) improve surveillance and biosecurity of our nation's recreational and drinking water resources.

2. *There is a need for rapid methods of analysis for pathogens in recreational and drinking water to improve surveillance and biosecurity of our nation's water resources.*

   Microbiological water quality surveillance in the U.S. relies on the detection of bacterial indicators of fecal pollution. Although epidemiologically related to gastrointestinal illness, these indicators do not fully describe the risks associated with recreational or drinking waters contaminated with some bacteria and most viruses and parasites. Furthermore, since conventional cultivation methods take 18-24 hours to yield a presumptive-positive result, a positive result today means that everyone drinking the water or swimming in it yesterday was exposed to unacceptable levels of fecal pollution.

   As such, there is a need to develop rapid and reliable methods for the detection of fecal bacterial indicators and overt pathogens in recreational and drinking waters. A tiered approach to rapid monitoring methods may be the most reasonable, starting with indicators and then adding pathogens as methods become available. It has been suggested that such technologies rely on nucleic acids analysis because the tests lend themselves to automation and are at present the most promising for rapid and specific quantitation of both fecal indicator organisms and viable microbial pathogens (Jothikumar *et al.*, 1998; Levin *et al.*, 2002; Straub and Chandler, 2003).

   Current technologies for rapid detection of the fecal bacterial indicators are being field tested against proven cultivation methods to develop guidelines for improving recreational water quality monitoring by the USEPA and CDC (USEPA, 2005). However, the near real-time detection of overt pathogens with very low infective doses, such as *E. coli* O157:H7, *Campylobacter jejuni*, and *Cryptosporidium* will require significant advances in technologies to concentrate these agents from large volumes of potentially dirty water. In particular, there is a need for effective and reliable sample concentration technologies capable of co-concentrating viruses, bacteria, and parasites into clean samples amenable to detection with nucleic acids technologies. At present, hollow fiber ultrafiltration systems may be the most promising to this end. However, the retention of a variety of pathogens from different waters by these filters needs testing and validation.

   Ultimately, the development of a unified and automated system for the detection of all waterborne pathogens is needed (Straub and Chandler, 2003). Hollow fiber ultrafiltration devices, renewable surface technologies for automated sample processing, and microarray technologies have shown promise as a basis of such a system (Chandler *et al.*, 2000a,b). However, such a system should be constructed in a way that it is simple, reliable, and technically less demanding than current nucleic acids technologies. The need for rapid pathogen detection technologies will remain a critical issue for biodefense where real-time identification of etiological agents may be imperative to protecting human health.

3. *There is a need for epidemiological data to establish regulatory guidelines for pathogens in manure, wastewater, recreational water, and drinking water.*

   Regulatory guidelines on the concentrations of pathogens in the manure, wastewater, recreational water, and drinking water protective of human health do not exist because (a) there is a lack epidemiological data to ascertain the risks of illness associated with exposure, and (b) there remain questions as to what level of risk is acceptable. There remains a need for epidemiological data to enable the identification of appropriate and safe limits of pathogens in manure, drinking water, recreational water, and in food. Based on surveillance of water and foodborne outbreaks in the U.S., priority should be given to *Salmonella* spp., *Campylobacter jejuni*, *E. coli* O157:H7, *Cryptosporidium*, *Giardia*, and viral agents such as swine hepatitis E virus.

4. *There is a need to identify inactivation kinetics of zoonotic pathogens in manures, soils, and environmental waters.*

   Relatively few studies are available describing the survival of zoonotic pathogens in environmental matrices, especially considering the broad range of properties of soils, manures, and waters that may potentially be contaminated. A significant limitation is the lack of information regarding the survival of antimicrobial-resistant bacteria in various *milieus*, including the persistence of phenotypic and genotypic antimicrobial-resistance traits. Most studies on the survival of pathogens have been carried out in the laboratory instead of *in-situ*, and only a few examined more than one environmental stressor simultaneously. Accurate information regarding the survival of pathogenic zoonoses and antimicrobial resistant bacteria is necessary for modeling their fate and transport from CAFOs.

   Based on these limitations, the following needs have been identified:

   - Comprehensive studies that examine the combined effect of several stressors simultaneously on the survival of zoonotic pathogens and antimicrobial-resistant bacteria in manures, soils, and surface water sediments, and natural waters are needed. Stressors that should be considered include:
     - Biological factors, such as antagonism, competition, and predation;
     - Physical factors, such as temperature, soils and sediment properties, and solar radiation;
     - Growth factors, such as pH and availability of nutrients.
   - There is a need to identify the effect of the retention of some pathogens on soils and sediments on survival in various matrices.
   - There is a need for small-scale studies to determine the concentration of antimicrobial compounds needed for an organism to maintain antibiotic resistance and the number of growth cycles that lead to the loss of the resistance trait.

5. *There is a need for fundamental research to characterize the transport of zoonotic pathogens over land, through soils and ground water, and in surface water bodies.*

   The movement of antimicrobial-resistant bacteria and other zoonotic pathogens from animal wastes through the environment is a complex issue. Research is needed to address significant data gaps regarding the properties of etiological agents that may affect their retention or mobilization in soils and stream bed sediments. In order to better address the transport of pathogens in the environment, several needs must be met, including:

   - Characterization of the properties of zoonotic pathogens that may affect their fate and transport in the environment, which, if understood, would allow them to be incorporated into existing hydrologic and geogaphical information systems (GIS)-based transport models.
   - Identification of the particle sizes with which zoonotic pathogens may be transported in the environment.
   - Identification of the potential effects of soil and sediment retention of some pathogens on overland transport and resuspension in stream bed sediments.
   - Verification that batch and column studies performed in the laboratory to determine pathogen fate and transport properties accurately describe field observations.

6. *There is a need for research to characterize the movement of antimicrobial-resistant bacteria and other pathogenic zoonoses into the environment following land application of animal manures with particular attention paid to the effects of hydrologic (rainfall) events.*

   Information is lacking regarding the concentrations of antimicrobial-resistant bacteria and zoonotic pathogens in the environments proximal to CAFOs and fields where their manures are applied. However, on a larger scale, significant microbial contamination in agricultural watersheds has been observed by the USEPA. Rainfall has been noted to increase concentrations of fecal indicator bacteria in agricultural watersheds, and much of the outbreaks of waterborne disease in the U.S. and Canada have been linked to heavy rainfall events.

   Surveillance of pathogens and antimicrobial resistant bacteria near several CAFOs with different confinement animals and manure management practices is needed to ascertain the potential pathways for pathogen transport from manured fields. Monitoring plans should also consider sampling at the sub-watershed and watershed scales. Field studies are needed to identify the role of drainage tiles and overland transport of pathogens to receiving waters during rainfall events. Continuous or event-triggered sampling devices should be used so that events are not missed. Samples should be taken following manure application and 24 to 48 hours after a substantial rainfall. Future studies should also consider management records on the use of antimicrobials on each specific farm that may be helpful to correlate farm practices with findings obtained through the studies.

7. *There is a need for continued research into methods for tracking fecal pollution in natural waters to its source.*

   Much of our nation's water resources are impaired due to high concentrations of fecal microorganisms. In many instances, the source(s) of fecal contamination are unclear. MST is an emerging technology that identifies the animal origin of fecal bacterial pollution. However, many caveats to the use of MST still exist, and much work is needed to improve these technologies for more widespread application. Some of the data gaps for the various methods include:

   - Poor survival of MST reference organisms in the environment may result in little or no detection, limiting the ability to identify the source of fecal contamination. Reference organisms need to be chosen so that they are useful at a distance from the potential source.
   - Variability in the survival of different phenotypes or genotypes of MST reference organisms in environmental matrices that may lead to divergence from host-specific fingerprints in source libraries need to be clearly defined. Limitations to interpretation of MST results dependent on these findings need to be documented.
   - Variability in transport and survival of the index organism(s) used to identify fecal pollution source(s) and pathogens of the same source that may lead to misidentification of the source of disease. Studies are needed to ascertain whether or not reference organisms are reliable indicators of pathogen transport. It may be that several reference organisms are needed to describe the full suite of pathogens that may contaminate water bodies.
   - Variability in the transport properties of different index organisms needs to be clearly defined to enable interpretation of MST results.
   - Advances in MST technology need to be made to reduce the time of analysis, the level of expertise required, and the cost. Host-specific molecular biomarkers offer the most promise for achieving this end, but significant advances in their development must be achieved before they are off-the shelf ready.
   - MST techniques need more field-scale testing to prove their utility in varied circumstances. Full-scale watershed type studies are needed to assess the potential of these technologies for future use.
   - There is a need for different levels of analytical methods to address microorganism tracking from simple indicators to methods for exact pathogen and source identification.
   - Additional research is needed in the area of spatial and temporal variability for library-independent MST methods.

8. *Fundamental studies on the efficacy of various manure management practices including uncertainty in their performance are needed.*

   Many management practices have been proven effective for reducing the discharge of stressors such as nutrients and sediment runoff to surface waters. However, the efficacy of different management practices for impeding the movement of zoonotic pathogens and antimicrobial-resistant bacteria to receiving waters following land application of animal manures remains uncertain. Based on studies using fecal indicator organisms, these practices may reduce the discharge of pathogenic microorganisms. However, the reductions associated with most practices are only on the order of 90-99%, a scant number considering that animal manures may contain billions to trillions of bacteria, viruses, and parasites per gram. Therefore, although specific management practices such as vegetative buffer strips will retain large fractions of microbial populations, they will not retain them well enough to protect receiving streams from contamination.

   There is a need to identify the performance of common barrier technologies such as infiltration basins, wetlands, and buffer strips for the retention and inactivation of pathogenic organisms. Studies should address retention in the context of factors related to the design of the systems such as size, slope, solids or hydraulic residence time, vegetation, undercutting by tile drainage, etc. Studies are also needed to address the impacts of rainfall on management practice performance. Of particular interest is exploration of a multibarrier approach versus single barrier BMPs.

   Aside from barrier technologies, there is a need to verify and field test manure treatment technologies like anaerobic digestion, not only for pathogen reduction, but also to identify the potential for fuel recovery. These technologies should be compared and contrasted to conventional manure storage technologies in terms of stressor reduction and cost. Vector attraction reduction and pathogen regrowth in treated materials should also be explored.

   Many of these questions are being addressed in the areas of public wastewater treatment and biosolids from public treatment works. Analogies for manure treatment and runoff barrier technologies for pathogens, as well as vector attraction reduction, may be drawn from the extensive pool of research available within the biosolids community. However, livestock animal wastes tend to be more concentrated than human sewage; thus, treatment solutions for human wastes need to be feild-tested for application at CAFOs. The most readily applicable technologies may be those for pathogen reduction in biosolids, but liquid separation and treatment may need to be performed prior to application of solids treatment technologies.

9. *Models are needed to better predict site-specific optimal manure treatment technologies and runoff management practices for pathogen and other stressor reductions*

   Better models of microbial behavior in the environment are needed to assist in planning for TMDL implementations and assessing plans for placement of new animal operations on the landscape. Of particular interest would be lifecycle assessment models capable of analyzing the effects of different treatment technologies and management practices. Models should be capable of predicting potential outcomes regarding not only pathogens but other stressors such as nutrients and pharmaceutically active compounds. Best possible treatment and management practice combinations, as well as sustainable livestock populations based on environmental and human health outcomes, should be predicted considering uncertainty in the performance of the various treatment technologies and management practices. Models that integrate the fate and transport of antimicrobial-resistant bacteria and zoonotic pathogens may be different from present models in many ways. The issues of multi-drug resistance, microbial reservoirs, horizontal gene transfer of resistance determinants, and the ranges of infectious doses resulting from various host characteristics are not part of current models for chemical risk assessment. These factors need to be integrated into CAFO models. Further, particular attention should be given to the relationship between pathogens and organic matter, sediments, and nutrients, particularly in terms of survival and facilitated transport during hydrologic (rainfall) events. These models will ultimately need to be proven at the sub-watershed and watershed scales.

10. *There is a need to improve the coordination of research activities and dissemination of technical information, methodologies, and new technologies between research scientists of the various agencies and to a vast array of end users such as educators, regulators, and CAFO owners and operators.*

    There is a confounding level of technical literature relevant to pathogens and livestock animals dating back more than 100 years, and literature propagates at an astounding rate. Researchers in the fields of engineering, microbiology, agronomy, epidemiology and infectious diseases, as well as the geological sciences and others, are conducting a wide variety of studies on pathogens and/or fecal bacteria relevant to CAFO issues. Interpreting the literature is difficult not only due to the massive amounts of technical information available, but also due to the diverse nature of these disciplines. As such, there remains a need for better integration of the various government research activities. The benefit of integration would include (a) pooling of resources, (b) broadening of technical expertise, (c) maximizing efficiency, (d) expanding the scope of work that can be performed, (e) avoiding duplication of effort, and (f) sharing information across interest groups. Without significant interdisciplinary integration and cooperation, the assimilation of available information into a comprehensive and meaningful form for the waste managers, educators, and regulators is unlikely.

Industrial Hog Operations in North Carolina
Disproportionately Impact African-Americans, Hispanics and American Indians

Steve Wing and Jill Johnston
Department of Epidemiology
The University of North Carolina at Chapel Hill
August 29, 2014

Summary

Background: In 2014, the North Carolina Department of Environment and Natural Resources (NC-DENR) issued a swine waste management general permit (the General Permit), which is expected to cover more than 2,000 industrial hog operations (IHOs). These facilities house animals in confinement, store their feces and urine in open pits, and apply the waste to surrounding fields. Air pollutants from the routine operation of confinement houses, cesspools, and waste sprayers affect nearby neighborhoods where they cause disruption of activities of daily living, stress, anxiety, mucous membrane irritation, respiratory conditions, reduced lung function, and acute blood pressure elevation. Prior studies showed that this industry disproportionately impacts people of color in NC, mostly African Americans.

Methods: We obtained records on the sizes and locations of permitted IHOs from NC-DENR and calculated the steady state live weight (SSLW) of hogs as an indicator of the amount of feces and urine produced at each IHO. We obtained block-level information on race and ethnicity from the 2010 census of the United States. We compared the proportions of people of color (POC), Blacks, Hispanics, and American Indians living within 3 miles of an IHO to the proportion of non-Hispanic Whites. We quantified relationships between race/ethnicity, presence of one or more IHOs, and the SSLW of IHOs, using Poisson regression and linear regression to adjust for rurality.

Results: Analyses based on a study area that excludes the state's five major cities and western counties that have no presence of this industry show that the proportion of POC living within 3 miles of an industrial hog operation is 1.52 times higher than the proportion of non-Hispanic Whites. The proportions of Blacks, Hispanics and American Indians living within 3 miles of an industrial hog operation are 1.54, 1.39 and 2.18 times higher, respectively, than the proportion of non-Hispanic Whites ($p<0.0001$). In census blocks with 80 or more percent people of color, the proportion of the population living within 3 miles of an industrial hog operation is 2.14 times higher than in blocks with no people of color. This excess increases to 3.30 times higher with adjustment for rurality. Adjusted for rurality, the SSLW of hogs within 3 miles of a census block increases, on average, 100,000, 64,000, 243,000, and 93,000 pounds for every 10 percent increase in POC, Black, Hispanic, and American Indian population ($p<0.0001$).

Conclusions: IHOs in NC disproportionately affect Black, Hispanic and American Indian residents. Although we did not examine poverty or wealth in this study, the results are consistent with previous research showing that NC's IHOs are relatively absent from low-poverty White communities. This spatial pattern is generally recognized as environmental racism.

Background

Swine production in North Carolina (NC) changed dramatically during the last decades of the 20th century. Between 1982 and 2006 the number of hog operations in the state declined precipitously while the hog population increased from approximately 2 to 10 million (Edwards and Driscoll 2009). Production became concentrated in eastern NC (Furuseth 1997).

Traditional NC producers raised small numbers of hogs, commonly fewer than 25, and hogs were one of several commercial crops on diversified farms (Edwards and Driscoll 2009). In contrast, industrial producers raise large numbers of hogs, often many thousands, in confinement houses that are designed to vent toxic gases and particles into the environment. Animal wastes are flushed into open cesspools and then sprayed on nearby fields. Pollutants emitted by IHOs include hydrogen sulfide, ammonia, a wide array of volatile organic compounds, and bioaerosols including endotoxins and other respiratory irritants (Cole et al. 2000) (Schiffman et al. 2001).

The negative impacts of particles and gases inside IHO confinements on worker health have been extensively described (Cole et al. 2000; Donham 1993; Donham et al. 1995; Donham et al. 2000; Donham 1990). Environmental pollutants from IHOs affect people who are more susceptible than workers due to young or old age, asthma or allergies, or other conditions. An extensive body of peer-reviewed scientific evidence shows that IHOs release contaminants into neighboring communities where they affect the health and quality of life of neighbors. Many of these studies have been conducted in NC. Hydrogen sulfide concentrations within 1.5 miles of IHOs in NC are associated with neighbors' ratings of hog odor and inability to engage in routine daily activities (Wing et al. 2008), increased stress and anxiety (Horton et al. 2009), irritation of the eyes, nose and throat, respiratory symptoms (Schinasi et al. 2011), and acute elevation of systolic blood pressure (Wing et al. 2013). A study of NC public middle school children who participated in an asthma survey, which was conducted by the NC Department of Health and Human Services, found that children attending schools within three miles of an IHO had more asthma-related symptoms, more doctor-diagnosed asthma, and more asthma-related medical visits than students who attended schools further away (Mirabelli et al. 2006). The same study reported a 23% higher prevalence of wheezing symptoms among children who attended schools where staff reported noticing livestock odor inside school buildings twice or more per month compared to children who attended schools where no livestock odor was reported (Mirabelli et al. 2006). Other studies in NC (Tajik et al. 2008) (Wing and Wolf 2000) (Bullers 2005) (Schiffman et al. 1995) and elsewhere (Donham et al. 2007) (Thu et al. 1997) (Radon et al. 2007) also document negative impacts of IHO air pollution on neighbors' health and quality of life.

Liquid contaminants from IHOs are released to the environment through leakage of animal waste storage pits, runoff from land application of liquid wastes, atmospheric deposition, and failure of the earthen walls of waste pits (Burkholder et al. 2007). Overflow of waste pits during heavy rain events results in massive spills of animal waste into neighboring communities and waterways. For example, in late September, 1999, 237 NC IHOs were located in flooded areas identified from satellite imagery provided by the NC Division of Emergency Management (Wing et al. 2002). Parasites, bacteria, viruses, nitrates, and other components of liquid IHO waste pose threats to human health (Burkholder et al. 2007; Cole et al. 2000).

Routine use of sub-therapeutic doses of antibiotics to promote weight gain of hogs promotes antibiotic resistance, making infections in humans more difficult to treat (Silbergeld et al. 2008). Airborne bacteria, including antibiotic resistant strains, have been isolated from IHO air emissions (Schulz et al. 2012) (Green et al. 2006) (Gibbs et al. 2006), and antibiotic resistant bacteria are associated with animal vectors near industrial animal operations, including flies (Graham et al. 2009), rodents (van de Giessen et al. 2009), and migratory geese that land on NC's IHO liquid waste pits (Cole et al. 2005). A recent medical records study from Pennsylvania shows that people living near IHO liquid waste application sites have elevated rates of infection with methicillin resistant *Staphylococcus aureus* (Casey et al. 2013). NC industrial livestock workers carry strains of *Staphylococcus aureus* that are associated with swine, including antibiotic resistant strains (Rinsky et al. 2013). These bacteria could be spread by liquid waste and airborne particles.

Using information from the United States Census of 1990 and locations of IHOs reported by the North Carolina Department of Environment and Natural Resources (NC-DENR) in 1998, we showed that the state's IHOs were disproportionately located in areas where more people of color (POC), primarily African Americans, live (Wing et al. 2000). We concluded that their disproportionate location in communities of color represented an environmental injustice. Since 1998 additional IHOs have obtained permission to operate and others are no longer in business. Additionally, between 1990 and 2010 the state's population size and spatial distribution changed due to births, deaths and migration. In this report we update our previous findings by evaluating whether IHOs operating under the general permit issued on March 7, 2014, will disproportionately impact POC, Blacks, Hispanics, and American Indians.

Materials and Methods

Lacking a list of the unique IHOs operating under the General Permit finalized in 2014, we used a list of all permitted industrial animal operations provided by NC-DENR on January 24, 2013 that we had prepared for prior research. First we excluded all non-swine operations from the list. Next we excluded swine operations with expired permits and permits with an allowable head count equal to zero. We also excluded permits that did not appear on a list of permitted animal operations published by DENR in January, 2014. We merged multiple permits issued for the same facilities to obtain a total head count for each operation. However the head count may be misleading as a measure of the pollution from each IHO because some facilities primarily house small pigs while others primarily house large hogs. We therefore calculated each facility's total steady state live weight (SSLW) using NC-DENR's formula based on the number and average weight of each growth stage of swine permitted at the facility. We interpret SSLW as a summary measure of the feces and urine produced by the swine of different growth stages at each facility.

Following the protocol provided in our previous study we excluded facilities operated by research institutions because they are subject to different location and management decisions than are commercial operations (Wing et al. 2000). Finally, we excluded facilities that do not hold a certificate of coverage to operate under the General Permit because they operate under individual permits or National Pollutant Discharge Elimination System general permits. The resulting facilities should closely approximate those expected to seek to continue operating under the renewed General Permit. The renewed General Permit takes effect on October 1, 2014, at which time we plan to update the list created for this research.

The vulnerability of people of any race/ethnicity to having polluting facilities nearby can be affected by the race and ethnicity of other people in their community. For example, African-Americans who live in areas primarily populated by non-Hispanic Whites have, generally, a lower susceptibility to being near polluting facilities than African-Americans who live in areas primarily populated by Hispanics or American Indians. We therefore conducted our primary analyses of disproportionate impact using the POC category. We also conducted analyses for specific racial/ethnic categories. We defined the following racial/ethnic categories: non-Hispanic White (non-Hispanics who identified as White and no other race), POC (all people not categorized as non-Hispanic white), Black (people who identified themselves as African-American or Black with or without any other race), Hispanic of any race, and American Indian (people who identified themselves as American Indian with or without any other race). We used block-level race/ethnicity-specific population counts from the US Census of 2010.

As large-scale agricultural facilities, IHOs are not located in major cities. Following the protocol adopted in our prior research, we defined a study area for our primary analyses that excluded census blocks in the five major metropolitan areas of NC (Charlotte, Winston Salem, Greensboro, Durham and Raleigh) as well as 19 western counties that neither have an IHO nor border a county that has an IHO. We conducted additional analyses for the entire state.

We considered residents of blocks to be affected by IHOs within three miles of the block centroid. Blocks were categorized as either having, or not having, an IHO within three miles. Additionally, we calculated the total permitted SSLW of hogs within three miles of the centroid of each block as a measure of the total potential influence of pollutants from nearby IHOs on the residents of the block.

As in our prior study, we also calculated the population density of each block, defined as the number of people per square mile. Population density is a measure of rurality, which is strongly related to the availability of land for agriculture and the price of land. Racial/ethnic groups in NC differ in their urban vs. rural residence, making them differentially susceptible to types of polluting facilities that locate in rural vs. urban locations. For example, a larger proportion of non-Hispanic Whites in NC live in remote rural areas than do Blacks, the racial comparison is affected not only by the susceptibility of Whites vs. Blacks to IHOs, but also by differences in whether they live in rural vs. urban areas. By adjusting for population density (or rurality), we compare racial vulnerability to IHOs for racial groups within each level of rurality. This adjustment is analogous to other statistical adjustments in epidemiology, as when the death rates of two countries are compared: even though death rates at every age may be higher in a poor than a rich country, the poor country may have a lower overall death rate simply because it has a younger age distribution. In that case, age-adjustment is used to compare mortality in the two countries just as we use density-adjustment to compare the proximity to IHOs in areas with different racial/ethnic make-up.

We used weighted Poisson regression to quantify relationships between race/ethnicity and the presence of one or more IHOs within three miles of a block. We used weighted linear regression to quantify relationships between race/ethnicity and the SSLW of hogs permitted within three miles of a block. We used census block populations as weights. In density-adjusted models we included variables for the natural log of population density raised to the first, second and third power. As in our prior analysis, this cubic model fit the data well and additional power terms added little to the model fit (Wing et al. 2000). For the two largest racial/ethnic groups other than non-Hispanic Whites, POC and Blacks, we categorized race/ethnicity in groups of blocks 20% in width compared to blocks with no POC using indicator variables. Due to smaller numbers in these categories we did not fit models with indicator variables for Hispanics and American Indians. We also considered the percent of population of each race/ethnicity as a continuous variable, estimating the added burden of IHOs for a 10% increase in the population.

This study involves neither random sampling nor randomization of exposure to IHOs, therefore statistical significance testing is inappropriate and confidence intervals do not correspond to the probability that the true values of measures of association are within the interval. However, the US-EPA considers statistical significance in its assessment of environmental racism. We therefore report p-values for differences in proportions of each racial/ethnic group within 3 miles of an IHO using t-tests. We report 95% confidence intervals (CIs) as measures of precision of the associations estimated from regression models. 95% CIs that exclude the null value (1.0 for ratios and 0.0 for differences) are commonly considered to be statistically significant at $p<0.05$.

Results

We estimate that 2,055 IHOs were operating under the General Permit in January 2014, and that they were permitted to house approximately 1.2 billion pounds of swine (Table 1). The 160 (7.7%) IHOs permitted to house between 20 and 100 thousand pounds accounted for only 1% of the total permitted SSLW. The 342 (17.2%) IHOs permitted to house between 1 and 10.2 million pounds accounted for 46.5% of the total.

Table 2 shows that there are over 6.5 million residents of the study area. Approximately 986,000 (15.1%) of these live in census blocks whose centroid is within 3 miles of an IHO that operates under the General Permit. This includes 602,380 non-Hispanic Whites and 383,522 POC. 13.1% of non-Hispanic Whites and 19.9% of POC in the study area live in blocks within 3 miles of an IHO.

Based on the study area population in Table 2, Table 3 shows ratios of percentage of POC living within 3 miles of an IHO compared to the percentage of non-Hispanic Whites living within 3 miles of an IHO. The percentage of POC living within 3 miles of an IHO is 1.52 times higher than the percentage of non-Hispanic Whites. The percentages of Blacks, Hispanics and American Indians living within 3 miles of an IHO are 1.54, 1.39 and 2.18 times higher, respectively, than non-Hispanic Whites. If residents of the study area had been randomized to live within 3 miles of an IHO, the probabilities of observing differences of these magnitudes or greater are less than 0.0001; the observed differences are considered to be highly statistically significant.

We calculated these same ratios based on the entire state population of 9,535,483. The percentages of POC, Blacks, Hispanics and American Indians living within 3 miles of an IHO are 1.38, 1.40, 1.26 and 2.39 times higher than the percentage of non-Hispanic Whites, respectively. These ratios are considered to be highly statistically significant.

Figure 2 shows the percent of people living within 3 miles of an IHO in relation to the percent of people of color in blocks. In areas with less than 20% POC, just over 10% of the population lives within 3 miles of an IHO. In areas with 60-80% POC, over 20% of the population lives so close to an IHO. In areas with more than 80% POC, more than a quarter of the population lives within 3 miles of an IHO.

Table 4 presents ratios of the percent of people living within 3 miles of an IHO in blocks with >0 to <20%, 20 to <40%, 40 to <60%, 60 to <80% and 80 to 100% POC compared to blocks with no POC. The total population in these categories ranges from 526,305 in blocks with 60 to <80% POC to 2,577,015 in blocks with >0 to <20% POC. Ratios are statistically significantly elevated for all areas with more than 40% POC with or without adjustment for rurality. Ratios on the right side of Table 4 are adjusted for rurality. These ratios increase with the percentage POC. The highest ratios occur in areas with more than 80% POC, where over three times as many people live near IHOs, adjusted for rurality, compared to areas with no POC. These excesses are considered to be highly statistically significant.

Table 5 shows the results of analyses for Blacks parallel results to in Table 4 for all POC. Although ratios are somewhat lower for Blacks than POC, the percent of people living within 3 miles of an IHO is statistically significantly elevated in all groups of blocks that are more than 40% Black, with or without adjustment for rurality. In areas that are 80% or more Black, twice as many people live within 3 miles of an IHO compared to areas with no Blacks, a disparity that increases to three times more with adjustment for rurality. These excesses are considered to be highly statistically significant.

Table 6 presents the increased percent of the population living within 3 miles of an IHO for each additional 10 percent of the population of POC, Blacks, Hispanics, and American Indians. This analysis is similar to the results in Tables 4 and 5, but rather than using categories, the relationship between race/ethnicity and proximity to IHOs is modelled as a linear function. For every ten percent increase in POC, the proportion of people residing within 3 miles of an IHO increases, on average, by 10.7%. These values are 9.4, 8.5, and 16.2 for Blacks, Hispanics, and American Indians, respectively. Adjusting for rurality, 14.8% more people reside within 3 miles of an IHO for each additional ten percent POC. Adjusted values are 13.0, 16.3 and 11.8 for Blacks, Hispanics and American Indians, respectively. These linear relationships between race/ethnicity and living near IHOs are considered to be highly statistically significant.

Table 7 shows the difference in SSLW of hogs within 3 miles of residents of blocks with >0 to <20%, 20 to <40%, 40 to <60%, 60 to <80% and 80 to 100% POC compared to blocks with no POC. Blocks in categories with more than 20% POC have, on average, between 177 and 510 thousand pounds more hogs within 3 miles than blocks with no POC. Adjusting for population density, blocks with more than 60 percent POC have, on average, more than three-quarters of a million pounds more hogs permitted within 3 miles than areas with no POC. These excesses are considered to be highly statistically significant.

Table 8 presents parallel results for percentage Black population. As for POC, areas with more than 20% Black residents have an excess SSLW of hogs compared to areas with no Black residents, and differences are greater with adjustment for rurality. Adjusted for population density, blocks with more than 40% Black residents have between 493,000 and 620,000 more pounds of hogs within 3 miles than areas with no Black residents. These excesses are considered to be highly statistically significant.

Table 9 provides the average additional SSLW of hogs permitted in areas with POC for each percent increase in specific racial/ethnic categories. Adjusted for population density, the permitted SSLW of hogs within 3 miles of blocks increases 100, 64, 242, and 92 thousand pounds for each ten percent increase in POC, Black, Hispanic, and American Indian population, respectively. These linear relationships between race/ethnicity and SSLW are considered to be highly statistically significant.

Figure 3 depicts the data analyzed above. Each dot represents an IHO that was operating under the General Permit in 2014. IHOs are concentrated in NC's Coastal Plain Region, between the Piedmont and Tidewater. The red areas of Figure 3 indicate that this region has more people of color than other parts of the study area.

Conclusion

IHOs operating under the NC-DENR General Permit in 2014 are disproportionately located near communities of color. The disparities are considered to be highly statistically significant for Blacks, Hispanics, American Indians, and all POC. IHOs pollute local ground and surface water. They routinely emit air pollutants that negatively impact the quality of life and health of nearby residents. In addition to their well-documented effects on physical, mental and social well-being, residents of areas with a high density of IHOs, and especially residents of color, have been subjected to intimidation including threats of legal action, violence, and job loss (Wing 2002). The industry's close ties with local and state government officials help it to avoid regulation that could protect neighbors, and creates barriers to democracy in rural communities of color (Thu 2001, 2003). These discriminatory impacts could be reduced by decreasing the density of production and use of technologies that prevent releases of pollutants.

Short Communication

Terra incognita: The unknown risks to environmental quality posed by the spatial distribution and abundance of concentrated animal feeding operations

Katherine L. Martin [a,b,*], Ryan E. Emanuel [a,b], James M. Vose [c]

[a] Department of Forestry and Environmental Resources, North Carolina State University, United States
[b] Center for Geospatial Analytics, North Carolina State University, United States
[c] Center for Integrated Forest Science, USDA Forest Service Southern Research Station, United States

HIGHLIGHTS

- Environmental risk assessments of CAFOs are complicated by a lack of spatial data.
- North Carolina CAFOs are concentrated in the Coastal Plain, subject to large storms.
- 19% of CAFO points (1262) across the state are within 100 m of streams.
- Data gaps prohibit landscape modeling of impacts under changing conditions.

ABSTRACT

Concentrated animal feeding operations (CAFOs) pose wide ranging environmental risks to many parts of the US and across the globe, but datasets for CAFO risk assessments are not readily available. Within the United States, some of the greatest concentrations of CAFOs occur in North Carolina. It is also one of the only states with publicly accessible location data for classes of CAFOs that are required to obtain water quality permits from the U.S. Environmental Protection Agency (EPA); however, there are no public data sources for the large number of CAFOs that do not require EPA water quality permits. We combined public records of CAFO locations with data collected in North Carolina by the Waterkeeper and Riverkeeper Alliances to examine the distribution of both permitted and non-permitted CAFOs across the state. Over half (55%) of the state's 6646 CAFOs are located in the Coastal Plain, a low-lying region vulnerable to flooding associated with regular cyclonic and convective storms. We identified 19% of CAFOs ≤ 100 m of the nearest stream, and some as close as 15 m to the nearest stream, a common riparian buffer width for water quality management. Future climate scenarios suggest large storm events are expected to become increasingly extreme, and dry interstorm periods could lengthen. Such extremes could exacerbate the environmental impacts of CAFOs. Understanding the potential impacts of CAFO agroecosystems will require remote sensing to identify CAFOs, fieldwork to determine the extent of environmental footprints, and modeling to identify thresholds that determine environmental risk under changing conditions.

1. Introduction

Beginning in the mid twentieth century, there was a significant shift in US agriculture toward concentrated animal feeding operations, or CAFOs (Mallin, 2000). The transition from small, family farms to consolidated operations began in the poultry industry during the 1950s, and the model was adopted by swine farmers in the Midwest during the 1970s and 80s. The trend of increasing CAFOs reached the southeastern US in the late 1980s (Mallin, 2000). As a result, North Carolina experienced a nearly four-fold increase in swine inventory from 1975 to 2000 (Yang et al., 2016). Poultry production has increased in North Carolina during the same approximate time period, and the state has been one of the top poultry producers in the United States (Yang et al., 2016). The state Department of Environmental Quality estimated that from 1992 to 2014, poultry inventory increased where it is most concentrated (16% increase Yadkin-Pee Dee River basin, 9% increase Cape Fear River basin), and expanded rapidly in new areas of the state (393% increase Lumber River basin, 331% increase Broad River basin) (Patt, 2017). Although CAFOs provide a rapid and profitable way to provide food to a growing human population, they present significant risks to human health and environmental quality (Burkholder et al., 2007; Greger and Koneswaran, 2010; Mallin et al., 2015). Due to the high volumes of animal waste produced, CAFOs have high potential to contribute to soil, air, and water pollution, posing health risks to nearby communities (Burkholder et al., 2007; Donham et al., 2007; Greger and Koneswaran, 2010; Nicole, 2013). These operations tend to be spatially clustered in areas with environmental regulations and zoning requirements that favor industrial agriculture, particularly the southeastern US (Mallin, 2000) and in rural, impoverished, minority communities (Emanuel, 2018; Nicole, 2013; Wing et al., 2002).

Understanding the impacts of CAFOs and developing and implementing best management practices to mitigate impacts, requires fine-scale spatial data on CAFO locations. Existing research on the spatial distribution of CAFOs and potential impacts to environmental and human health have been conducted at relatively large spatial scales, such as counties (Yang et al., 2016) or watersheds (Harden, 2015). County level agricultural statistics such as the total number of animals housed are available from USDA (https://www.nass.usda.gov/). However, county-scale assessments and similar large-scale studies are not aligned with many ecological processes, and thus are limited in their ability to evaluate the potential impacts of CAFOs on nutrient cycling and water resources at scales that are most appropriate for improving management practices. Data are not publicly or readily available at finer spatial scales or scales more aligned with ecological processes, such as watersheds.

Recognizing the potential environmental and human health risks of CAFOS, some federally mandated best management practices have been developed and implemented. Large CAFOs that meet the EPA definition of >1000 animal units using a liquid waste disposal system are recognized as point sources of pollution and thus, a water quality permit is required (hereafter, permitted CAFOs). Liquid waste disposal is primarily used in swine, egg-producing poultry operations, and some cattle operations. The EPA considers an animal unit to be the equivalent of 1000 pounds of live weight, and large CAFOs are defined as having a minimum of 1000 head of beef cattle, 2500 swine, or 125,000 broiler chickens. The site must also house confined animals for at least 45 days a year and not sustain vegetation during the normal growing season over any portion of the lot to meet the regulatory CAFO definition. CAFO water quality permits regulate waste lagoons, from which liquid waste is generally transferred to a spray field, often of Bermuda grass (Mallin et al., 2015). EPA permitted CAFOs also require Comprehensive Nutrient Management Plans that detail feed, manure, and land management. States can add requirements to permits; for example, all CAFOS are inspected annually in North Carolina. As long as farms maintain a nutrient management plan, spray fields are not regulated by the water quality permit (Centner and Feitshans, 2006). Therefore, the locations or extents of spray fields associated with permitted CAFOs are generally unknown (Patt, 2017). The regulatory assumption is that nutrients and other contaminants from spray fields will remain on site, although this is not always the case (Wing et al., 2002). The environmental risk posed by spray fields is likely underestimated because impacts on agricultural runoff, groundwater recharge, or dispersal of airborne substances cannot be assessed without additional data. Further, public perceptions might not include farmland and spray fields as potential sources of CAFO impacts, resulting in an underestimate of the full risks to their communities posed by this form of industrial agriculture.

Farms with <1000 animal units and CAFOs without liquid waste disposal systems are not regulated in the same way as larger, permitted operations (hereafter, non-permitted CAFOs). Most poultry operations and some cattle operations generate dry litter waste and are thus not required to have water quality permits. In North Carolina, the state Department of Environmental Quality estimates that over 96% of poultry and over 88% of cattle operations use dry waste disposal (Patt, 2017). Waste from these operations is commonly spread on fields as fertilizer, often after transport far from the source farm, complicating the geography of the environmental impact (Patt, 2017).

Our goal was to identify the distribution of potential CAFO risk in a region with high CAFO concentrations as a first step toward improving the ability to evaluate and project the footprint of CAFO land use on environmental quality, including the export of nutrients, microbes, pathogens, and pollutants throughout surface water, ground water, the atmosphere and the terrestrial system. This assessment is also a first step toward assessing the effectiveness of mitigation practices. In some US states, locations of permitted CAFOs are publicly available. For example, an online search identified that Wisconsin, Michigan, Missouri, and North Carolina have publicly available, spatial datasets of permitted CAFOs; however, public records or datasets on the spatial locations are not available for non-permitted CAFOs. In some states, such as North Carolina, private nonprofits (e.g., Waterkeeper and Riverkeeper Alliances) have collected data on non-permitted CAFO locations. As location data are available for both permitted and non-permitted CAFOs, and because of the proliferation of CAFOs throughout the state, North Carolina provides an excellent case study to examine the spatial distribution of CAFOs.

We determined how CAFOs were distributed spatially among and within watersheds in North Carolina. We also evaluated the predominant NLCD land cover classifications surrounding CAFOs. In the United States, the National Land Cover Database (NLCD) is a publicly available dataset that aims to provide information necessary to assess ecosystem health and facilitate nutrient modeling, land use planning, and the development of best land management practices (BMPs) (Homer et al., 2015). The NLCD is scaled to at a 30-m resolution grid and updated every 5 years. Watershed models frequently use NLCD data to inform hydrologic simulations by assuming relationships between land cover and nutrient loading rates, infiltration capacities, or other factors that influence water availability and quality (Karcher et al., 2013). NLCD data layers are considered the most comprehensive, publicly available, datasets of land cover. Previous studies (Burkholder et al., 2007; Rothenberger et al., 2009) have identified the NLCD category “hay/pasture” as animal agriculture and thus, a proxy to identify CAFO locations; however, the EPA defines CAFOs as areas that do not produce crops, forage, or other vegetation. We tested whether CAFO locations are consistently categorized this way or whether they fall into other NLCD categories that are not typically associated with the water quality footprints of CAFOs.

2. Methods

We collected data on permitted CAFO locations from the North Carolina Department of Environmental Quality, which maintains a publicly available spatial dataset (https://deq.nc.gov/cafo-map). Spatial point data for non-permitted CAFOs were shared by the Waterkeeper and Riverkeeper Alliances who created the dataset by inspecting satellite imagery in Google Earth. In the imagery, large, rectangular barns used in poultry operations were identified; therefore, this dataset would not include dry waste cattle operations. We also assume that identification of the distinct geometry of a large, rectangular barn several times longer than its width, or sets of such barns, without manure lagoons is an accurate representation of a non-permitted CAFO. From the dataset, we independently verified 800 randomly selected sites (approx. 20%) using Google Earth Pro imagery set to December 2016, in accordance with the timing of the Riverkeeper assessment. We found that 710 (88.8%) of the points were within the footprint of the facility (on barns or within groupings of barns) and an additional 10.5% were and average of 24.3 m from the facility footprint, less than the width of one NLCD pixel. We found only two points (0.3%) not located adjacent to a farm and three points (0.4%) where barns had been removed but were present in imagery within the previous 2–5 years.

We used the National Watershed Boundary dataset (http://datagateway.nrcs.usda.gov/) to determine the distribution of both permitted and non-permitted CAFOs among major river basins. The National Hydrography Dataset (NHD) (U.S. Geological Survey, 2013) was used to determine the straight-line distance between CAFO points and the nearest stream channel. Then, using the most recent NLCD, 2011, we examined the distribution of land cover classification of CAFO sites.

We determined the land cover at CAFO points by taking the modal (most frequent) land cover from the 2011 NLCD layer within a 50-m buffer of each CAFO point. NLCD data for North Carolina were downloaded from the USGS National Map data platform (TNM Download V1.0: https://viewer.nationalmap.gov/basic/). The NCLD includes 16 different land cover categories derived from Landsat imagery (Homer et al., 2015). The two primary categories for agricultural land cover are cultivated crops, and hay/pasture. The cultivated crops category is defined as actively tilled land or land where annual or perennial crops represent at least 20% of the total vegetation (Homer et al., 2015). The hay/pasture land cover category is defined as areas with at least 20% coverage by grasses or legumes. Some (Burkholder et al., 2007; Rothenberger et al., 2009) categorize hay/pasture as animal agriculture, although the EPA defines CAFOs as areas that do not produce vegetation.

3. Results

3.1. Spatial distribution of CAFOs

North Carolina had a total of 6646 CAFOs as of 2015, including 2679 permitted CAFOs (40%) and 3967 non-permitted CAFOs (60%). Permitted CAFOs were primarily for swine (87%) with a few cattle operations (10%) and few egg producing poultry operations (1%) or other types of operations (2%). Permitted CAFOS are concentrated in the Coastal Plain physiographic region of southeastern North Carolina (2241/2679, 84%, Fig. 1). Non-permitted CAFOS are distributed primarily across the Piedmont (62%) and Coastal Plain (36%).

Half of the permitted CAFOs and 28% of the non-permitted CAFOS were located in the Cape Fear River basin, which is a large (23,735 km^2) basin that drains 18% of the state. Within the Cape Fear, CAFOs are concentrated heavily within the Black River and Northeast Cape Fear River sub-watersheds. Together, the two sub-watersheds drain only 6% of the state land area, but they contain 43% of the state's permitted CAFOs. The Upper Yadkin basin covers only 5% of the state

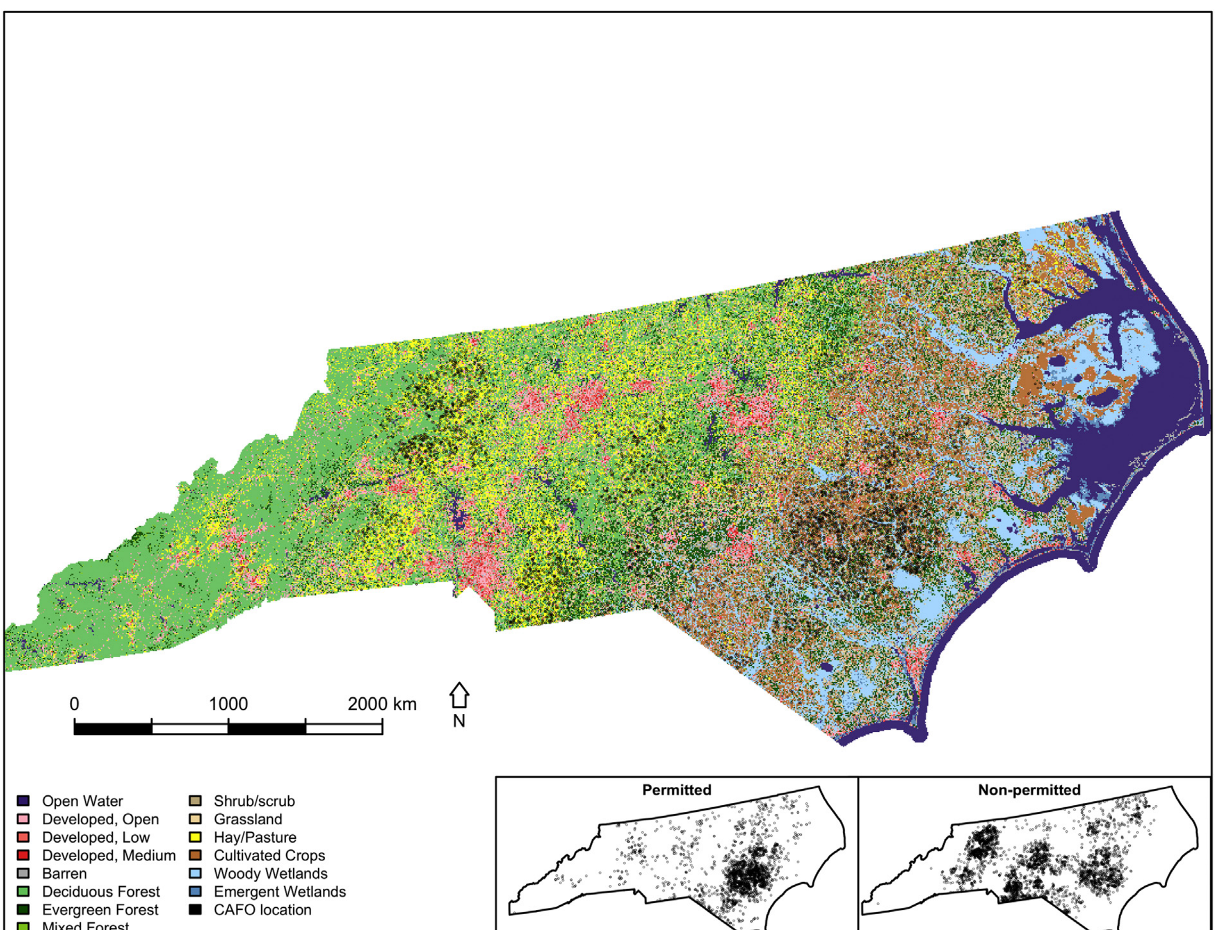

Fig. 1. Locations of CAFOs throughout the NLCD land cover classification of North Carolina.

land area but contains the highest concentration of non-permitted CAFOS, at 11% or 437 CAFOs. The concentration of CAFOs suggests that certain parts of the state, namely sub-watersheds of the Cape Fear and Yadkin River basins, are at higher risk of water quality degradation and other environmental impacts (Fig. 2).

Statewide, half of CAFOs are located within 203 m of a stream (205 m for permitted, 202 m for non-permitted, Fig. 3). We identified 1189 CAFOs (19%) within 100 m of the nearest stream. Of these operations, 67 permitted and 38 non-permitted CAFOs were less than ~15 m (50 ft) from a stream, which is the North Carolina State forestry recommended forest riparian buffer width for perennial water bodies (http://www.ncforestservice.gov/water_quality/bmp_manual.htm). (Aside from forestry, riparian buffer recommendations or regulations vary by watershed within the state). When analyzed by watershed rather than by CAFO type, there was some variability in the median distance to the stream (Fig. 4). Not only does the Northeast Cape Fear watershed contain a high CAFO concentration, but the median distance to a stream was 97 m, and 24 CAFOs were within the 15 m of streams.

3.2. NLCD land cover classification of CAFOs

Previous studies on the environmental impacts of CAFO land use have used the NCLD hay/pasture category is used as a proxy for animal agriculture and CAFO locations (Burkholder et al., 2007; Rothenberger et al., 2009). In our analysis, only 13% of permitted and 42% of non-permitted CAFOs were categorized as hay/pasture. We found that CAFO locations were frequently classified by the NLCD as cultivated crops, including 57% of permitted and 35% of non-permitted CAFOs. Considering both hay/pasture and cultivated cropland, 70% of permitted CAFOs and 77% of non-permitted CAFOs were characterized as an agricultural land cover type by the NLCD.

The remaining CAFOs were primarily classified as natural ecosystems. Thirteen percent of permitted CAFOs and 8% of non-permitted CAFOs were classified as natural terrestrial ecosystems (forest, scrub/shrub, or grassland). An additional 14% of permitted CAFOs and <1% of non-permitted CAFOs were classified as aquatic ecosystems (wetland or open water). Overall, 27% of permitted CAFOs and 8% of non-permitted CAFOs were classified as a natural land cover type by the NLCD. Permitted CAFOs were classified as developed land 3% of the time, but the rate for non-permitted CAFOs was much higher, at 12%. A small number of each CAFO type was classified as barren land by the NLCD (<1%permitted, and 1% non-permitted).

4. Discussion

Proliferation of CAFOs has significantly altered nutrient cycling in the United States (Robertson et al., 2013; Yang et al., 2016). From 1930 to 2012, Yang et al. (2016) identified manure loading increases of 46% for nitrogen and 92% for phosphorus. These increases were spatially clustered as CAFOs proliferated, concentrating manure nutrients in regions including the southeastern US and western Mississippi River basin. North Carolina produces the highest concentration of manure per acre of farmland in the country, (U.S. Enviornmental Protection Agency, 2013), and Yang et al. (2016) estimate manure N and P increased >70% across the state from 1930 to 2012. While this suggests nutrient loading is a spatially clustered environmental risk, the pathways these nutrients and associated manure pollutants (antibiotics, pathogens) take through the terrestrial, aquatic, and atmospheric systems are not well quantified. In a study of small (3.1–45.3 km^2) agricultural watersheds in eastern North Carolina, Harden (2015) found that the presence of CAFOs was often associated with degraded surface water quality. Such studies suggest the need for larger scale studies that

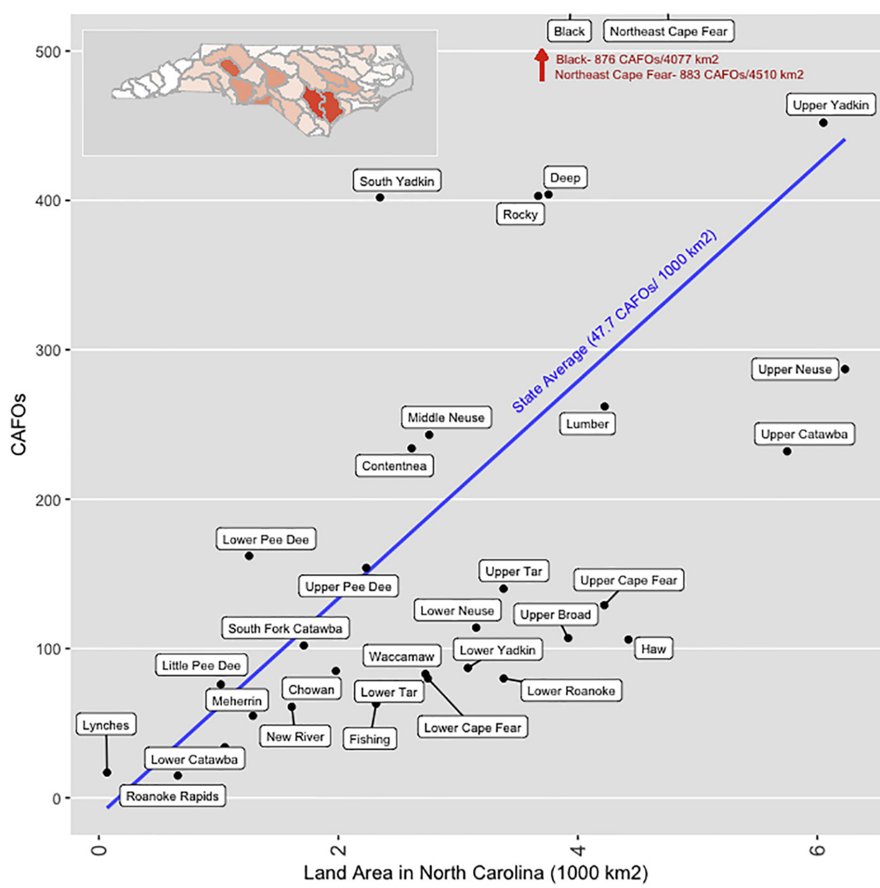

Fig. 2. CAFO density across North Carolina Watersheds. Boundaries are Hydrologic Unit Code (HUC) 8 boundaries designated by the National Hydrography Dataset. Inset map indicates increasingly concentrated CAFO density with darker colors.

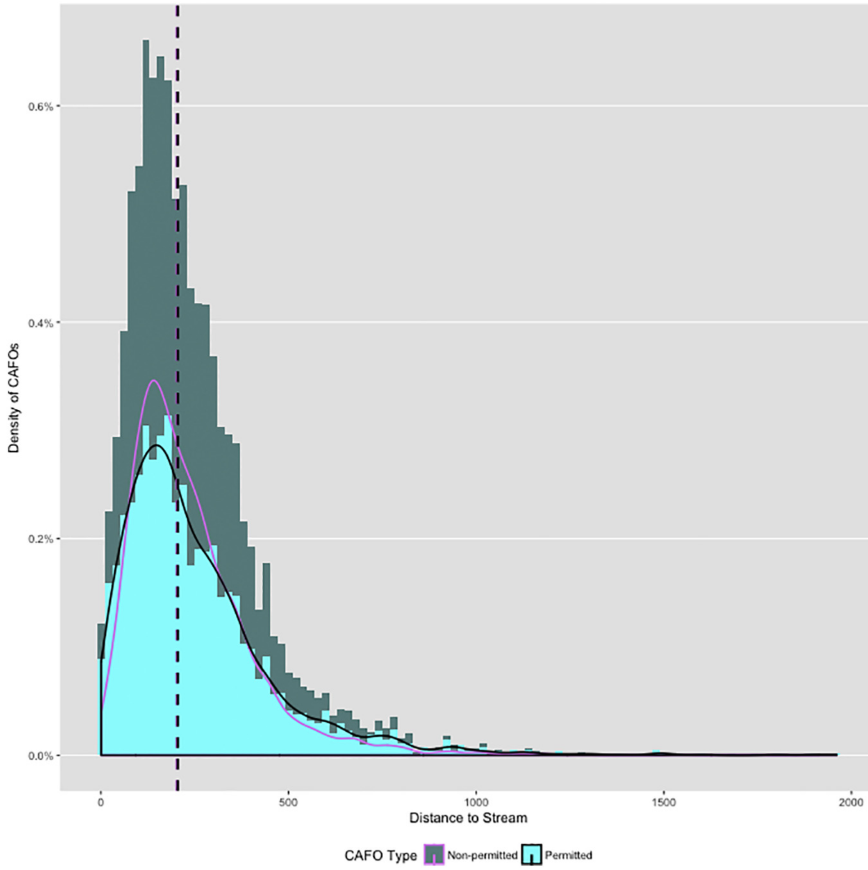

Fig. 3. Distribution of CAFO spatial data points to the nearest stream identified in the NHD database.

assess CAFOs at variable distances to the stream and in multiple land cover types in order to develop and implement BMPs that mitigate environmental impacts.

Our data indicate half of the 6646 CAFO points in the state of North Carolina are within at least 200 m of the nearest stream, and some are within 15 m; therefore, manure-based pollutants may pose a risk to water quality. The magnitude of the risk is not clear, particularly as the location of the points may vary within operations and the overall size of individual operations is not currently quantified. Our analysis included an implicit assumption that the point data are unbiased estimates of facility centroids, but does not include any analysis on the size of operations, which varies and was not available. Much of the data on individual permitted operations are protected as private in the state of North Carolina (Patt, 2017). Non-permitted operations in our dataset were identified using imagery and points are located on barns or within groups of barns, but the number of barns vary for each operation.

Landscape scale studies of the current environmental and human health risks posed by CAFOs would provide the foundation to understand and mitigate impacts in the context of global change. CAFO air quality impacts are known to pose human health risks, causing effects ranging from respiratory symptoms, headaches, nausea, eye irritation (Greger and Koneswaran, 2010; Heederik et al., 2007; Ogneva-Himmelberger et al., 2015; Schiffman et al., 2005). Climate change may exacerbate air quality-related human health risks associated with CAFOs (Fran et al., 2016; Pachauri et al., 2014). Livestock farming emits ammonium (NH_3) and nitrogen oxides (NO_x), which contribute to the formation of particulate matter and tropospheric ozone (Leip et al., 2015), both of which are expected to be problematic under climate change scenarios (Fran et al., 2016). There is a high level of confidence that extreme heat events will increase across the Southeast and that precipitation events will become more extreme. At the same time, tropical cyclones will include heavier precipitation, and likely be more intense (Carter et al., 2014; O'Gorman and Schneider, 2009; Pachauri et al., 2014; Robertson et al., 2013; Wuebbles et al., 2017). Further, regional water stress is expected to increase due to the combination of declining water yields and increasing demand from a rapidly expanding population (Carter et al., 2014; Emanuel, 2018; McNulty

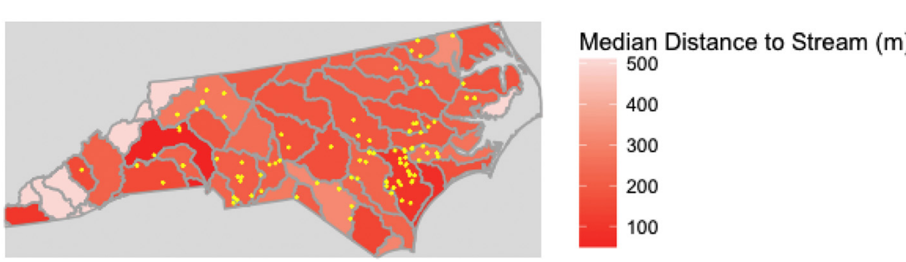

Fig. 4. HUC 8 watersheds coded by median distance between CAFO spatial data points and the nearest stream identified in the NHD database. Points indicate CAFO spatial data points within 15 m (50 ft) of streams, a commonly used riparian buffer distance.

et al., 2013; Sun et al., 2008). To minimize the environmental impacts of CAFOs under increasingly an increasingly extreme climate future, an increased understanding of their distinct environmental impacts is required, including impacts of agricultural stormwater runoff from CAFO barns, lagoons, and waste fields.

In North Carolina, CAFOs are concentrated in the Coastal Plain (Fig. 1), which is particularly vulnerable to catastrophic flooding following hurricanes (Mallin et al., 2002). Since 1990, 15 named tropical cyclones have made landfall in coastal North Carolina and an addition 20 have affected the state without a direct hit. Some of these storms have resulted in flooding and breaching of swine waste lagoons, particularly in the Northeast Cape Fear watershed (Fig. 2), which has one of the highest concentrations of CAFOs in the country (Mallin et al., 2002) and our data indicate many of these CAFOs are very near streams. Mallin et al. (2002) estimated that over 10% of permitted CAFOs were within the area inundated by Hurricane Fran in 1996.

Recognition of the environmental risk posed by CAFOs prompted a moratorium on new or expanding swine operations in 1997, following Hurricane Fran, and this moratorium was made permanent in 2007 (McDonald, 2016). During the most recent tropical cyclone, Hurricane Matthew (October 7–9, 2016), rainfall totals exceeded 38 cm in portions of Eastern North Carolina and the best information available suggests 14 industrial scale swine and poultry operations were flooded, with only two manure lagoons reported breached (McDonald, 2016; Musser et al., 2017). Animal waste contains high concentrations of nutrients as well as antibiotic and pharmaceutical contaminants (Burkholder et al., 2007). Recently, low levels of antimicrobial resistance have been detected in enteric bacteria collected from surface and ground water monitoring sites near CAFOs in the North Carolina Coastal Plain (Casanova and Sobsey, 2016). Catastrophic flooding associated with hurricanes and tropical storms can distribute these and other contaminants far downstream. Therefore, it is important to be able to model the impact of the entire operation, including spray fields that may be flooded or continue to operate during periods of saturated soil (Wing et al., 2002). Substantial data gaps concerning the spatial distribution and size of CAFOs limit the development of projections and other research projects to evaluate the potential impacts of CAFOs associated with catastrophic flooding. Such flooding not only affects surface water quality but poses risk to the large number of residents who depend on private groundwater wells for drinking water (Gibson and Pieper, 2017; Wing et al., 2002). It is possible that the moratorium on swine operations provided some mitigation or at least stabilized the risk. However, there are not sufficient data to determine the impacts of a stable number of swine operations and expanding poultry operations (Patt, 2017). Beyond flood events, long term monitoring is also needed, as animal waste lagoons can leak nutrients into soils and groundwater, reaching problematic levels gradually (Huffman and Westerman, 1995; Mallin, 2000; Ritter and Chirnside, 1990).

Given the widespread use of NLCD data as a spatial proxy for nutrient loading and other water quality parameterizations in environmental models(Almasri and Kaluarachchi, 2007; Karcher et al., 2013; Lehning et al., 2002; Nejadhashemi et al., 2011; Tran et al., 2010), the rate at which CAFOS are considered as natural systems by the NLCD is concerning. Forests and grasslands absorb nutrients and dampen hydrologic extremes by allowing for water percolation into soils, which are not functions provided by CAFOs. Even more than forests, the classification of CAFOs as wetlands in the NLCD is a significant concern for efforts to understand landscape scale nutrient pathways.

Wetlands concentrate and retain excess nutrients, sediments, and other contaminants associated with human activity, and wetland biogeochemical processes such as denitrification and adsorption can transform or sequester potential water contaminants (Zedler and Kercher, 2005). In some ways, CAFOs function as opposites of wetlands; they produce excess nutrients in the form of animal waste, and they often disperse these contaminants over wide areas using wastewater irrigation (Burkholder et al., 2007). Although only 12% of CAFOs in North Carolina are classified as wetlands by the NLCD, these operations could have outsized impacts on water quality in aquatic ecosystems.

5. Conclusions

In the US, there are approximately 450,000 CAFOs, and this form of industrialized agriculture is common in Europe and increasingly being adopted globally (Mallin et al., 2015). A growing body of work highlights tradeoffs between CAFO production and risks to the environment and human health (Burkholder et al., 2007; Donham et al., 2007; Greger and Koneswaran, 2010; Heederik et al., 2007; Mallin, 2000; Mallin and Corbett, 2006; Mallin et al., 2015; Nicole, 2013). However, a full understanding of both the risks and mitigation practices cannot be achieved without finer scale information about this emerging land use type. To this end, we encourage the development of tools and procedures to identify and incorporate CAFOs as a distinct land cover type within landscape datasets such as the NLCD.

The NLCD is produced by the Multi-Resolution Land Characteristics Consortium, a federal interagency organization with missions in science and environmental quality management issues related to land use and land cover https://www.mrlc.gov/about.php. The consortium has taken an adaptive approach since the original NLCD product in 1992, continually updated methods and datasets to improve its representation of land cover. The emergence and expansion of industrial agriculture since 1992, the large size of individual CAFO sheds compared to NLCD pixels, and the distinct waste footprints of these operations all point toward CAFOs as a land cover category that could be incorporated into NLCD. For this to happen, we suggest first steps: 1. Remote sensing studies to identify the spectral signatures of CAFO structures, feedlots, waste lagoons, and wastewater spray fields 2. Field studies to identify the diffusive waste footprints of CAFOs and determine whether there are differences between CAFO type (i.e., swine, poultry, beef) or management techniques to delineate the boundaries of CAFO agroecosystem footprints. These steps can help researchers, managers, and decision-makers move forward with watershed and regional studies of potential CAFO impacts under current conditions as well as scenarios of potential future climate.

Acknowledgements

The authors acknowledge the Waterkeeper and Riverkeeper Networks for sharing their spatial data on non-permitted CAFOs. This study grew from a conversation between authors and did not receive any external funding.

BURLEIGH DODDS SERIES IN AGRICULTURAL SCIENCE

Reducing greenhouse gas emissions from livestock production

Edited by Dr Richard Baines, Royal Agricultural University, UK

burleigh dodds SCIENCE PUBLISHING

Reducing greenhouse gas emissions from livestock production

It is widely recognised that agriculture is a significant contributor to global warming and climate change. Agriculture needs to reduce its environmental impact and adapt to current climate change whilst still feeding a growing population, i.e. become more 'climate-smart'. Burleigh Dodds Science Publishing is playing its part in achieving this by bringing together key research on making the production of the world's most important crops and livestock products more sustainable.

Based on extensive research, our publications specifically target the challenge of climate-smart agriculture. In this way we are using 'smart publishing' to help achieve climate-smart agriculture.

Burleigh Dodds Science Publishing is an independent and innovative publisher delivering high quality customer-focused agricultural science content in both print and online formats for the academic and research communities. Our aim is to build a foundation of knowledge on which researchers can build to meet the challenge of climate-smart agriculture.

For more information about Burleigh Dodds Science Publishing simply call us on +44 (0) 1223 839365, email info@bdspublishing.com or alternatively please visit our website at www.bdspublishing.com.

Introduction

Recent IPCC reports have highlighted the environmental impact of livestock production as a major source of non-CO_2 emissions: methane (CH_4), nitrous oxide (N_2O) and ammonia (NH_3). The livestock sector must react to these reports and develop or implement methods that can reduce greenhouse (GHG) emissions from livestock production.

Part 1 of this volume focuses on the analysis of greenhouse gas emissions from livestock, specifically drawing attention to the range of methods that can be used to reduce these emissions. Chapters in Part 2 discuss breeding, animal husbandry and animal management and how improving these elements can help to reduce the environmental impact of livestock production. Part 3 concentrates on nutritional approaches such as improving feed efficiency, forage quality and using plant bioactive compounds to reduce GHG emissions. Chapters also review the use of feed supplements and how modifying the rumen environment can also help to reduce GHG emissions.

Part 1 Analysis

Chapter 1 looks at the key techniques used for measurement of CH_4 and other gas emissions from livestock production, ranging from individual animal measurements to herd scale measurements for grazing animals and whole farm emissions such as feedlots. Individual animal measurement techniques discussed include whole-animal respiration chambers and head capture measurement. Herd scale measurements include micrometeorological methods and the eddy covariance technique.

Expanding on topics previously covered in Chapter 1, Chapter 2 discusses greenhouse gas emissions in livestock production, focusing specifically on modelling methods, methane emission factors and mitigation strategies. The chapter begins by reviewing systems analysis and how it can be used to quantify GHG emissions from livestock. It then looks at the various stages of life cycle assessment and how it can be used to analysis the environmental effects of livestock production. Modelling applications and the importance national greenhouse gas inventory submissions are also considered in the chapter.

Part 2 Breeding, animal husbandry and manure management

The first chapter of Part 2 analyses the contribution of animal breeding to reducing the environmental impact of livestock production. Chapter 3 begins by addressing the impact of livestock production on the environment. It then goes on to discuss the environmental impact of broilers, layer hens, pigs and dairy cattle and how improving breeding techniques for all of these species can help to reduce the emissions they produce. The chapter also highlights future research directions and provides resources for further information on the subject.

Chapter 4 focuses on the environmental impact consequences of endemic livestock health challenges that lead to deterioration in animal health, and on the potential impacts arising from their mitigations. The first part of the chapter concentrates on the potential of animal health to affect the environmental impact of livestock systems. It also reviews the literature to date which has quantified the impact of health challenges for the environmental impacts of livestock systems. The potential of successful health interventions to mitigate negative environmental impacts represents a point of synergy between concerns around environmental sustainability and animal welfare, both of which represent 'hot topics' in the discourse surrounding the livestock industry and its sustainability. The chapter concludes by highlighting the challenges associated with modelling health interventions and their potential to mitigate environmental impacts.

The subject of Chapter 5 is sustainable nitrogen management for housed livestock, manure storage and manure processing. The chapter begins by discussing the various forms nitrogen can take, focusing specifically on ammonia, nitrous oxide and di-nitrogen. It then goes on to review livestock feeding and housing for dairy and beef cattle, pigs and poultry. The chapter also examines manure storage, treatment and processing by discussing the principles of emissions produced from these processes as well as mitigation measures that can be used. It also addresses the best practices and priority measures for livestock feeding, housing and manure storage, treatment and processing.

Chapter 6 discusses developments in anaerobic digestion (AD) to optimize use of livestock manure, particularly the use of livestock manure in the production of biogas. The chapter begins by reviewing the quantities and risks of livestock manure, which is then followed by a discussion of the biogas potential of livestock manure. The chapter also examines mono- and co-digestion and the various factors that can affect the efficiency of anaerobic digestion. It also discusses the use of biogas slurry and residues. The chapter shows how AD can play an important role in promoting circular agriculture. A case study on the use of AD in practice in Henan Province in China is also included.

Part 3 Nutrition

Part 3 opens with a chapter that examines the impact of improving feed efficiency on the environmental impact of livestock production. Chapter 7 starts by discussing the relation between greenhouse gases and dairy production, highlighting how important it is to the dairy sector to find ways of decreasing greenhouse gas output. The chapter then moves on to discuss the origins of methane and reactive nitrogen excretions in ruminants. A section on improving feed conversion efficiency is also included, which is then followed by a review of the nutritional practices that can be used to enhance feed conversion efficiency and decrease methane excretion. The chapter also examines the nutritional practices that can be used to increase milk protein efficiency and nitrous oxide excretion as well. Discussions on genetics and feed conversion efficiency and postabsorptive metabolism and feed conversion efficiency are also provided.

Chapter 8 reviews grazing management strategies that can contribute to reducing livestock greenhouse gas emissions. Strategies discussed include grazing season length and timing as well as sward structure and quality, including dry matter and clover content. The chapter also discusses the use of condensed tannin legumes such as chicory and plantain, as well as measurement issues including life cycle assessment.

Chapter 9 focuses on the opportunity to use plant bioactive compounds in ruminant diets for their potential to mitigate greenhouse gas emissions, particularly enteric methane. Nitrous oxide emissions related to urinary nitrogen waste are addressed when information is available. The main families considered are plant lipids and plant secondary compounds (tannins, saponins, halogenated compounds and essential oils). The effects of these compounds in vivo, their mechanisms of action, and their potential adoption on farms are discussed, and future trends in this research area are highlighted.

The next chapter looks at the use of feed supplements to reduce livestock greenhouse gas emissions, specifically focusing on direct-fed microbials. Chapter 10 outlines the strategy of using feed supplements for the reduction of greenhouse gas emissions in ruminants, including methane (CH_4), carbon dioxide and nitrous oxide, given that feed intake is an important variable in predicting these emissions. The chapter focuses on direct-fed microbials, a term reserved for live microbes which can be supplemented to feed to elicit a beneficial response. The viability of such methods is also analysed for their use in large scale on-farm operations.

Chapter 11 focuses on modifying the rumen environment to reduce greenhouse gas emissions. Ruminants were among the first domesticated animals and have been providing food, leather, wool, draft and by-products to humanity for at least 10 000 years. However, rumen methanogens reduce CO_2 to CH_4 in association with other rumen microbes that generate substrates for methanogenesis. Consequently, other rumen microbiota can directly and indirectly impact the abundance and activity of methanogens. Enteric methanogenesis from ruminants accounts for approximately 6% of total anthropogenic greenhouse gases emissions and can represent from 2% to 12% of the host's gross energy intake. A myriad of strategies to mitigate CH_4

emissions have been investigated, but few have been adopted by industry. This chapter reviews rumen- and feed-associated factors affecting CH_4 production and outlines the challenges associated with achieving a reduction in enteric CH_4 emissions. The pros and cons of these strategies are discussed in an attempt to define the best approaches to mitigate CH_4 emissions from ruminant production systems.

Part 1

Analysis

Chapter 1

Measuring methane emissions from livestock

Trevor Coates, Agriculture and Agri-Food Canada, Canada; and Deli Chen and Mei Bai, University of Melbourne, Australia

1 Introduction

Methane (CH_4) gas was first isolated by the Italian physicist Alessandro Volta in 1776 and described as the 'inflammable air native of marshes'. Although recognized as a local gas associated with decaying biological matter, CH_4 was thought to be a relatively static and minor component of the atmosphere. It would be another 200 years before advances in gas chromatography (GC) allowed Rasmussen and Khalil (1981) to show that CH_4 concentration in the atmosphere was not static but was increasing by an estimated 2% per year. With continued atmospheric monitoring and a lengthening historic record derived from ice-core data, the nature of rising CH_4 concentration and its relevance to global warming became increasingly apparent.

The establishment of the Intergovernmental Panel on Climate Change (IPCC) in 1988 and a growing awareness of the need to curb emissions sparked a flurry of research related to cattle CH_4 emissions beginning in the 1990s. Mitigation of enteric CH_4 emissions and the development of measurement techniques to validate the effectiveness of mitigation practices continue to be ongoing areas of research. Strategies that alter the rumen environment and the digestion process (Hristov et al., 2013) through the use of feed additives

http://dx.doi.org/10.19103/AS.2020.0077.03
Published by Burleigh Dodds Science Publishing Limited, 2021.

(Grainger et al., 2008) can improve feed efficiency and decrease enteric CH_4 emissions per kg of meat produced. Farm management and grazing strategies can also influence CH_4 emissions and the genetic selection of more efficient cattle (kg CH_4 per kg live weight) is also an ongoing promising area of research (Basarab et al., 2013).

Mitigation of CH_4 emissions requires emission measurements that are sensitive enough to measure the difference between standard practices and proposed mitigation strategies. Emission measurement methods also need to be operational at a range of spatial scales from the individual animal to *in situ* measurements under typical animal management conditions. This chapter reports on key techniques used for measuring CH_4 emission in agriculture at a variety of spatial scales. Advances in these techniques and promising new approaches to measure CH_4 emissions are also discussed.

2 Individual animal measurement techniques: whole-animal respiration chambers and head capture measurement

2.1 Whole-animal respiration chambers

The first estimates of CH_4 emissions from ruminants came from chamber studies, long before CH_4 had ever been measured in the atmosphere. The animal nutrition laboratory of the Pennsylvania State College constructed a respiration calorimeter in 1902 as a key component to better understanding animal physiology and ruminant nutrition (Armsby and Fries, 1903). Animal CH_4 production was recognized as a loss in feed energy and the Armsby respiration chamber, as it came to be known, was instrumental in generating feed ration and nutrition guidelines for America's expanding cattle industry. Measurement of CH_4 emissions was accomplished by routing a known volume of chamber air to a combustion furnace (Fries, 1910) and recording the change in combustion end products. After many years of experiments, Bratzler and Forbes (1940) developed a simple model relating animal CH_4 production with carbohydrate intake.

Modern chambers are more sophisticated, offering fine control of temperature, humidity and airflow, and advances in sensor technology have allowed for analysis of more components. Construction of chambers represents a considerable expense, but the importance of CH_4 as a source of agricultural greenhouse gas (GHG) emission has hastened their development. Whole-animal respiration chambers are now found at animal research facilities throughout the world. Chamber results have contributed to the current understanding of animal energetics and are considered a 'gold standard' measurement technique. Chambers offer a direct measure of emissions with few assumptions and a methodology that can be easily validated through gas release and recovery tests (McLean and Tobin, 1988). While whole-animal respiration chambers have been extremely valuable for mitigation work

Published by Burleigh Dodds Science Publishing Limited, 2021.

and quantifying treatment effects, the chamber represents a constrained environment, and it is less certain to what extent results can be extrapolated to actual cattle production systems (Johnson et al., 1994).

2.2 Head capture measurement

Measurement techniques capable of operating within real agricultural production environments are necessary for validating methane mitigation measures under typical animal management conditions. As an alternative to large animal chambers, a variety of systems have been designed to measure emissions, principally through focused airflow and concentration measurements of the area around the animal's head. These methods include:

- sniffer methods, where a sampling unit is incorporated into feed troughs;
- ventilated hood or headbox systems, which provide a more controlled environment but allow the animal access to food and water; and
- mask systems, which are fitted to the animal's nose and mouth.

The latter two techniques are also known as flux methods since they involve greater control of the airflow to capture emitted gases and measure CH_4 fluxes. A different approach is the use of handheld laser methane detectors (LMD) which are pointed by an operator at an animal's nostrils to measure methane column density along the length of the laser beam.

These techniques can be used within existing barn facilities and, depending upon the design, can be used to measure emissions continuously over a 24-h period or through spot measurements over the course of the day (Hammond et al., 2016a; Kebreab, 2015). Similar to respiration chamber measurement, these techniques can be affected by decreased feed intake, and intensive training is required for animals to become familiar with the hood apparatus, making it impractical to measure large numbers of animals (NASEM, 2018).

Sniffer methods are based on continuous breath analysis of exhaled air from animals using feed troughs in environments such as automated milking systems. A sampling unit is placed in the feed trough, and the air around the animal's muzzle is continuously monitored during feeding. Sensor systems detect the animal and activate breath analyzers located in the troughs, including Fourier transform infrared (FTIR) and non-dispersive infrared (NDIR) techniques. Measurements can then be used to develop an index of CH_4 emissions during milking as a product of peak frequency and mean peak area of CH_4 concentration (Garnswothy et al., 2012), or using the ratio of CO_2 to CH_4 (Lassen et al., 2012; Lassen and Løvendahl, 2016; Bell et al., 2014). Sniffer methods may be more affected by variable air-mixing conditions due to factors such as the geometry of the feed trough, muzzle position and movement, suggesting that flux techniques are more reliable (Huhtanen et al., 2015). However, recent research suggests that results from sniffer and flux methods are both comparable with each other and with respiration chambers, suggesting a growing degree of accuracy (Sorg et al., 2018; Difford et al., 2018).

The GreenFeed system (GF) (C-Lock Inc, Rapid City SD, USA) incorporates elements of the ventilated hood chamber into an automated feeder that dispenses a programmed amount of pelletized feed as bait to encourage visits to the GF. The GF is a robust system and can be incorporated into the production environment with one GF unit capable of measuring many animals consecutively. A proximity sensor in the head chamber identifies the visiting animal through its ear tag and initiates a gas sampling routine during which bait pellets are dispensed to keep the animals head in the feeder for 3–7 min during which time an emission rate is calculated. The procedure for deriving emission rates is reported by McGinn et al. (2021).

The GF unit can be programmed to limit the number of permitted visits per day but this measurement method is dependent on the animal's desire for the bait in the feeder, and the actual number of visits each animal makes per day will vary as will the number of animals that visit the device. For this reason, measurements are typically accumulated over several weeks to establish a daily emissions pattern for each animal that regularly uses the GF (Hammond et al., 2016b; Hristov et al., 2015; Huhtanen et al., 2019). When using spot measurements to determine daily emissions, care must be taken to prevent sampling bias by ensuring sampling times are appropriate for the daily feeding cycle of the animals using the device (Hammond et al., 2016a). As with ventilated hood chambers and head masks, the GF system is unable to capture the small emission eructed through the rectum, which has been reported to be between 4% and 8% of the total emission from cattle nose, mouth and rectum (Grainger et al., 2007b; McGinn et al., 2006a; Ulyatt et al., 1999). Muñoz et al. (2012) assumed 3% ± 1.5% emission was from the rectum.

3 Individual animal measurement techniques: tracer techniques

Tracer techniques rely on the co-location of a tracer gas source (with a known release rate) and the source to be measured, based on the assumption that both gases will be transported in the atmosphere in the same manner. Concentration measurements of the tracer gas and the source gas are made at some distance downwind. The ratio of gas concentrations is used with the known release rate of the tracer to determine the emission rate. Tracer techniques offer the advantage of a strictly ratiometric measure independent of meteorological conditions.

Published by Burleigh Dodds Science Publishing Limited, 2021.

3.1 Sulfur hexafluoride tracer technique

The sulfur hexafluoride (SF_6) tracer technique (Johnson et al., 1994) was developed to overcome the limitations of chamber measurements, providing individual animal emission estimates without constraints on the animal's typical behavior in the production environment. The technique requires placing a small permeation tube in the animal's rumen which emits SF_6 at a pre-calibrated rate. This tracer gas is expelled through eructation along with the CH_4 produced in the rumen, while a collection device attached to the animal slowly draws air, usually for 24 h, from the nose and mouth region through an intake affixed to a halter. This technique provided the first measurements of animal emissions from grazing systems (Lassey et al., 1997; McCaughey et al., 1997). It also provided a means to monitor the dynamics of pasture conditions by conducting short measurement programs over a year (Pavao-Zuckerman et al., 1999; Ulyatt et al., 2002).

The technique gained in popularity as many agricultural research facilities already had the capacity for gas chromatographic analysis of the air samples collected with the SF_6 technique. With a modest outlay to construct the sampling apparatus and prepare the permeation tubes, a technique was now available to obtain measurements of animal CH_4 emissions from their typical production environment. With an increasing number of users, the technique was improved through a better understanding of animal emission variability compared with chamber measurements (Grainger et al., 2007a), the release characteristics of the permeation tubes with time (Lassey et al., 2001), the effect of permeation rate on emissions estimates (Vlaming et al., 2007), the effect of background measurements (Williams et al., 2011) and the importance of the sample collection rate (Deighton et al., 2014).

The SF_6 tracer technique has proven valuable for mitigation work and is well suited to measurements on small groups of animals, particularly within dairy systems where animals are accustomed to daily handling and sampler changes can be coordinated with daily milking. Implementation in grazing systems is more problematic as cattle require extensive training to become accustomed to handling and the fitting of yokes (DeRamus et al., 2003). The technique is also limited by higher between-cow variability in measurement accuracy (Pinares-Patiño et al., 2011). In addition to the permeation tube approach, SF_6 has also been used as a tracer gas to estimate CH_4 emissions from whole farms by releasing gas along barn vents and pen railings (McGinn et al., 2006b) and collecting downwind air samples for GC analysis of SF_6 and CH_4.

3.2 Other tracer techniques: nitrous oxide-tracer Fourier transform infrared spectroscopy

Tracer studies have also been carried out using open-path FTIR and nitrous oxide (N_2O) as tracer gas (Griffith et al., 2008). The open-path FTIR has proven to be a robust instrument for trace gas studies with stable performance and high precision of concentration measurement. Concentrations of CH_4 and N_2O can be measured by one FTIR concentration sensor at a short interval (e.g. 3-min interval). The CH_4 emission rate (Q_{CH4}) is calculated following Eq. 1:

$$Q_{CH_4} = Q_{N_2O} * \left(\Delta CH_4 / \Delta N_2O\right) \tag{1}$$

where Q_{N2O} is the known N_2O release rate and ΔCH_4 and ΔN_2O are the enhanced mixing ratios of CH_4 and N_2O above the local background level.

Griffith et al. (2008) monitored grazing dairy animals by affixing release points along a fence line of a grazing paddock. Animals were confined within a narrow paddock with respect to the prevailing wind so as to minimize the tracer to animal distance and reduce errors arising from the separation of the emission source and the tracer. This technique has also been utilized with gas release canisters affixed to halters on individual animals (e.g. dairy cattle and sheep) (Bai, 2010; Jones et al., 2011) to better collocate the tracer with the emission source. The tracer canisters emit tracer gas N_2O at a known rate similar to SF_6 permeation tubes, and the concentrations of CH_4 and N_2O are measured simultaneously downwind of the animals with an open-path FTIR instrument. This provides a herd-emission rate rather than individual animal emissions. Similar to the SF_6 technique, the method requires daily animal handling for canister replacement. The N_2O tracer-FTIR approach and its need for animal confinement and daily animal handling make this technique more suited to short-term intensive field campaigns. Care must also be taken to ensure the measurement paddock is not a significant source of N_2O as might arise with an irrigated/fertilized grazing paddock.

Another application of the ratiometric technique was reported by Laubach et al. (2014) and McGinn et al. (2019). The ratio of the above background concentration of a target gas measured downwind from two different sources (a control and a treatment) is used to infer the emission reduction of the treatment (numerator) as a fraction of the control (denominator). The assumption used was that the wind flow and physical dimensions of the two sources were identical, thus satisfying the requirement of a single gas transfer coefficient for the calculation of both emissions.

4 Herd-scale measurement techniques: micrometeorological methods

Micrometeorological methods (MM) are by nature non-interference techniques and the most applicable tool for herd-scale emission measurement. In principle, they can be used to study animals at the farm scale without the requirement for animal handling. MM require measurements of atmospheric CH_4 concentration and meteorological variables above or downwind of the animals to infer emissions.

McGinn (2006), in a review of MM techniques, suggested that the mass difference (MD) technique, the integrated horizontal flux (IHF) technique and inverse dispersion (ID) methods were all appropriate choices for measuring emissions of free-ranging animals. The MD and IHF techniques are both mass balance (MB) methods where differences in concentration profiles upwind and downwind of the source are used with a wind speed profile to infer emissions. The MD technique was first proposed by Denmead et al. (1998) and subsequently used for estimating CH_4 emissions from sheep (Leuning et al., 1999) and from grazing animals (Harper et al., 1999). Instrumentation and set-up demands were significant in each of the studies, requiring pumps and switches to manage multiple sampling lines on each face of the pen running to a central CH_4 analyzer. The IHF technique similarly requires logistically complex profile measurements, and as with MD, it is spatially constrained by the downwind profile height, and the source area must be kept small. Application on a grazing landscape requires the animals to be confined, and this effectively restricts both the number of animals and the length of time for measurement.

ID methods rely on atmospheric dispersion models to compute the theoretical relationship between concentration and emission rate from a defined source. Flesch et al. (1995) described a backward-time Lagrangian stochastic model and its application for deriving emissions requiring only a single-concentration measurement of the plume, a known background concentration and wind statistics recorded with a three-axis sonic anemometer. This model has since been incorporated into a commercial software platform WindTrax® (http://www.thunderbeachscientific.com/) providing a convenient tool for mapping source and sensor locations and visualizing model runs. A model run consists of thousands of ‘particles’ (fluid elements) released from the sensor and followed backward in time with trajectories that are consistent with the averaged wind and turbulence statistics of the surface. Particles that ‘touch down’ within the defined source area are accumulated and their velocity at touchdown is used in the final calculation of the ratio of concentration to flux. The model can also operate in a forward mode where particles are ‘released’ from the source and any trajectories that intercept with the sensor volume are accumulated. This technique has since become the most popular MM technique for estimating animal methane emissions (Table 1).

Open-path sensors such as tunable diode lasers (TDL) and FTIR spectrometers have been used because of their ability to spatially integrate concentration measurements and are ideally paired with the WindTrax software. Similar to the MB methods, ID modeling requires a known background measurement and sensors with sufficient sensitivity to accurately sense the increase above background due to the source. Confinement of animals may be

required on a grazing landscape to achieve a sufficient rise in concentration and to ensure an uncontaminated background (prevention of wandering animals). McGinn et al. (2015) demonstrated that ID was effective with confined grazing animals at a stocking density of ten animals/ha but measurement of grazing cattle emissions remains a challenge due to the spatial limitations of sensor footprints and the need to manage cattle according to the changing pasture conditions over the grazing season (Todd et al., 2019).

Overall, reviews of MM suggest that results are comparable with other emission monitoring methods and verification of MM can be achieved through controlled gas release/recovery experiments (McGinn, 2013). The use of MM to distinguish treatment effects is more challenging due to the number of variables that must be considered but with care this can be achieved (Laubach et al. 2013; McGinn et al., 2019).

5 Herd-scale measurement techniques: the EC technique

The theory behind the EC technique is based on fundamentals of turbulent transport based on the early work of Reynolds (1894) and Taylor (1915) (Taylor, 1938) that set the theoretical framework for EC. However, it would be many decades before sensors were developed that could confirm the theoretical functions and explore potential applications. The flux of a given scalar quantity (F_s) can be described simply by Eq. 2:

$$F_s = w\rho_s \tag{2}$$

where w is the vertical wind velocity and ρ_s is the molar density of the trace gas of interest. Applying Reynolds decomposition, the above can be separated into a mean component (product of the mean vertical wind and the mean gas density over an averaging period) and a fluctuating component (the product of the deviations from the mean for the same variables $w'\rho_s'$) to give Eq. 3:

$$F_s = \overline{w\rho_s} + \overline{w'\rho_s'} \tag{3}$$

where $\overline{w\rho_s}$ represents the product of the mean vertical wind and the mean molar gas density, and $\overline{w'\rho_s'}$ represents the mean product of the instantaneous deviations from the mean for the same components.

One of the assumptions made to simplify the above equation is that, over a set averaging period, the mean vertical wind speed should be zero and that, as part of processing, the turbulence components are processed through a coordinate rotation such that the mean vertical wind velocity for the measurement period is zero. With the first component removed, the basic equation for EC becomes (Eq. 4):

$$F_s = \overline{w'\rho_s'} \tag{4}$$

where the flux of the gas component is calculated as the mean covariance between the instantaneous fluctuations of the vertical wind velocity and the molar density of the trace gas.

5.1 The use of the technique in agriculture

Although the theoretical underpinnings of EC were in place early in the 20th century, the instrumentation to measure the fluctuating components of wind and concentration with a time response sufficiently fast to capture the range of eddy sizes would not be available for several decades. The first EC measurements associated with agriculture explored fluxes of heat, momentum and water (Swinbank, 1951). Early attempts were made to measure CO_2 fluxes over an agricultural crop using a propeller-type anemometer to record vertical wind fluctuations (Desjardins, 1974) but a loss of high-frequency data associated with the slow response times of the instrumentation led to an underestimate of fluxes.

EC techniques increased in popularity throughout the 1980s as the development of the microprocessor facilitated the manufacture of three-axis sonic anemometers. This coupled with sensor improvements and digital data acquisition systems led to further use of EC to generate flux data over crops (Anderson et al., 1984; Desjardins et al., 1984). As the availability of robust commercially available sonic anemometers and stable fast-response sensors increased, so too did the number of monitoring sites. The accumulation of data from carbon balance studies and the need for spatial integration across various ecosystems led to the development of regional and global flux networks throughout the ’90s (Baldocchi, 2003).

With the rapid expansion of flux networks and the accumulation of long-term flux data, there came a need for a more standardized approach to data analysis to allow meaningful comparison between sites. Quality control testing and assessment of data quality became an increasing concern (Foken and Wichura, 1996; Vickers and Mahrt, 1997). This emphasis on the documentation of analysis procedures led to the convergence of analysis protocols and to the development of a number of software packages designed to incorporate analytical processing options, quality-control tests and sensor-dependent corrections (Table 2). The use of a standardized analysis platform allows for a more consistent approach to data processing. Data can be shared in a manner that clearly documents the analysis steps taken. A programmed approach also aids in the reanalysis of datasets when software is updated to incorporate improvements in processing steps or additional corrections.

5.2 The use of EC techniques to measure livestock emissions

The vast flux networks that began in the ’90s were focused on characterizing ecosystem productivity through measurement of the carbon, water and

energy exchanges between the homogenous extensive surfaces (grasslands, forests, etc.) and the atmosphere. This decade, however, also saw the first measurements of CH_4 fluxes using EC with closed-path CH_4 analyzers (Denmead, 1991; Verma et al., 1992). These first-generation analyzers were lab-based instruments requiring temperature control, mains power and pumps to draw air through the analyzer, and field measurements were limited to short-term intensive testing. The development of a low-power open-path CH_4 analyzer (McDermitt et al., 2011) has since enabled the deployment of EC systems to monitor CH_4 fluxes from a variety of landscapes including wetlands (Matthes et al., 2014), rice paddies (Alberto et al., 2014) and tundra (Raz-Yaseef et al., 2016).

Although EC has grown to be a well-tested micrometeorological technique for measuring exchanges between the surface and the ground, this is typically done in association with an extensive homogenous source, and fluxes are calculated on an area basis. In fact, this calculated flux will represent a spatially weighted average of surface fluxes from a defined portion of the underlying surface. Areas of the surface that contribute to the calculated flux (and their relative contributions) constitute the flux footprint (Schuepp et al., 1990). Typically, the footprint encompasses the immediate vicinity of the sensor and extends upwind. The shape of the footprint and its upwind extent vary with sensor height, aerodynamic roughness of the surface and atmospheric conditions but are generally in the range of a few hundred meters. Atmospheric stability plays a large role, however, with the footprint contracting substantially in unstable conditions and increasing potential to hundreds of meters during stable conditions (Göckede et al., 2004). When EC is used over a homogenous extensive surface, the calculated vertical flux is representative of the surface-emission rate, expressed in terms of g m^{-2} s^{-1}. When EC is used to infer emissions

Published by Burleigh Dodds Science Publishing Limited, 2021.

from point sources (or spatially limited area sources), the relationship between emission and flux is more complex as the contribution of these distinct sources to the EC flux will be dependent on the source location within the footprint.

Grazing systems represent a challenging and complex environment for the application of EC. The sensitivity of EC to the presence of grazing animals on the landscape has created difficulties for those who are interested in ecosystem fluxes. Herbst et al. (2011) found CH_4 peaks in their flux data from wetland emissions and utilized a camera system to show that these anomalies were correlated with grazing animals upwind of their measurement tower. Baldocchi et al. (2012) found that the presence of cows on the landscape was easily detected in their flux measurements and became a challenge in monitoring the emissions from a peat landscape as the influence of nearby cows resulted in fluxes many times higher than the typical landscape fluxes they sought to measure. A tower-mounted camera was installed so that periods with animals in the vicinity could be eliminated from the dataset, although the authors suggested they could, at a future date, use this data to estimate animal emissions.

Intentional measurement of ruminant emissions using EC was first performed by Dengel et al. (2011) who used an EC flux tower to capture CH_4 fluxes of a sheep-grazed paddock. The movement of sheep in and out of the measurement footprint led to high variability in the individual analysis periods, and no means of recording animal locations were available. However, by integrating the fluxes over a 7-month measurement period and dividing by the stocking density, a rough estimate of emissions was obtained. Grazing animals introduce extreme temporal and spatial heterogeneity on the landscape, and CH4 fluxes measured by EC fluxes will fluctuate widely depending on the number of animals in the footprint and their locations relative to the sensor (Fig. 1).

The application of EC to estimate emissions in the grazing environment will generally require an analysis of the footprint and its overlap with animal positions. Tallec et al. (2012) accounted for animal position by confining groups of animals in small pens around a central tower. Felber et al. (2015) used EC with free-ranging cattle and tracked animal position with global positioning system (GPS) collars. Both Tallec et al. (2012) and Felber et al. (2015) used the footprint weighting tool of Neftel et al. (2008), based on the 2D analytical footprint model of Kormann and Meixner (2001), as the basis of interpretation of EC fluxes to generate emission estimates. While the authors concluded that EC was sufficiently accurate for animal emission studies, a systematic underestimation of emissions when animals are far from the tower was noted. Felber et al. (2015) proposed that the use of a more sophisticated Lagrangian footprint model (as used in the present work) could yield more accurate estimates. Recent studies highlight the value of the technique in

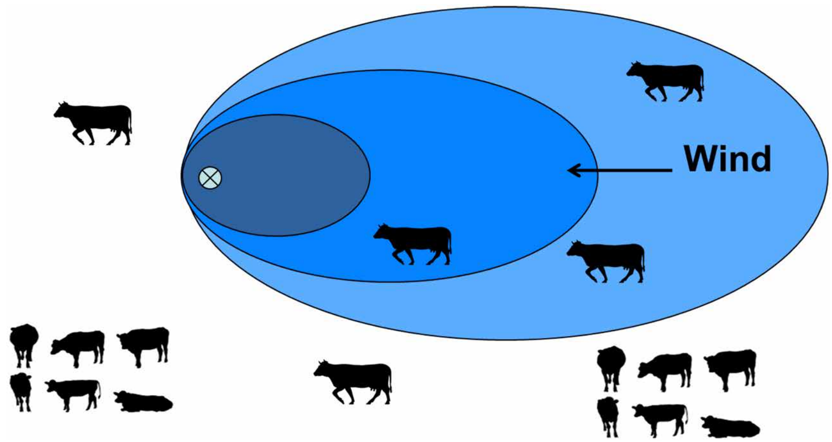

Figure 1 Representation of the flux footprint on a grazing landscape. In this representation only three animals contributed to the flux. Animals closer to the measurement point (marked by the x) contributed more than those further away.

assessing emissions in grazing environments but the challenges in accounting for variables such as wind and other atmospheric variables as well as animal distribution and movement continued (Prajapati and Santos, 2017, 2018; Coates et al., 2018).

6 Conclusion and future trends

Measuring methane emissions from livestock remains challenging yet there is a compelling urgency to continue to refine existing techniques and explore new opportunities as technologies evolve. The ability to reliably and repeatedly make valid measurements under a range of animal production scenarios is vital to support ongoing GHG mitigation efforts from the livestock sector. The expanding options for measurement are encouraging and the research community will continue to explore techniques best suited to their unique access to available equipment and expertise. The precision of respiration chambers will continue to play an important role in demonstrating effectiveness of new diet strategies for methane mitigation. Other techniques more applicable to actual farm conditions and a higher throughput of measurements have a role to play by accounting for animal variability. Recent studies comparing respiration chambers with the LMD, sniffer, SF_6 and GF techniques have found that results from the latter techniques correlated well overall with those from respiration chambers, but there was a lower correlation between techniques and degree of repeatability within individual techniques (with head enclosure techniques such as GF and SF_6 performing best) (Garnsworthy et al., 2019; Zhao et al., 2020). This suggests that a way forward is to combine techniques with appropriate weightings and target them for specific applications, whether emissions monitoring (using techniques such as respiration chambers and head enclosure methods) or using applications such as genetic evaluation in breeding cattle with lower emissions (using techniques such as GF, sniffer or LMD methods). MM methods will continue to be important for herd scale emissions and in understanding the relationship between animals and the rangeland ecosystem. Results from analytical methods can also be used both to validate and inform the range of increasingly sophisticated models predicting GHG emissions from livestock, allowing rapid analysis of a range of scenarios and parameters to help farmers improve their operations (Jose et al., 2016).

7 Where to look for further information

The following books provide helpful overviews on respiration chamber measurements, hood measurements and the SF_6 tracer technique:

- Animal and Human Calorimetry (McLean, J. A. and Tobin, G. 1988. Cambridge University Press, Cambridge).
- Measuring methane production from ruminants (Makkar, H. P. and Vercoe, P. E. 2007. Springer).

The following references provide valuable insights into meteorological approaches for flux measurement:

Chapter 2

Greenhouse gas emissions from livestock production: modelling methods, methane emission factors and mitigation strategies

Donal O'Brien, Environment, Soils and Land Use Department, Teagasc, Ireland; and Laurence Shalloo, Animal and Grassland Research and Innovation Department, Teagasc, Ireland

1 Introduction

An integral component for quantifying greenhouse gas (GHG) emissions from livestock production systems is whole-farm modelling. In contrast to the International Panel on Climate Change (IPCC) method, whole-farm modelling does not specify the estimation of GHG emissions by sector, but by the definition of system boundaries (Schils et al., 2005). This allows a complete analysis of methane and GHG emissions that is not possible within the framework of the IPCC method, as on-farm GHG emissions emanating from livestock farming systems are reported in three different sectors (Soussana et al., 2010). These sectors are agriculture, land-use change and forestry, and energy. Furthermore, the IPCC method is limited to national GHG emissions. Thus, even if GHG emissions from national sectors are combined to quantify total emissions, any emissions generated outside of the national boundaries are not included (Cerri et al., 2009). For example, a large proportion of concentrate feeds used within winter milk production systems are sometimes produced outside a nation's borders, but the associated GHG emissions from

http://dx.doi.org/10.19103/AS.2020.0077.04

cultivation and harvesting are included in the inventories of the nation(s) that produce the concentrate feeds instead of the inventory where they are consumed.

An alternative to the production-focussed IPCC method is consumption-based GHG accounting. Peters and Hertwich (2008) outlined the methodology in detail and argued that emissions are driven by consumption, not by production. Estonia has demonstrated it is possible to use the consumption approach at a national scale to quantify GHG emissions (Gavrilova and Vilu, 2012). Quantifying national GHG emissions using both methods, that is, production and consumption could potentially identify any major transfers of GHG emissions from one nation to another (carbon leakage). This is an issue as some nations have less focus on reducing GHG emissions than others. The consumption approach, however, requires the development of harmonized farm models capable of quantifying GHG emissions associated with the life cycle of goods and services, that is, carbon footprint and methane emission intensity (Peters, 2008). Whole-farm models often use LCA methodologies to quantify emissions, and LCA methodologies often use farm models to complete the LCAs. Both of these modelling methods use a systems approach to quantify GHG emissions. When these modelling approaches are applied using the same set of assumptions (e.g. boundaries, unit of expression, methane emission factors), the results should be similar. This chapter will discuss the systems analysis and life cycle assessment modelling approaches and will go on from there to look at a range of model applications. These applications include use within the national inventories of various countries across species, including discussions around the use of different emission factors. The chapter concludes with applications to quantify emissions at the farm level and a discussion around some of the mitigation strategies that have been modelled.

2 Systems analysis

Systems analysis has been widely used by researchers to quantify GHG emissions from the ruminant system and assess methane mitigation strategies (Beukes et al., 2010; O'Brien et al., 2011; Clarke et al., 2013). The main stages of system analysis focus on the definition of a conceptual framework, with the precise aim and boundary of the model and its application.

2.1 Conceptual framework

In general, the first step of systems analysis is to formulate a conceptual model of the farming system of interest. The delimitation of the system boundaries of conceptual models is determined by the objective of the study and the precise aim of the model use. The objective of the analysis required should be used when decided on an appropriate model to complete an analysis. Generally, whole farm models that have quantified GHG emissions from livestock production systems estimate emissions from on- and off-farm sources related to the livestock product(s) up to a point it is exported from the farm (Olesen et al., 2006). Off-farm emissions from the production of external farm inputs such as concentrate feed and fertilizers are included with methane and other GHG emissions.

2.2 Model development

The second step of systems analysis entails creating a mathematical model of the production system defined. During this stage a series of algorithms are assembled and connected to mathematically model the farming system. In most cases, these equations are based on empirical relationships from representative field studies (Shalloo et al., 2004). Occasionally, experimental data from the farming system under study is used to estimate methane and other GHG emissions (Schils et al., 2005; del Prado et al., 2013). Within livestock system simulation models, emission factors in conjunction with livestock activity data are used to compute farm emissions. Sometimes these emission factors are obtained from the IPCC (2006) guidelines for on-farm emission sources. However, the IPCC emission factors are designed to enumerate national-level emissions. Thus, they often lack the refinement, model functions and emission factors, necessary to quantify the effect that changes to the production systems have on GHG emissions from individual farms (Schils et al., 2006). As a result, direct emission measurements, published in the scientific literature, are sometimes used to generate emission factors for subsequent inclusion in models in the pursuit of assessing on-farm emissions. In the case of off-farm emissions, almost all emission factors are obtained from literature sources or databases, for example, Ecoinvent (2010). Normally, data collected on-farm or representative information such as regional statistics are used as input data to operate whole-farm GHG models. For bovine production systems, several models have been developed to quantify GHG emissions from conventional pasture-based or confinement systems and organic systems (Beukes et al., 2010; Rotz et al., 2010; O’Brien et al., 2011). Results from previous livestock GHG models have been expressed per farm, per hectare of farmland and per unit of product, for example, per kg of fat and protein corrected milk (FPCM) or kg carcass weight (Thomassen et al., 2008; Clarke et al., 2013).

3 Life cycle assessment

Life cycle assessment considers the environmental effects of a product or service system (ISO, 2006a). The method also adopts a systems approach, but in contrast to systems analysis, the general step and principles of the LCA methodology are internationally standardized (ISO, 2006a,b). The International Organisation for Standardisation (ISO) originally developed standards for LCA in 1997, which were subsequently revised in 2006 (ISO 14040-14044). The main phases of LCA accordingly are goal and scope definition, life cycle inventory analysis, life cycle impact assessment and life cycle interpretation.

3.1 Goal and scope definition

This stage requires clearly stating the aims and objectives of an LCA project and the intended audience (ISO, 2006a). The goal definition determines what level of detail and what accuracy is needed for prediction/analysis. The scope of an LCA study should clearly describe the system under study and define the boundaries of the studied system (ISO, 2006a). Typically, the system boundaries of livestock LCA studies are defined to assess GHG emissions from all processes up until the point the primary product is sold from the farm (Beauchemin et al., 2011). This is commonly referred to as a 'cradle to farm gate' LCA. Some studies have also analysed further production stages, for instance, the processing stage and distribution to the retailer (Berlin, 2002; Hessle et al., 2017). The main environmental impacts evaluated in previous LCA studies of livestock are GHG emissions (global warming potential), acidification potential, eutrophication potential, land use and energy use (de Vries and de Boer, 2010; de Vries et al., 2015).

3.2 Life cycle inventory analysis

The second phase of LCA involves the compilation of inputs, outputs and emissions for a given product system throughout its lifecycle (ISO, 2006b). The aim of this stage of LCA modelling is to develop a model that quantifies the different resources used and the amount of waste and emissions generated per functional unit (Rebitzer et al., 2004). Resources used on-farm are normally collected directly or computed using relevant data sources. Emissions from on-farm processes are mainly estimated by applying emission factors from the literature or the IPCC (IPCC, 1997, 2006). For most LCA studies of livestock systems, international databases, for example, Ecoinvent (2010) or literature sources are used to estimate the resources used and emissions generated from processes that are indirectly related to the production system of interest, for example, data on fuel and fertilizer production.

3.3 Life cycle impact assessment

The inventory analysis phase lists the various substances used and pollutants emitted from a livestock production system (Thomassen et al., 2008). These results are generally difficult to interpret. Thus, a further stage known as life cycle impact assessment is needed to complete LCA of livestock systems (ISO, 2006a,b). This phase aggregates resources and emissions from the inventory analysis phase and computes (characterization) various potential environmental effects (Guinee et al., 2002). Environmental impacts are computed by converting the results of the inventory analysis stage using relevant characterization or equivalency factors. For instance, the global warming potential metric in CO_2-equivalents is applied during this stage to assess the climate impact of methane and other GHG emissions (Basset-Mens et al., 2009). The life cycle impact assessment stage allows the environmental effects of a livestock system to be assessed in a more interpretable way.

4 Modelling applications

Recent LCA and whole-farm GHG models from cool or temperate livestock regions were assessed. Table 1 provides a description of the modelling methods and emission factors used for analysis in 11 dairy studies, 9 beef studies, 3 sheep studies and 2 pig studies. In many situations, models calculated GHG emissions according to the approaches reported in national GHG inventories and the IPCC guidelines. A few studies used alternative equations for these sources such as Capper et al. (2009) or measured emissions directly as part of an on-farm research trial, for example, Doreau et al. (2011). Whole farm or LCA models were used for the following purposes:

- Quantify the environmental performance of farm systems and the effect of mitigation strategies on GHG emissions;
- Estimate the environmental sustainability of commercial farmers, for example, Bord Bia sustainable livestock assurance schemes; and
- Investigate the effect modelling decisions have on GHG emissions through sensitivity analysis.

4.1 Farm systems considered

Studies modelling GHG emissions from livestock farms have compared a variety of different systems including organic and conventional production systems, extensive and intensive systems, and confinement and grazing systems. These comparisons were generally representative of farms for a particular region. Many modelling studies that compare contrasting production systems aimed to assess the effect of intensification, defined as increased use of inputs per ha (e.g. fertilizer) have on GHG emissions. The results of these studies highlight that the effect of intensification on GHG emissions varies depending on the unit of expression. For instance, when dairy-farm GHG emissions are quantified per

Table 1 Summary of studies modelling greenhouse gas (GHG) emissions from livestock systems since 2009

Livestock species	Study	Farm description	Study goal(s) and methodology	GHG emission factors
Beef	Beauchemin et al. (2011)	Average farm in Western Canada	Life cycle assessment – multi-year model that assessed strategies to mitigate GHG emissions intensity from suckler beef	IPCC (2006)
Beef	Capper (2011)	Average US farm	Whole farm model – compared 1977 beef system GHG emissions to modern conventional systems	IPCC (2006) and literature sources
Beef	Clarke et al. (2013)	Irish research farm	Life cycle assessment – combined LCA model with a suckler beef bio-economic model and examined emissions from farms differing in stocking rate and finishing system	Ireland national GHG inventory method
Beef	Doreau et al. (2011)	French research farm	Life cycle assessment – completed an LCA of finishing or feedlot beef bull systems and estimated the effect different diets have on their GHG emission	Enteric methane emissions were measured. IPCC (2006) was used for manure
Beef	Hessle et al. (2017)	Average Swedish farm in Vastra Gotaland region	Life cycle assessment – assessed the effect four environmental improvement scenarios have on GHG emissions, nutrient loss and energy use from beef and milk	Swedish national GHG inventory method and IPCC (2006)
Beef	Murphy et al. (2017)	Irish research farm	Whole farm model – coupled a beef GHG model with a dairy beef bio-economic model to quantify effect of diet and slaughter age on GHG emissions	Ireland national GHG inventory method and literature sources
Beef	Ridoutt et al. (2013)	Commercial Australian farms	Life cycle assessment – assessed carbon, water and land-use footprints of contrasting cow-calf beef systems	Australian national GHG inventory method
Beef	Stackhouse et al. (2012)	Industry-simulated Californian farm	Life cycle assessment – quantified effect a growth promoter has on GHG emission from suckler beef	

Beef	Veysset et al. (2014)	Commercial French farms	Life cycle assessment – conducted a technical-economic survey on 53 suckler beef farms and quantified GHG emissions and fossil fuel use	French literature sources
Dairy	Bell et al. (2011)	UK research farm	Life cycle assessment – a Markov chain was used with LCA to compare GHG emissions from cows offered different levels of forage	IPCC (1997) and IPCC (2006)
Dairy	Beukes et al. (2010)	Average New Zealand farm in Waikato region	Whole farm model - integrated three models to investigate the effect different management scenarios have on dairy farming systems GHG emissions.	New Zealand national GHG inventory method
Dairy	Capper et al. (2009)	Average US farm	Whole farm model – compared GHG emissions from mid-1940 dairy system and modern conventional system	IPCC (2006) and literature sources
Dairy	Chobtang et al. (2016)	Commercial New Zealand farms in Waikato region	Life cycle assessment – evaluated the cradle-farm gate environmental performance of 53 commercial farms using dairy-base dataset.	New Zealand national GHG inventory method
Dairy	Del Prado et al. (2013)	Commercial farms in northern Spain	Life cycle assessment – coupled LCA and nutrient cycling models to estimate 17 dairy farms GHG emissions and nutrient-use efficiency	IPCC (2006) and literature sources
Dairy	Dolle et al. (2009)	Average farms for four French regions	Life cycle assessment – evaluated the effect different allocation methods have on dairy farms GHG emission intensity	Literature sources
Dairy	Mc Geough et al. (2012)	Average farm in Eastern Canada	Life cycle assessment – multi-year model that assessed the effect different allocation methods have on the GHG emissions intensity of raw milk	IPCC (2006)
Dairy	O'Brien et al. (2011)	Irish research farm	Whole farm model - combined a bio-economic dairy model with a GHG model to examine the effect genetic potential and grazing system has on dairy GHG emissions	Ireland national GHG inventory method

(*Continued*)

Table 1 (*Continued*)

Livestock species	Study	Farm description	Study goal(s) and methodology	GHG emission factors
Dairy	O'Brien et al. (2015)	Commercial Irish farms	Life cycle assessment – related the GHG emission intensity of 221 dairy farms to economic performance using the Teagasc national farm survey	Ireland national GHG inventory method
Dairy	van Middelaar et al. (2013)	Average Dutch farm	Life cycle assessment – coupled LCA with an economic model to assess the effect different feed strategies have on GHG emissions	Dutch national GHG inventory method
Dairy	Zehetmeier et al. (2012)	Average German farm	Whole farm model – assessed the effect increasing dairy cow milk yield has on GHG emissions from the dairy and beef industries	German national GHG inventory method
Pig	McAuliffe et al. (2017)	Commercial Irish farms	Life cycle assessment – compared GHG emissions and environmental metrics of average and top-performing pig farms	Ireland national GHG inventory method
Pig	Reckmann et al. (2013)	Average farm in northern Germany	Life cycle assessment – quantified GHG emissions and environmental metrics for a typical pig farm	IPCC (2006) and literature sources
Sheep	Jones et al. (2014)	Commercial sheep farms	Whole farm model- analysed GHG emissions from 64 sheep farms and identified areas for improvement	IPCC (2006) and literature sources
Sheep	O'Brien et al. (2016)	Average and commercial sheep farm	Life cycle assessment – evaluated the effect of intensification on GHG emissions and resource use of sheep farms	IPCC (2006) and literature sources
Sheep	Wiedemann et al. (2015)	Average Australian, UK, and New Zealand sheep farms	Life cycle assessment – evaluated the effect allocation methods have on GHG emissions from typical sheep farms	Literature sources

hectare of land, whole-farm models usually show that reducing the intensity of dairy systems reduces GHG emissions (Beukes et al., 2010; O'Brien et al., 2011). However, when GHG emissions are assessed on per unit of product basis (GHG emission intensity), intensification usually reduces GHG emissions (Capper et al., 2009; O'Brien et al., 2011). Given the rising demand for livestock products such as milk, this implies that GHG emissions should not be assessed in isolation from milk or meat production. The impact of livestock systems on emissions should also be contextualized with other production systems and countries.

A potential option for reducing GHG emissions from livestock, according to (Capper et al. 2009; Capper, 2011), is sustainable intensification. Capper et al. (2009) modelled GHG emissions from US beef and dairy systems and demonstrated increasing livestock output reduces GHG emissions through improved productive efficiency, defined as 'units of milk or meat produced per unit resource inputs'. Improving productive efficiency facilitates the dilution of maintenance effect, whereby the total resource cost per unit of product is reduced (Bauman et al., 1985). The land the strategy spares can potentially further reduce emissions by sequestering carbon in soil or woody biomass. The effect of sustainable intensification and livestock productivity on GHG emissions is not accounted for in national inventories that use the basic IPCC tier 1 approach but can be partially captured by inventories that use higher tiers. Many inventories could better reflect the influence livestock efficiency has on GHG emission intensity by updating important nutritional parameters. Further improvements may be possible to make once appropriate emission factors are established to determine the benefits of methane-reducing feed additives. Including additives or supplements within the inventory calculations as well as having the activity data captured could cut methane emissions from enteric fermentation of feed by 15–30% (Hristov et al., 2013).

Intensification may have undesirable effects on emissions as well and can lead to declines in soil organic matter or carbon levels (Zehetmeier et al., 2012; van Middelaar et al., 2013). For instance, van Middelaar et al. (2013) reported that converting grassland to arable land to support higher stocking rates improved dairy-farm production levels, but also dramatically increased soil carbon losses. Consequently, intensification nearly doubled GHG emissions per unit of product. A production system in a steady state, in terms of on-farm land use, is less likely to cause a land-use change effect, unless the origin of feed ingredients contained in compound concentrate feeds brought into the system change. O'Brien et al. (2016) noted that GHG emissions from livestock systems were sensitive to changes in these ingredients and showed including carbon sequestration in grassland resulted in extensive hill sheep farms emitting less GHG emissions per unit of output than intensive lowland farms. The inconsistent effect of intensification on livestock farms GHG emissions indicates that emissions and carbon sequestration should be assessed together. Within this context, the short-term effect of, for example, CO_2 versus the long-term effects captured through the GWP coefficients need to be taken into account in any computations.

Beef modelling studies report that GHG emission intensity can be mitigated by rearing beef from the dairy herd instead of the suckler herd. Switching to a dairy calf to beef production system eliminates suckler cows from the beef herd, which significantly reduces the GHG emission intensity of live weight or carcass weight as 80–90% of dairy cows' emissions are allocated to milk (Zehetmeier et al., 2012). The reduction is lower in terms of live weight because the terminal traits of surplus dairy cattle are inferior to suckler cattle. Some farmers generally select sires that are easy calving and have shorter gestation, which has a negative influence on carcass weight production. This may be possible to change by using new animal breeding technologies, for example, genomic selection.

5 National greenhouse gas inventory

Livestock methane emission factors reported in national GHG inventory submissions to the United Framework Convention on Climate Change (UNFCCC) were reviewed for annex 1 (developed) countries and 5 non-annex 1 countries, that is, Brazil, China, India, South Africa and Uruguay. The review was carried out on 2017 annex 1 national inventory submissions, which estimated GHG emissions for the period 1990–2015 (UNFCCC, 2017a). Unlike annex 1 countries, non-annex 1 nations do not report emissions annually. The latest reports available for these nations were 2–3 years older and estimated GHG emissions generated prior to 2013 (UNFCCC, 2017b). The appraisal of annex 1 and non-annex 1 GHG inventories considered the methods that nations use to estimate emission factors for enteric fermentation in livestock and livestock manure. The findings of this international methodological evaluation were summarized for livestock categories using the IPCC tier(s) (tier 1, tier 2 or 3) that each nation uses for emission calculations. The categories of livestock evaluated were: dairy and non-dairy cattle (bovine), sheep, pig, poultry and other livestock (e.g. rabbits, horses, mules). The results of the review for each category were compared to pertinent Irish livestock methane emission factors.

5.1 Bovine

Differences in dairy cow methane emission factors were related to the calculation and reporting methodology used, as well as cow productivity. For example, Ireland's tier 2 methane emission factors for bovines were generally lower than nations with heavier and higher-yielding cows such as the United States and higher than nations with lighter and lower-yielding cows (Table 2).

Most countries used tier 2 enteric methane emission factors for dairy and non-dairy cattle (Table 3). In official inventory terminology, anything more detailed than a tier 2 methodology is termed tier 3. However, it is not uncommon for people to use the term tier 2+ to describe situations where the tier 2 equations are used, but country-specific parameters are used. The tier 3 model can be an empirical or mechanistic model describing the fermentative and digestive processes in the gastrointestinal tract of dairy cattle. Tier 3 models operate with greater levels of activity data allowing regional, system and animal-based simulations. Tier 1 emission factors were not applied to compute dairy cow's enteric methane emission and were only used by Cyprus and the United Kingdom (UK) for mature beef cattle and younger stock (together known as non-dairy). Tier 3 emission factors were used by Ukraine and France (not implemented yet) to quantify enteric methane emissions from dairy cows and non-dairy cattle. Tier 3 emission factors were not used for estimating methane emission from dairy cow manure (exception being the Netherlands having a model capable of simulating methane, ammonia and manure methane at a tier 3 level) and rarely used for this source for non-dairy cattle.

Generally, nations that reported a higher tier method to estimate bovine enteric methane emissions used more data-intensive and detailed emission algorithms. Tier 3 equations were normally derived from published national research projects that measured and/or modelled methane. For example, a French project derived tier 2 and 3 methane emission factors for several categories of dairy cows and other cattle, considered as representative of the nation's breeding situations. Each category was associated with a breed, an average mass, a milk yield if necessary, as well as energy needs.

The Swiss tier 2 approach estimates cow feed and gross energy requirements using recommended national feeding standards that are widely used by Swiss farmers because they are a basis for their basic support payment. The Swiss Ym, methane conversion rate expressed as a fraction (i.e. the fractional loss of GEI as combustible CH_4), depends on the diet. The Ym value comes from national projects that measured methane from dairy cows in open and closed calorimeter chambers. The Swiss and French methods to estimate enteric methane emission factors for dairy cows aligned better with inventories like the Irish one rather than the complex tier 3 approaches applied by the Netherlands and Germany. Briefly, the Netherlands used Bannink et al. (2011) mechanistic, dynamic model of the rumen fermentation process to estimate methane from enteric fermentation in dairy cows. The inputs required to operate the Dutch model were feed intakes, the chemical composition of feed and degradation characteristic of the constituents of feed (e.g. crude protein). Cow feed intakes were estimated according to national feeding standards, and nutritional data was provided by a widely used Dutch agricultural laboratory.

Table 2 Live weight, milk yield, energy requirement and methane emission factors from selected annex 1 parties to the United Nations Framework Convention on Climate Change reported for dairy cows in production year 2015 (UNFCCC, 2017a)

	Ireland	United Kingdom	USA	New Zealand
Average live weight, kg	535	608	680	448
Milk yield, kg/cow per year	5458	7705	10 268	4362[a]
Gross energy required, MJ/d	261	300	IE[b]	IE
Methane from enteric fermentation, kg/year	117.2	130.0	146.0	84.3[c]
Methane from manure, kg/year	11.2	17.4	74.0	5.8[c]

[b] Not reported.
[c] Includes dairy heifers.

Detailed nutrition data was used in the German approach to estimate dairy cow enteric methane as well. Their method, described by Rosemann et al. (2017), accounted for the effects of feed composition and feed properties using a German model developed by Kirchgessner et al. (1994). This model, like the Dutch model, was data-intensive and required information that is unlikely to be feasible to collect in the short term at a national level in some other countries that practice extensive grazing and/or where detailed quality information is not available most of the time.

Bovine feed intakes and OM digestibility estimates were required to estimate methane emissions from manure in most national inventories reviewed. The tier 3 method was only used to estimate methane from the manure of Australian beef cattle fed on feedlots. The calculation used measured methane conversion factors from Redding et al. (2015) for Australian manure storage systems. Australia was not the only nation that used country-specific methane conversion factors for manure management. Other examples included New Zealand, Denmark and Austria. A few national inventories such as the UK reported the proportion of cattle slurry systems that form a natural crust cover. In reality, it can be rather arbitrary whether a country declares themselves as operating at a tier 2 or tier 3 level within their inventories.

Several countries recognize that methane emissions from bovine and livestock manure are linked to other GHG emissions from this source, for example, nitrous oxide. For consistency, some countries use a comprehensive model that simultaneously quantified GHG and ammonia emissions from livestock. This approach was recommended in the EU 2017 submission to the UNFCCC for its member states but is only applied by a few nations, for example, the German GAS-EM model, Denmark's IDA model and Ireland.

5.2 Sheep

Methane emissions from sheep are generally estimated by national inventories using tier 2 or tier 1 emissions factors (Table 4). The tier 2 method was used more often than the tier 1 approach. Generally, countries that applied the tier 2 method used the IPCC (2006) equations to estimate sheep feed requirements, manure excretion and methane emissions. France used a more advanced method to calculate enteric methane emission factors for sheep and New Zealand reported applying a country-specific tier 2 method. The French method for sheep is similar to the approach described earlier for French bovines, except for the calculation of methane from enteric fermentation. The New Zealand approach to calculate emissions from enteric fermentation and manure management in sheep was similar to that used for bovines. The tier 2 emission factors for both species were developed by Clark et al. (2003) and are regularly improved using new experimental research. The New Zealand computations for sheep enteric methane are carried out on a monthly basis and use country-specific data for sheep populations, pasture quality and productivity (e.g. milk yield and live weight). This data is generally available only at a national scale for sheep and beef cattle.

5.3 Pigs

The IPCC tier 1, enteric methane emission factors for pigs were used by 30 of the 47 nations reviewed (Table 4). The remaining countries used a tier 2 method for this source, except France which used tier 3. Tier 2 emission factors from the IPCC (2006) were primarily used to estimate methane from pig manure. Only 10 nations used a tier 1 method for this source. Most nations that used tier 2 emission factors entail computing pig's gross energy and protein intakes to meet feed requirements and estimating manure excretion from feed intake and diet digestibility. Methane emissions from manure are computed using survey data on manure storage systems and relevant IPCC conversion factors. This tier 2 method is slightly more advanced in some nations because manure excretion is based on national data instead of default excretion estimates provided by the IPCC.

The tier 2 and tier 3 methods that nations used to estimate enteric methane from pigs do not differ to that described for bovines and sheep. The Ym for pigs was normally derived from the references of the IPCC (2006) guidelines. Country-specific Ym values were also developed by a few nations, for example, Germany, but these estimates were similar to the IPCC estimate differing by <0.1 units.

5.4 Poultry

Nations are not required to estimate enteric methane emissions from poultry. This category is considered by the IPCC to emit negligible emissions. Thus, there are currently no tier 1 emission factors for this source. Nevertheless, 12 nations estimated enteric methane emissions from poultry and 3 reported using tier 2 emission factors (Table 5), because the method was developed from national research in their countries. The emission factors from such research, for example, Wang and Huang (2005) could potentially be applied to estimate enteric methane from poultry in other countries. A slightly higher number of nations estimated methane from poultry manure using tier 2 emission factors instead of tier 1. Australia was the only nation that reported a tier 3 method. The quantity of manure excreted by poultry was estimated using national data or IPCC default values.

5.5 Other livestock

The other livestock category enteric fermentation methane emissions were usually calculated by nations using tier 1 emission factors (Table 5). Nations seldom applied the tier 2 method to estimate enteric methane emissions from all species that are part of this livestock category. Most nations only used tier 2 emission factors to estimate methane emissions from a few economically important production species within the other livestock category, for example, for goat and deer. In general, the tier 2 approach in computing enteric methane emissions from other livestock species was very similar to the IPCC method for cattle and sheep, apart from the Ym parameter, which was not necessarily species-specific. For example, the South African Ym parameter for goats was based on sheep measurements. This approach to estimate Ym is generally acceptable as long as species have similar digestive systems. This approximation method is also recommended by the IPCC for other livestock species not listed in their guidelines and can be applied based on live weight for tier 1 emission factors.

Almost half of the nations reviewed used a tier 2 method to estimate methane from the manure of a species contained within the other livestock category. Of these nations, 13 used tier 2 methane emission factors for manure for all species within this category. The IPCC tier 2 equations and default manure excretion rates were generally used to estimate methane emissions from other livestock species manure.

5.6 Methodology conclusions

Livestock methane emissions factors can be computed more accurately using a tier 2 method instead of a default tier 1 approach because there is country-specific information available around methane emissions for the major production species. This approach is widely used by annex 1 nations to estimate methane from key livestock categories, for example, bovine, pigs and sheep. In addition, several annex 1 nations use this method for all species and integrate

with other methods to estimate air pollutants, for example, ammonia. The tier 2 method that nations applied were generally similar (i.e. emission factor and an estimate of intake to drive percentage losses), but the equations and parameters that nations used to calculate important inputs required to derive methane emissions, such as feed intakes, Ym and manure excretion were often based on national research. These country-specific equations are usually more accurate than the IPCC alternatives and should be used by the inventory where possible, for example, sheep. There may also be potential to develop more advanced methane emission factors for bovine and sheep by using national measurements of enteric methane emissions from these species.

6 Mitigation strategies

Whole-farm GHG models have assessed the effect of several farm practices on emissions. This section describes what can be captured, how they can be captured within models. Examples include selecting higher-yielding livestock, improving fecundity, reducing replacement rates, varying the grazing period, treatment of managed manure and improving nutrient management. The effect of breeding higher-yielding livestock on GHG emissions has varied between studies. Murphy et al. (2017) showed that a 13% increase in beef cattle live weight gain per day reduced GHG emission per unit of carcass weight by 19%. Similar results were reported by Bell et al. (2011) for milk production. In both studies, the reduction was explained by a decrease in methane emission due to improvements in feed conversion efficiency (kg of milk or meat/kg of feed) and decreasing maintenance costs. In contrast, O'Brien et al. (2011) reported Holstein-Friesian cows with higher milk yields increased emissions per unit of the product relative to lower-yielding cows. This was primarily caused by higher-yielding Holstein-Friesian cows having lower herd fertility rates and a shorter lifespan, which increased replacement heifer requirements and thus GHG emissions (O'Brien et al., 2011). The study indicates that it is important to consider a combination of genetic traits to reduce GHG emission intensity.

Beukes et al. (2010) modelled the effect of reducing herd replacement rates on GHG emissions from dairy systems. The analysis showed that a 10% reduction in replacement rate reduced GHG emission per unit of a product by an average of 14%. This decrease in GHG emissions occurred due to a decline in the number of non-productive animals. Bovine fertility is possible to improve through genetic selection and better reproductive management, that is, heat detection aids (Vellinga et al., 2011). Improving reproductive management can also reduce emissions from sheep farms. For instance, Ledgard et al. (2011) reported higher lambing percentages were partly responsible for a 22% reduction in GHG emission from New Zealand sheep production. Increased animal yields and farm profitability were the main drivers of this change.

The influence of the length of the grazing period on GHG emissions was evaluated by Schils et al. (2005) and O'Brien et al. (2015). Schils et al. (2005) investigated the effect of reducing the grazing period and reported that the strategy decreases nitrous oxide emissions from animal excreta deposited on pasture, but increases methane and nitrous oxide emissions from manure storage to a similar extent. Thus, the strategy had no net effect on GHG emissions. Furthermore, Schils et al. (2005) reported that the strategy has undesirable effects on other types of pollution, for example, ammonia. Thus, this demonstrates that models should also consider the undesirable secondary effects (pollution swapping) of GHG mitigation strategies (del Prado et al., 2013). The effect of extending the grazing period was examined by O'Brien et al. (2015). The study showed the strategy caused a greater reduction in methane and nitrous oxide emissions from manure storage than an increase in nitrous oxide emissions from animal excreta deposited on pasture. In addition, the strategy reduced dairy systems' GHG emission intensity by 0.17% per day and improved economic performance.

The potential for feed additives and growth promoters to mitigate methane emissions were assessed by Beauchemin et al. (2011) and Stackhouse et al. (2012). Beauchemin et al. (2011) reported that dietary oils mitigated the GHG emission intensity of western Canadian beef systems by 2–8%. However, Hristov et al. (2013) reported that this strategy was economically risky and highlighted that the long-term mitigation efficacy of oils and fats was uncertain. It also may be difficult to record this mitigation potential in national GHG emission inventories. Stackhouse et al. (2012) showed that antibiotic growth promoters reduced GHG emission intensity by 5–9% for California beef cattle, but these growth implants are proscribed in the EU. Few models directly assess strategies to mitigate methane from manure storage. McAuliffe et al. (2017) highlighted anaerobic digestion as a promising technology to mitigate the environmental impact of pig manure. The strategy can also capture bioenergy and produce electricity but requires more favourable tariffs.

6.1 Commercial farm

The environmental sustainability of commercial livestock farms often has been estimated in developed nations using whole farm or LCA models. O'Brien et al. (2015) estimated the milk carbon footprints of 221 Irish dairy farms using a life cycle approach and evaluated economic performance. The research showed a wide range in Irish dairy farms carbon footprints (0.50–1.97 kg of CO_2-equivalent/kg of fat and protein corrected milk). Generally, dairy farms with lower milk footprints were more profitable. For example, the milk carbon footprint of the top-third of farms in terms of net margin per hectare was 15% less than the bottom-third. Partial least square regression indicated that

farm practices which increase milk solids yield per hectare and the utilization of grazed grass mitigated GHG emission intensity and improved economic performance. The average methane emission factor for dairy cows (110 kg methane/cow) fell within the range of recent Irish inventory estimates.

Chobtang et al. (2016) and Del Prado et al. (2013) carried out similar research as O'Brien et al. (2015) for New Zealand and Spanish dairy farms. Del Prado et al. (2013) reported similar levels of variability among farms' carbon footprints as O'Brien et al. (2015), but Chobtang et al. (2016) found less variability for New Zealand dairy carbon footprints. This may be due to farms operating at a similar level of efficiency, but there was significant farm performance variability. Chobtang et al. (2016) also assessed other environmental measures such as acidification and health measures such as effects on human health. The variability across farms for these measures was generally much higher than the carbon footprint. Off-farm impacts were important for several environmental and health measures assessed and could be improved by increasing forage utilization. Veysset et al. (2014) also recommended the latter to mitigate GHG emissions from commercial French suckler beef farms. The authors highlighted that farms which produced the best forage and heaviest cattle mitigated GHG emission intensity by 50% compared to the least productive in the group. The least productive French farms were larger in the area and operated mixed crop-livestock systems.

Jones et al. (2014) estimated lamb carbon footprints for lowland, upland and hill sheep farms in the UK and reported lowland farms had the smallest mean footprint. There was substantial variability across lamb carbon footprints, and this was largely driven by animal and grassland productivity. The authors recommended a suite of management practices to reduce the carbon footprint of lamb, including improving lambing rates (lambs/ewe), increasing lamb growth rate and optimizing mating rates and concentrate usage. These improvements are likely to be problematic for hill farms where local conditions are much more challenging. Nevertheless, some improvement should be possible as Jones et al. (2014) reported top-performing hill farms outperformed the mean performance of lowland farms.

6.2 Modelling decisions

Quantifying GHG emissions from livestock systems involves making important modelling decisions such as the definition of system boundaries and allocation of emissions to co-products. O'Brien et al. (2011) examined the influence that different system boundaries have on GHG emissions from dairy farms varying in cow genotype and concentrate supplementation. This analysis showed that high-concentrate dairy systems reduced on-farm GHG emissions per kg of milk solids, but the opposite occurred for the New Zealand strain of Holstein Friesian when the system boundary was expanded to include off-farm GHG emissions. Further research by O'Brien et al. (2012) demonstrated similar results for grass-based and confinement dairy systems and highlighted that reducing national GHG emissions to comply with EU targets is likely to increase GHG emissions from dairy production through carbon leakage. This research demonstrates that livestock systems GHG emissions should be assessed using a complete approach like LCA to ensure changes to dairy systems reduce GHG emissions. O'Brien et al. (2011) recommended integrating the LCA method into the Irish inventory framework. This may be possible using datasets like the Teagasc national farm survey.

Various criteria or methods were evaluated for allocating GHG emissions to the products of sheep and dairy systems. Wiedemann et al. (2015) compared seven different criteria to allocate GHG emissions between sheep products, that is, live weight and greasy wool. The case study results were relatively similar when GHG emissions were expressed per kg of total products but varied widely when emissions were split between products based on their economic value. The study recommended allocating GHG emissions between sheep products according to their protein requirements or using the mass of protein sold. Dolle et al. (2009) and Mc Geough et al. (2012) showed similar variability in dairy systems GHG emission intensity due to the allocation method. The authors identified advantages and disadvantages with several methods. Mc Geough et al. (2012) recommended basing the allocation decision on the needs and availability of data, which agrees with the conclusions of Rice et al. (2017) for Irish dairy systems. Rice et al. (2017) reported simple mass allocation was the best approach in terms of the pedigree of data but advised using a range of allocation methods to understand the uncertainty associated with the decision.

7 Conclusion

Most environmental modelling studies use a life cycle approach to quantify livestock's GHG emissions and overall environmental performance. Generally, modelling studies estimated livestock methane emissions according to the calculations provided in national inventory reports or the IPCC guidelines, which ensure the compliance of approaches between different entities modelling at a national level. These calculations vary widely from country to country due to local conditions and livestock research capabilities, but normally show improvements in animal productivity and switching from suckler to dairy beef systems mitigate GHG emission intensity. There is significant potential to use models at a national level to estimate GHG emissions from commercial bovine systems to generate national footprints. Moreover, there is scope to use LCA and national inventory models to benchmark performance across countries and over time. Some national sustainability initiatives, for example, Origin Green are already employing these tools to improve farmers and the wider community understanding of GHG emissions from livestock production. Farm-scale models could be used to pin point the direction in relation to emissions reduction strategies, but it is important that models use an LCA approach to ensure that the analysis completed is robust and not facilitating carbon leakage. Models that are used in these situations should be peer reviewed, validated and evaluated against detailed experimental data.

8 Future research

The key future research required in the area of methane centres on biogenic methanes impact on global warming. Given the fact that methane is a short-lived gas there is increasing questions around its impact on climate change. There is a requirement for the IPCC and LCA methodologies to be relooked at in this context. It would be expected that the over-riding conclusions from this research will be that the impact of ruminant agriculture on climate change maybe over-estimated. Further information can be found at Cain et al. (2019).

Breeding, animal husbandry and manure management

Chapter 3

The contribution of animal breeding to reducing the environmental impact of livestock production

Yvette de Haas, Wageningen University and Research, The Netherlands; Marco C. A. M. Bink, Hendrix Genetics Research, Technology & Services B.V., The Netherlands; Randy Borg, Cobb Europe B.V., The Netherlands; Erwin P. C. Koenen, CRV, The Netherlands; Lisanne M. G. 1 Introduction

The world human population is expanding, and the demand for food in the year 2050 is expected to be approximately 70% greater than in 2010 (FAO, 2009). Demand for meat and other livestock products is highly elastic to income (Delgado et al., 1999), and therefore as population affluence improves, the demand for livestock products will increase further. Also, the global human population is ageing, and older people typically consume larger quantities of animal-derived protein than children (Steinfeld et al., 2006). The expected 70% increase in food demand requires an annual increase in food production of

http://dx.doi.org/10.19103/AS.2020.0077.05

1.3% per annum. This increase in food demand requires an increased efficiency of food production, both animal and crop derived. Moreover, competition for land from other industries (e.g. biofuels) implies this increased animal and crop production must be achieved from an ever-declining land base. Although feed efficiency, as currently defined, is not synonymous with production efficiency, it undoubtedly will be a major contributor to increasing production from an ever-decreasing food-producing land base. The global production of red meat is expected to increase from 229 million tonnes in 1999–2001 to 465 million tonnes in 2050, while global milk production is expected to increase from 580 to 1043 million tonnes in the same period (Steinfeld et al., 2006). This increased production must, however, be achieved in an environmentally responsible and sustainable manner.

There is considerable commentary nowadays on climate change and its implications, as well as possible mitigation strategies. Animal production generates greenhouse gas (GHG) emissions as methane (CH_4) from enteric fermentation and manure, nitrous oxide (N_2O) from the widespread use of nitrogenous fertilizers and animal manure and carbon dioxide (CO_2) from the fossil fuels for energy usage plus land-use change. Methane, however, is not only an environmental hazard but is also associated with a loss of carbon from the rumen and therefore an unproductive use of energy (Johnson and Johnson, 1995). There is a wide variation in documented calculations of animal agriculture contributions to GHG (Herrero et al., 2011). O'Mara (2011) stated that animal agriculture is responsible for 8.0% to 10.8% of global GHG emissions based on calculations from the Intergovernmental Panel on Climate Change (IPCC), but if complete lifecycle analysis (i.e. accounting for the production of inputs to animal agriculture as well as the change in land use such as deforestation) is undertaken, this figure can be up to 18%. Cattle are the largest contributors to the global emission of CH_4 from enteric fermentation (O'Mara, 2011).

In December 2015, 195 nations signed the Paris Agreement. The Paris Agreement's central aim is to strengthen the global response to the threat of climate change. Therefore, in this century, the global temperature rise should at least be kept well below 2°C above pre-industrial levels. To pursue efforts to limit the temperature increase even further, a more stringent aim is set to a threshold of 1.5°C, instead of 2°C. Additionally, the agreement aims to increase the ability of countries to deal with the impacts of climate change and to make finance flows consistent with low GHG emission and climate-resilient pathways. All sectors have to reduce their environmental impact, including the livestock sector. In this chapter, we will review the current environmental impact of livestock species, show historical trends and quantify the contribution of animal breeding in reducing the environmental impact of livestock species.

Published by Burleigh Dodds Science Publishing Limited, 2021.

2 The environmental impact of livestock production

Animal production is responsible for 14.5% of total anthropogenic GHG emissions (Gerber et al., 2013). Approximately half of these emissions originate directly from animal production, whereas the other half comes from feed production. Of the total of 7.1 gigatonnes CO_2-equivalents produced by the global livestock sector, beef production is responsible for 41%, cattle milk production for 20%, pig meat production for 10%, chicken meat production for 6% and chicken egg production for 3%. The remaining 21% is produced by other species and purposes, like buffalo and small ruminants for milk and meat, and by draft power, manure as fuel, and so on (Gerber et al., 2013).

Several tools have been developed to assess the environmental impacts of animal agriculture on a product basis. One of these tools is FeedPrint (Vellinga et al., 2013; Wageningen Livestock Research, 2015). FeedPrint is a life cycle analyses (LCA) tool for the assessment of environmental impacts of animal production, especially GHG emissions, developed primarily for the Dutch animal feed industry. FeedPrint, therefore, contains a full database of animal feed ingredients and their respective impacts from cradle to farmgate, including, for example, fertilizer production and application, field emissions, energy use for field work, transport and feed production. Based on data available in this tool, we could show that the GHG emissions for the production of 1 kg of pig meat are higher than for 1 kg of broiler meat, followed by chicken eggs and dairy production (Fig. 1a). Although results differ between studies, this ranking is in line with, for example, De Vries and De Boer (2010) or Williams et al. (2006). The relatively low numbers of GHG emissions for the production of milk and eggs are mainly due to the high water content of these products compared to meat and the fact that animals do not need to be slaughtered to acquire the product. When values of GHG emissions are recalculated to per kg protein basis, numbers come much closer together, with broiler meat being among the best-performing products (De Vries and De Boer, 2010; Williams et al., 2006). Beef production is outside the scope of this chapter, but, in general, calculated GHG emissions per kg product and kg protein are much higher for beef than for the other animal products.

There are different sources of GHG emissions related to animal production. The best-known and most-investigated one is enteric methane (CH_4) emission from ruminants. For dairy production, animal-related CH_4 emissions account for over one-third of total GHG emissions (Fig. 1b). However, in general, about half of the GHG emissions related to animal production come from feed-production-related processes (Gerber et al., 2013). For poultry in The Netherlands, even more than 80% of GHG emissions are related to feed production (Fig. 1b), with CO_2 being the predominant contributor, followed by nitrous oxide (N_2O).

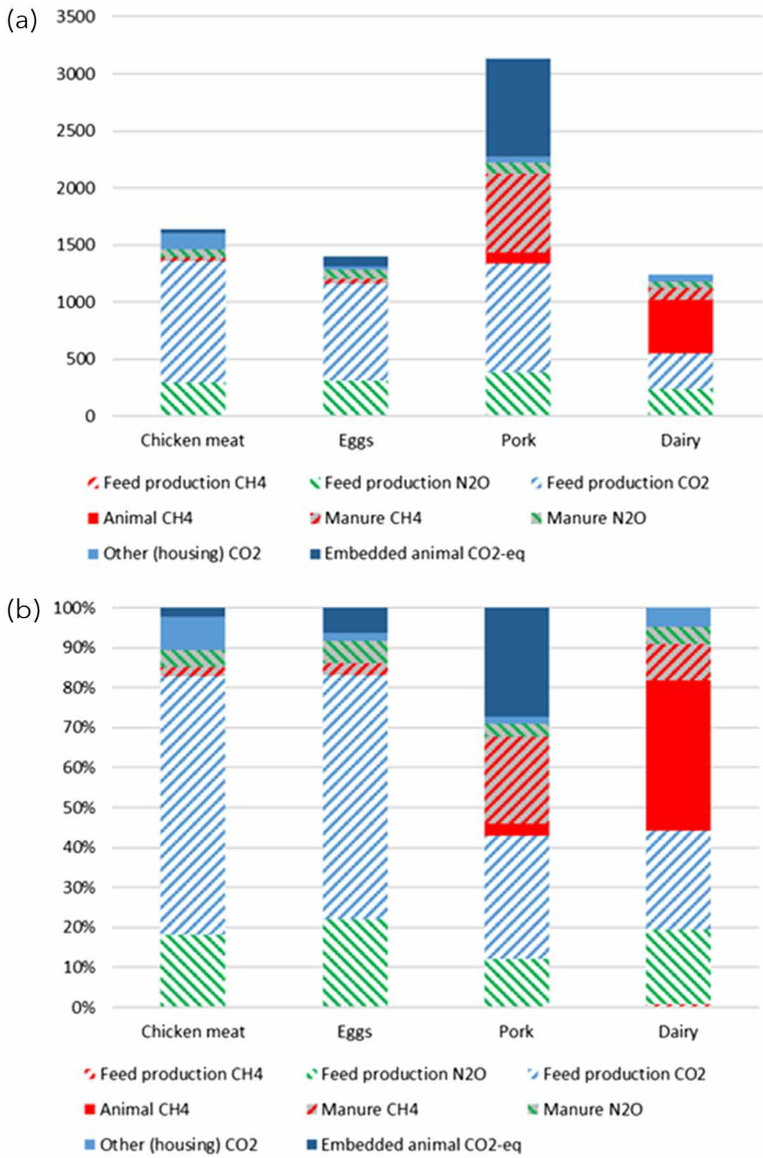

Figure 1 Greenhouse gas emissions (kg CO_2-equivalents) per tonne product (a) and relative contribution (%) to total greenhouse gas emissions (b) for four main animal products in The Netherlands based on FeedPrint (Vellinga et al., 2013; Wageningen Livestock Research, 2015). (Embedded animal = emissions caused by parent and young stock which are accounted to the final product).

Published by Burleigh Dodds Science Publishing Limited, 2021.

Next to the emission of GHG, nitrogen (N)– and phosphorus (P)–related environmental impacts, like acidification, eutrophication and depletion of P resources, are important when animal products are concerned (e.g. Thomassen and de Boer, 2005). These impacts could be assessed using lifecycle analysis but more straightforward by nutrient balances and derived efficiency parameters (Mu et al., 2016). The efficiency of N and P usage at animal level seems to be a relevant indicator for animal breeding, as animal breeding aims at improving animal production and efficiently using resources, resulting in a reduction of the environmental impact. The objective of this study was to quantify the contribution of animal breeding to reducing the environmental impact of the four major livestock species in The Netherlands, namely broilers (meat), laying hens (eggs), pigs (meat) and dairy cattle (milk).

In this chapter, we will show both the historical trends and the quantification of the contribution of animal breeding to the environmental impact of several livestock species: broilers, layers, pigs and dairy cattle. At the end of the chapter is a summarizing conclusion with recommendations.

3 Broilers: environmental impact and the contribution of breeding

3.1 Historical trends

Havenstein et al. (2003) performed a study where they compared the feed conversion of broilers genetically representative of animals for the years 1957 versus 2001 when fed broiler diets representative for diets fed in 1957 and 2001. Average body weights on 42 and 84 days of age for the 1957 broiler on the 1957 diets were 539 and 1430 g versus 2672 and 5520 g for the 2001 broiler on the 2001 diets, respectively. The 42-day feed conversion (FC) for the 1957 broiler on the 1957 diets was 2.34, and for the 2001 broiler on the 2001 diet was 1.63. The 2001 broiler on the 2001 feed was estimated to have reached 1815 g BW at 32 days of age with an FC of 1.47, whereas the 1957 broiler on the 1957 feed would not have reached that BW until 101 days of age with an FC of 4.42. Their conclusion was that 85–90% of the improvement in the performance of broilers is due to genetic selection, and 10–15% due to nutrition (Havenstein et al., 2003).

Havenstein et al. (2003) also showed that the slaughter weight increases over the years. This distorts the trend of the feed conversion ratio (FCR) over the years. Therefore, LEI (currently Wageningen Economic Research) calculated the trend in FCR corrected to a slaughter weight of 2.15 kg based on Dutch data, which showed that the FCR decreases with almost 1% per year (Fig. 2).

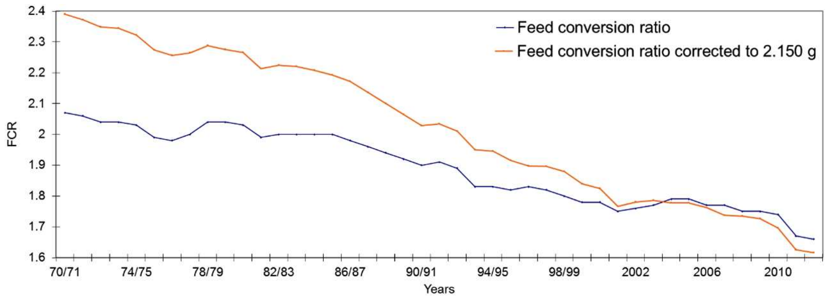

Figure 2 Trend in the feed conversion ratio of Dutch broilers (based on data from LEI (currently Wageningen Economic Research)).

Table 1 Summary data of broiler dataset with reference year, date of first and last placement, number of flocks, average number of animals per flock (Avg. numb.), average age at slaughter (Avg. age), average final body weight (after 1 day fasting) (Avg. weight) and average feed conversion ratio (Avg. FCR)

Year	First	Last	# flocks	Avg. numb.	Avg. age	Avg. weight	Avg. FCR
2014	07-05-13	28-08-14	12	33 105	37.2	2.2	1.66
2018	16-06-17	07-08-18	10	63 716	40.3	2.7	1.56

3.2 Quantification of contribution of animal breeding

3.2.1 Materials and methods

Data on the performance of Dutch commercial flocks were obtained from a broiler breeding company (Cobb Europe B.V., Boxmeer, The Netherlands) and contained 12 flocks with placement date in the period from May 2013 to August 2014, referred to as 2014, and 10 flocks from the period June 2017 to August 2018, referred to as 2018 (Table 1).

Feed composition was assumed to be equal in both periods and was derived from FeedPrint 2015.03 (Vellinga et al., 2013; Wageningen Livestock Research, 2015). Emissions of GHG related to the production of feed ingredients, and their N and P content, were collected from the database of FeedPrint 2018 (Wageningen Livestock Research, 2018).

Emissions of GHG are expressed in CO_2 equivalents (CO_2-eq.), which is a unit to express the contribution of different GHGs to their global warming potential (GWP), relative to CO_2. Methane (CH_4) and nitrous oxide (N_2O) have a GWP of respectively 36.75 (34 for biogenic CH_4) and 298 CO_2-eq (Myhre et al., 2013).

Efficiencies of N and P are expressed in percentages and calculated as N and P in output, for broilers in live animals, over input with feed. To express the output in kg N and P, body composition after 1 day fasting was based on Caldas (2015).

Published by Burleigh Dodds Science Publishing Limited, 2021.

3.2.2 Results

The environmental impact caused by GHG emissions from broiler production decreased with 1.6% per year, and N and P efficiency increased with 1.7% per year (Table 2). This decrease in environmental impact was fully caused by a decrease in FCR (Table 1, 1.5%), which was larger than expected based on a literature overview of the development of FCR, where FCR decreased with about 1%.

3.2.3 Discussion

As data were available only for the broiler growing phase, data analysis focused on this phase. This phase, however, is responsible for the vast majority of the GHG emissions of the whole broiler production chain (Fig. 1), with feed production in the broiler growing phase being responsible for 83% of total GHG emissions. Results, therefore, could be considered representative for the whole broiler production process.

The dataset used for this study was based on commercial flocks, instead of a research dataset. Therefore, it showed some peculiarities, for example, a considerable increase in flock size and age at slaughter, the latter also causing an increase in final body weight. These differences represent a global shift in slaughter weights for the broiler industry. However, for purposes of comparing GHG emissions, slaughter age and flock size differences could have contributed to an underestimation of the decrease in FCR, resulting in high reduction percentages. However, even with a more conservative estimation of 1% decrease in FCR, we could conclude that GHG emissions decrease and N and P efficiency increases with the current breeding goal for broilers.

4 Layers: environmental impact and the contribution of breeding

4.1 Historical trends

Pelletier (2018) provided an evaluation on the extent of and plausible reasons for the change in the life cycle environmental footprint of conventional Canadian

Table 2 Emissions of GHG and N and P efficiency of broiler production in 2014 and 2018

Year	GHG emissions (kg CO_2-eq/kg BW)	N efficiency (%)	P efficiency (%)
2014	1.43	53.2	46.0
2018	1.34	56.7	49.1

Published by Burleigh Dodds Science Publishing Limited, 2021.

egg production over a 50-year interval spanning from 1962 to 2012. For this, the historical trajectory of the industry toward more sustainable practices was elucidated. Supply chain acidifying emissions declined by 61%, eutrophying emissions by 68% and GHG emissions by 72%. Despite the >50% increase in annual egg production volumes – from 43.4 million dozen to 65.7 million dozen eggs in 1962 and 2012, respectively, the industry's overall environmental footprint actually decreased across all emissions and resource use domains considered. These observed changes are attributable to a combination of factors, including improved feed efficiency, changes in diet composition and manure management.

A similar study was performed by Pelletier et al. (2014) on the comparison of the environmental footprint of the egg industry in the United States in 1960 and 2010. They showed a similar reduction in GHG emissions by 71%.

The increase in egg production and the decrease in FCR were also present in Dutch data (Fig. 3), based on national data collated yearly (KWIN, 2011, 2013, 2017).

4.2 Quantification of contribution of animal breeding

4.2.1 Materials and methods

For laying hens a full LCA model was available (Van Winkoop, 2013), which takes into account parent stock and layers, both including their rearing phase.

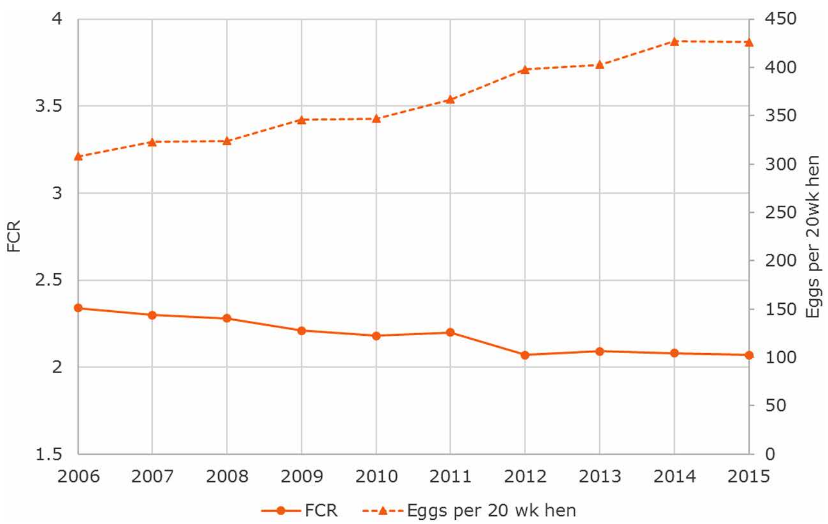

Figure 3 The trends in egg production and feed conversion ratios per Dutch laying hen from 2006 to 2015.

Published by Burleigh Dodds Science Publishing Limited, 2021.

For the calculation of genetic progress, however, only changes in the laying period were incorporated in the calculations.

Data on the development of modern commercial brown and white layer lines were obtained from a breeding company (Institut de Sélection Animale B.V. a Hendrix Genetics Company, Boxmeer, The Netherlands) and contained for the brown layers data for the years 2008 and 2017 (Table 3) and for the white layers for the years 2009 and 2017 (Table 3). These data should be considered to be from top-performing flocks and were available for the egg production phase only. These data were used to assess the rate of improvement, as this was anticipated to be representative for top-performing and average-performing commercial flocks. For a full LCA assessment, however, more data were needed and were derived from the 'commercial product' guides (Institut de Sélection Animale B.V. a Hendrix Genetics Company, Boxmeer, The Netherlands; Table 4). These data were also used for calculating environmental impacts for the commercial situation. It should be noted that these guides should hold for a broad range of commercial settings, including more challenging environments.

Feed composition was assumed to be equal in all periods and was derived from FeedPrint 2015.03 (Vellinga et al., 2013; Wageningen Livestock Research,

Table 3 Summary data of top-performing brown and white layers with reference year, total life time, mortality rate during laying period (from 18 weeks onwards), number of eggs per housed hen, total egg mass and average feed conversion ratio (Avg. FCR) during the laying period

Line	Year	Lifetime (weeks)	Mortality rate (%)	Eggs per housed hen	Total egg mass (kg)	Avg. FCR
Brown	2008	75	6	324	20.6	2.25
	2017	90	5	429	27.0	2.14
White	2009	75	6	329	20.7	2.16
	2017	90	5	433	27.3	2.05

Table 4 Summary data of commercial brown and white layers, total life time, mortality rate during laying period (from 18 weeks onwards), number of eggs per housed hen, total egg mass and average feed conversion ratio (FCR) during the laying period

Line	Lifetime (weeks)	Mortality rate (%)	Eggs per housed hen	Total egg mass (kg)	Avg. FCR
Brown	80	7.8	353	22.1	2.29
White	90	7.5	411	25.9	2.24

Source: Product guides, Institut de Sélection Animale B.V. a Hendrix Genetics Company, Boxmeer, The Netherlands.

2015). Emissions of GHG related to the production of feed ingredients, and their N and P content, were collected from the database of FeedPrint 2018 (Wageningen Livestock Research, 2018).

Emissions of GHG are expressed in CO_2 equivalents (CO_2-eq.), which is a unit to express the contribution of different GHG to global warming, their global warming potential (GWP), relative to CO_2. Methane (CH_4) and nitrous oxide (N_2O) have a GWP of, respectively, 36.75 (34 for biogenic CH_4) and 298 CO_2-eq (Myhre et al., 2013).

Efficiencies of N and P are expressed in percentages and calculated as N and P in output over input with feed. For laying hens, only eggs were considered as output and N and P contents were calculated with N and P content of raw egg (edible part; Finglas et al., 2015) applied to total egg mass (Tables 3 and 4) corrected for 15% shells (pers. Comm., Institut de Sélection Animale B.V. a Hendrix Genetics Company).

4.2.2 Results

Results for commercial brown and white layers (Table 5) show that impacts do not differ much.

The environmental impact caused by GHG emissions from egg production decreased by 0.7% per year for brown layers and by 0.9% per year for white layers (Table 6). N and P efficiency increased with 0.5% per year for brown layers and with 0.7% per year for white layers. The decrease in environmental impact was only partly caused by a decrease in FCR as also the production period was extended, due to genetic progress (Table 3). Especially for the assessment of GHG emissions, for which a full LCA including parent stock and rearing was used, the extended production period considerably contributed to the reduction of environmental impacts.

4.2.3 Discussion

As data for calculating genetic progress were only available for the laying period, total improvements could be expected to be larger when also improvements

Table 5 Emissions of GHG and N and P efficiency of egg production by commercial brown and white laying hens

in parent stock and rearing would be taken into account. The laying period, however, is responsible for the vast majority of the GHG emissions of egg production (Fig. 1), with feed production in the laying period being responsible for 83% of total GHG emissions.

Based on this analysis we conclude that genetic progress is considerable in both brown and white layers, where white hens currently perform better and also improve faster than brown hens with respect to the environmental impact of production. As most brown hens produce brown eggs and most white hens produce white eggs and consumers in some countries prefer brown over white eggs, both types of layers still exist.

5 Pigs: environmental impact and the contribution of breeding

5.1 Historical trends

The feed efficiency of growing pigs has been a matter of serious commercial and scientific interest since at least 1970, but early recording technology made it difficult to produce accurate feed intake data at the individual level (Knap, 2009). Since electronic feeders were introduced, the pig breeding industry has been making good genetic improvement in feed conversion ratio (FCR), but this has been mainly due to genetic improvement of growth and body composition traits. A 35-year time trend illustrated by Knap and Wang (2012) shows very clearly that the average commercial FCR has come down from 3.3 to 2.6, with a quite considerable bandwidth among terminal crosses which does not show any signs of narrowing over time (Fig. 4).

5.2 Quantification of contribution of animal breeding

5.2.1 Materials and methods

Data from an experiment, which is described in Sevillano et al. (2018), were obtained from a pig breeding company (Topigs Norsvin Research Center B.V.,

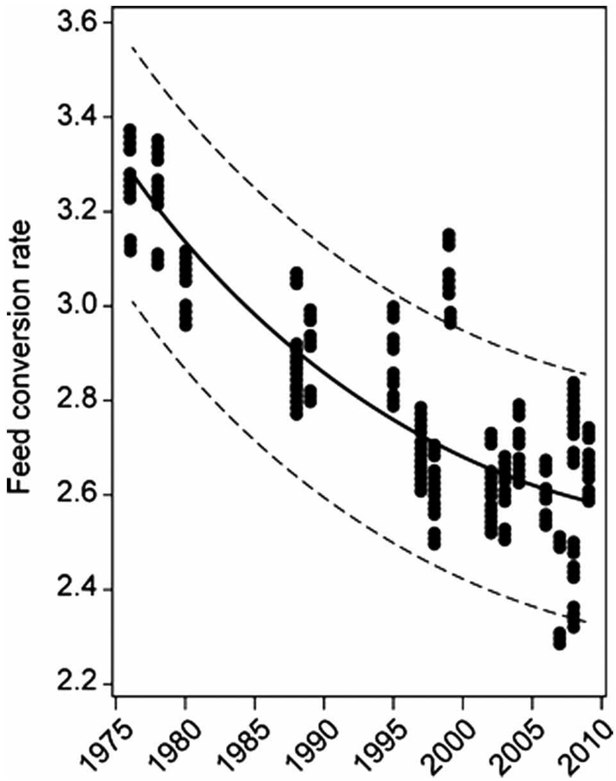

Figure 4 Time trends of feed conversion ratio in grower-finisher pigs of 103 terminal crosses, as recorded in public commercial product evaluation trials in Denmark, France, Germany, The Netherlands, UK and the United States. Unadjusted phenotypic population means, data from 18 literature and internet sources. The trend line is a spline interpolation plot through the data, with its 95% confidence limits. Figure copied from Knap and Wang (2012).

Beuningen, The Netherlands). In this experiment a corn/soybean meal (CS) diet and a cereals/alternative ingredient (CA) diet was fed to intact boars and gilts. The CS diet resembles American practice, but the impact of feed ingredients was calculated as fed in The Netherlands, which means, for example, that soybean meal mainly originated from Argentina and Brazil. The CA diet resembles Dutch practice, with many by-products in the diet. For calculating genetic progress, data from 400 pigs in 2014 (December 2013–May 2014) and 401 pigs in 2016 (November 2015–March 2016) were used (Table 7). Data only considered the growing-finishing phase (i.e. from 22 kg to approximately 120 kg of live weight). Feed composition was derived from Sevillano et al. (2018).

Emissions of GHG related to the production of feed ingredients, and their N and P content, were collected from the database of FeedPrint 2018

(Wageningen Livestock Research, 2018). Emissions of GHG are expressed in CO_2 equivalents (CO_2-eq.), which is a unit to express the contribution of different GHG to global warming, their global warming potential (GWP), relative to CO_2. Methane (CH_4) and nitrous oxide (N_2O) have a GWP of respectively 36.75 (34 for biogenic CH_4) and 298 CO_2-eq (Myhre et al., 2013). Efficiencies of N and P are expressed in percentages and calculated as N and P in output over input with feed. Protein deposition was calculated as described by Sevillano et al. (2018) and was used to calculate N deposition, whereas P deposition was calculated based on Pettey et al. (2015).

5.2.2 Results

The environmental impact caused by GHG emissions from pig production decreased by 0.6–0.7% per year dependent on the diet (Table 8). Nitrogen efficiency increased by 1.6–1.7%, whereas P efficiency increased by 0.4–0.6% over the two years. On all environmental indicators, boars performed slightly better than gilts. The N efficiency could be calculated more precisely than P efficiency because back fat thickness was measured in the experiment and used to calculate protein deposition. Therefore, the decrease in environmental impact was not only caused by a decrease in FCR (lower feed intake at same growth rate; Table 7) but also by higher protein deposition at similar growth.

5.2.3 Discussion

Data analysis focused on the grower-finisher phase because good-quality, detailed information was available for this phase. Furthermore, the chosen method for GHG emission calculation accounted for the effect of feed production on GHG emissions only. The full analysis of the whole production cycle could have given different results, as Groen et al. (2016) showed that CH_4 emissions from manure management, crop yields and reproduction performance are important processes determining whole chain GHG emissions from pig production. These results correspond well with data, shown in Fig. 1, where reproduction and rearing phase (27%) and emissions from manure (25%) contribute considerably to the total impact of pig production. Groen et al. (2016), however, also showed that FCR is the most important factor, with the highest influence on whole chain GHG emission from pig production. This is in agreement with the data shown in Fig. 1, where feed production alone explains more than 40% of GHG emissions from pig production.

Differences in the environmental impact of pigs, fed either a CS or CA diet, were most clear in P efficiency, caused by low digestibility of P in some by-products in the CA diet (e.g., rapeseed and sunflower meal). When the CS diet would have been calculated as fed in the country where corn and soybean

Table 7 Summary of pig dataset on corn/soybean meal (CS) and cereals/alternative ingredients (CA) diet with sex (Male = M, Female = F), reference year, average daily feed intake (ADFI) on starter, grower and finisher feed, average daily gain during the growing-finishing phase (ADG), average final empty body weight at slaughter and protein deposition during the growing-finishing phase

CA	F	2016	1.76	42.5	25.5

were grown, GHG impacts of pigs fed the CS diets probably would have been lower.

From this analysis we could conclude that current breeding goals decrease the environmental impact of producing pig meat and that boars are more efficient and, therefore, have a lower environmental impact than gilts.

6 Dairy cattle: environmental impact and the contribution of breeding

6.1 Historical trends

Over the past 100 years, the range of traits considered for genetic selection in dairy cattle populations has progressed to meet the demands of both industry and society (Miglior et al., 2017). At the turn of the twentieth century, dairy farmers were interested in increasing milk production; however, a systematic strategy for selection was not available. Organized milk performance recording took shape, followed quickly by conformation scoring. Methodological advances in both genetic theory and statistics around the middle of the century, together with technological innovations in computing, paved the way for powerful multi-trait analyses. As more sophisticated analytical techniques for traits were developed and incorporated into selection programs, production began to increase rapidly, and the wheels of genetic progress began to turn. By the end of the century, the focus of selection had moved away from being purely production oriented toward a more balanced breeding goal. This shift occurred partly due to increasing health and fertility issues and partly due to societal pressure and welfare concerns. Traits encompassing longevity, fertility, calving, and health, have now been integrated into national selection indices.

With these indices, milk production is still increasing per year. As shown in Fig. 5, milk production in The Netherlands has increased by 46% between 1990 and 2017. Because of the increased milk production, the feed intake has increased but to a lesser extent than milk production; therefore, the efficiency of dairy production (kg milk/kg feed) has improved over the years.

6.2 Quantification of contribution of animal breeding

6.2.1 Selection indices

Selection indexes are utilized by livestock breeders of many species around the world and aid in the selection of animals for use within a breeding program where there are several traits of economic or functional importance. Selection indexes provide an overall 'score' of an animal's genetic value for a specific purpose and are calculated based on weightings placed on individual traits that are deemed to be important for that purpose. Selection indexes assist producers in making 'balanced' selection decisions. The derivation of a selection index starts with the definition of the overall breeding objective.

The next stage in developing a selection index is to calculate economic values for each trait, generally with a bio-economic model, where the economic value is the increase in revenue from a unit change of a trait while everything else is held constant. Then, selection index theory (Hazel, 1943) is commonly used to calculate the most appropriate index weights and responses to

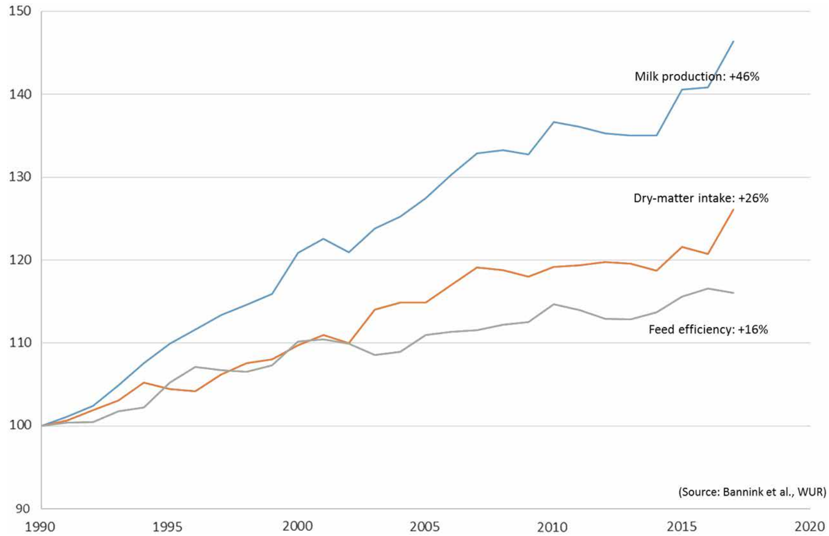

Figure 5 Trends in milk yield, feed intake and feed efficiency of the Dutch dairy cattle population between 1995 and 2017 (extended and based on Bannink et al. (2011)).

Published by Burleigh Dodds Science Publishing Limited, 2021.

selection for a set of traits given the genetic and phenotypic (co)variances and the economic values of traits in the index. The resulting selection index is the sum of n estimated breeding values (EBVi) for each trait multiplied by their respective index weights b_i.

$$\text{Index} = b_1\text{EBV1} + b_2\text{EBV2} + \ldots + b_n\text{EBVn}$$

6.2.2 Quantification effect of breeding

In our case, we started with a selection index representing the national breeding goal for dairy cattle of The Netherlands (CRV, 2018). The Dutch national breeding goal consists of milk component traits, longevity, health traits (udder health, claw health), fertility traits (interval first-last insemination, calving interval), conformation traits (for udder and for feed and legs), calving traits (calving ease and vitality of calves) and feed efficiency (Table 9). We added enteric CH_4 emissions to this index as a correlated trait. Genetic parameters were obtained from the literature (Lassen and Lovendahl, 2016). The heritability for enteric CH_4 production is 0.21, and genetic correlations with milk lactose, protein, fat and dry matter intake are 0.43, 0.37, 0.77 and 0.42 (−0.42 for feed saved), respectively. Correlations between enteric CH_4 production and other traits in the breeding goal were set to zero. All phenotypic correlations were also set to zero.

Selection index calculations show how much the traits are predicted to change per year. This is plotted in Fig. 6 for both CH_4 production (g/d) and for CH_4 intensity (CH_4 production expressed per kg of milk). It shows that CH_4 production per cow will steadily increase as a correlated response to selection for the current breeding goal. However, the methane intensity drops. Further reductions could be achieved when actively selecting on lower methane-emitting cows, by adding more weight on CH_4 in the national breeding goal. Selecting actively against methane would result in healthy, fertile, long-living cows that emit less CH_4. Actively selecting against CH_4 emission, however, requires large-scale recording of individual CH_4 emissions.

6.2.3 Discussion

The predicted future trends in enteric methane production are based on the genetic parameters used in the selection indices. The correlation of 0.77 between protein yield and enteric methane production is strong and impacts the results. Further research is needed to estimate reliable genetic parameters between enteric methane production and other traits of interest (e.g., the traits in the breeding goal). Estimating these genetic parameters requires that a large enough dataset is built, which includes records of enteric CH_4 emission of many individual cows.

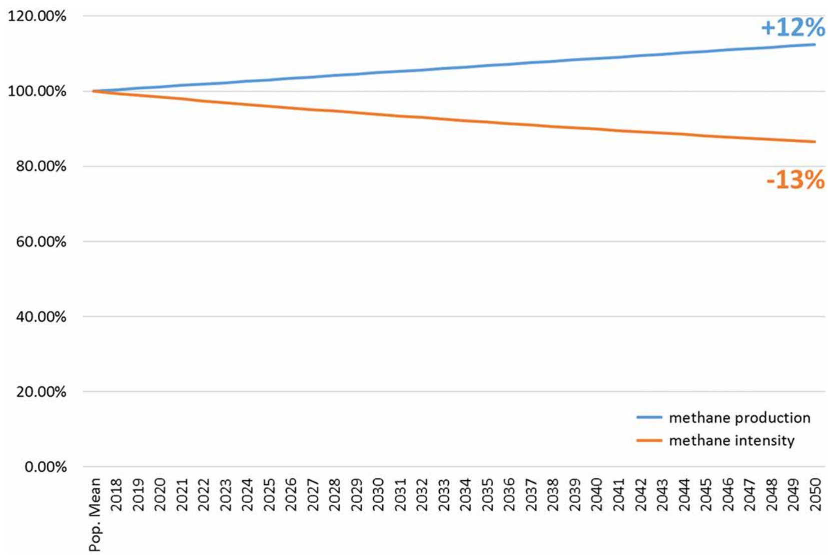

Figure 6 Expected future trends in CH_4 production (g/d) and CH_4 intensity (g/kg milk) for the Dutch dairy cattle population with breeding on the current national breeding goal.

7 Conclusion

Animal production is responsible for 14.5% of total anthropogenic GHG emissions. Approximately half of these emissions originate directly from animal production, whereas the other half comes from feed production. Animal breeding aims at improving animal production and efficient use of resources, which results in a reduction of the environmental impact. The objective of this study was to quantify the contribution of animal breeding in reducing the environmental impact of the four major livestock species in The Netherlands, namely broilers (meat), laying hens (eggs), pigs (meat) and dairy cattle (milk).

A literature review was performed to assess the current status of and historical trends in environmental impact, mainly focused on GHG emissions, and general performance criteria, like feed efficiency and lifetime production. Emissions related to the feed production dominate the impacts by broilers and laying hens. For pigs, the emissions during feed production and from manure are important contributors. For dairy cattle, as being ruminants, enteric methane emission is a large contributor to total GHG emissions. Historical trends show considerable improvements in efficiency over the last decades, in which breeding has an important role. The literature review showed that the contribution of breeding to reducing the environmental impact of animal production is led by an indirect response through selection on increased efficiency.

Published by Burleigh Dodds Science Publishing Limited, 2021.

Also a quantitative assessment was made on the current environmental impact of the four animal products and the effect of recent genetic improvements. For broiler meat, chicken eggs and pig meat the focus was on GHG emissions, and nitrogen (N) and phosphorus (P) efficiency, whereas for dairy the focus was on enteric methane emissions, an important contributor to GHG emissions. Data were partly provided by breeding organizations, that is, the partners in the Breed4Food consortium (www.breed4food.com).

The analyses in this chapter demonstrate that animal breeding can provide a mitigation tool to lower the environmental impact of livestock species. Genetic improvement of livestock is a particularly cost-effective technology, producing permanent and cumulative changes in performance:

- For broilers, it was shown that GHG emissions decreased with 1.7% and N and P efficiency increased by 1.6% per year due to the current breeding goals.
- For laying hens, white and brown hens were considered and it was concluded that white hens currently have a lower GHG impact and better N and P efficiency than brown hens and that improvements over the past 10 years went faster for white hens.
- For pigs, data were available from a well-controlled study with two diets and animals divided by sex over a time frame of two years. Results showed that in the growing-fattening phase of pigs, GHG emissions decrease and N and P efficiency increase with the current breeding goal. Furthermore, boars had a lower environmental impact than gilts.
- For dairy cattle, results showed that with the current breeding goal, CH_4 production per cow per day increases but CH_4 intensity (i.e. CH_4 production per kg milk) decreases.

All reported results are achieved without specific selection on environmental traits, but as an indirect response of the current breeding goals for each species, which is a combination of health, growth and (feed) efficiency. If direct selection of environmental traits is desired, recording of new traits is required, for example, N and P contents of meat and eggs and methane emission of individual dairy cows.

Direct measurement of GHG impact of animal production is difficult, but not impossible, which hampers active selection against GHG emissions of animals. In the short run, indirect selection against GHG emissions could be further optimized by putting more selection pressure on efficiency traits, while accounting for the effects on other important traits, for example, health, longevity and reproduction. In the long run, recording schemes could be set up to either record the desired traits on commercial farms (for dairy) or in parental stock (for pigs and poultry).

The LCA analyses performed in this study could be further improved by also including information of the parent stock and rearing phases. It is expected that when including genetic progress in parent stock and rearing phases of parents and commercials, the contribution of genetics to reduce GHG emissions per kg product has an even bigger impact.

Chapter 4

Quantifying the contribution of livestock health issues to the environmental impact of their production systems

Stephen G. Mackenzie, Trinity College Dublin, Ireland; and Ilias Kyriazakis, Queen's University of Belfast, UK

1 Introduction

There is an increased interest about the consequences of animal health on the environmental impact of livestock systems. This should not be surprising given the association between animal health and the efficiency with which they utilise the important resource inputs to livestock production, which are key factors in determining the environmental impact of these systems (de Vries and de Boer, 2010; McAuliffe et al., 2016; Tallentire et al., 2018). Animal health has major consequences on how animals utilise their resources, including feed, increasing inputs, including medication, and reducing outputs, such as amount of milk or meat produced per animal, or per unit of input (Perry et al., 2018).

While the consequences of animal health for the environmental impacts of livestock systems have been addressed to a limited extent, for example (ADAS, 2015; Mostert et al., 2018; Skuce et al., 2016), to date the focus has been almost exclusively on the implications of conditions which impact on ruminant systems and the implications of these for greenhouse gases (GHGs). This focus is natural, due to the high profile nature of both the issue of anthropogenic GHGs and the large contribution of ruminant systems to this issue (Gerber

http://dx.doi.org/10.19103/AS.2020.0077.07

et al., 2013). However, the environmental issues facing the livestock industry are much broader than this: livestock systems have a major impact on global land use (Weindl et al., 2017), water use (Doreau et al., 2012) and the acidification of soils and waterways (Leip et al., 2015), to name just some of the issues. In addition, the majority of meat consumed globally is from pigs and poultry (FAO, 2019), but these production systems cause less GHGs than ruminants (Gerber et al., 2013). With consumption of non-ruminant livestock products expected to increase dramatically to 2050 (FAO, 2011), non-ruminant animal farming faces concerns around the impact of feed production (particularly the associated land and water use), and the pollution caused by their manure (de Vries and de Boer, 2010; Poore and Nemecek, 2018). These issues represent important future challenges that the industry must overcome to maintain its public acceptability.

Climate change is expected to exacerbate animal health issues, which in turn would affect the environmental impact of livestock systems, thus creating a vicious circle that links animal health, environmental impact and climate change. A combination of changes in air temperature, precipitation, as well as the frequency and magnitude of extreme weather events are all expected to have a negative impact on outcomes for livestock health and welfare (Lacetera, 2019). Climate change may also affect the quantity, quality and composition of animal feed, both directly and indirectly. The increase in the incidence of fungal contamination of animal feedstuffs is one such indirect effect on animal health due to increased concentration of mycotoxins in the feed (Bernabucci et al., 2011).

The focus of our chapter is on the environmental impact of endemic livestock health challenges that lead to deterioration in animal health, and on the potential impacts arising from their mitigations. This is because, while epidemics may have devastating effects on livestock systems, these would be usually controlled through stamping out by eradication of affected herds and flocks (Geering et al., 1999). In some instances, where large-scale eradication is unacceptable, other control measures, such as vaccination programmes supplemented by other disease control measures, can be used to eliminate many epidemic health and welfare challenges (Roth, 2011). The dearth of information on this issue in relation to the environmental impacts of epidemic health challenges for livestock means we are unable to give the latter issue detailed consideration in our chapter.

The first part of our chapter concentrates on the potential of animal health to affect the environmental impact of livestock systems. Because in several ways animal health affects environmental impact of livestock, that is, through decreases in productivity and efficiency and increases in culling, applies to all livestock systems, we review the consequences of animal health on resource inputs and outputs across livestock systems. This includes the implications for a variety of important variables for environmental impacts, such as the utilisation of nutrients in feed, mortality/culling rates, breeding performance and also milk quality in the case of dairy systems (ADAS, 2015). Subsequently, we review the literature to date which has quantified the impact of health challenges for the environmental impacts of livestock systems.

The potential of successful health interventions to mitigate negative environmental impacts represents a point of synergy between concerns around environmental sustainability and animal welfare, both of which represent 'hot topics' in the discourse surrounding the livestock industry and its sustainability. This is a topic that has been under-represented in the literature, both because of the difficulty to address it in practical terms, and because of a lack of framework that will allow us to do so (Rushton, 2017). The challenges associated with modelling health interventions and their potential to mitigate environmental impacts constitute the last section in our chapter. This part has a heuristic value, given the current lack of information in the literature.

2 Consequences of health challenges on resource inputs and outputs of the animal and production system

Given that a large part of the environmental impact assessment of livestock systems is done on the basis of the principle of mass flows (FAO, 2016a, 2018), below we review the consequences of health challenges on how an animal uses the nutrient resources it consumes. One of the most profound consequences of health challenges is a decrease in the efficiency of how nutrient resources are used (Kyriazakis and Houdijk, 2007; Sandberg et al., 2007), which in turn will have consequences on the fate of nutrient excretion. However, in addition to this, health challenges may have indirect consequences on the resource inputs required to produce the key outputs of livestock production systems, such as milk, eggs and meat. These indirect consequences would arise from the fact that system outputs may need to be discarded because of their quality or for safety reasons; individual animals may need to be culled because their performance is no longer considered economically viable by their keepers; and ultimately some animals may succumb to the consequences of the health challenges. Alternatively, some health challenges would require inputs from pharmaceuticals or specialist management, which in turn utilise resources for their production. For these reasons, both the direct and indirect consequences of health challenges on resource inputs into animals and their production system are considered below.

2.1 Anorexia during health challenges

A reduction in the voluntary food intake, henceforth called anorexia, is associated with most challenges that affect livestock health (Kyriazakis, 2014). During subclinical infections, anorexia manifests as a ~20% reduction in voluntary food intake and is frequently the only indication that an animal's health is being challenged (Hite et al., 2020; Kyriazakis et al., 1998). In more severe infections, there may be a complete cessation of eating, but this is usually associated with severe infection outcomes, such as death (Lough et al., 2015). Anorexia is also associated with metabolic diseases, such as acidosis or ketosis in ruminants, and is often used as an indicator that the management of the animals has not been appropriate and requires attention (González et al., 2008). Ketosis in lactating cows, which results from a severe energy gap between intake and output, may lead to complete cessation of eating, but intake returns almost immediate to its previous levels after appropriate treatment (Andersson, 1988; Berge and Vertenten, 2014).

With all other things being equal, anorexia during health challenges would be expected to lead to a reduction in animal performance, and therefore, the animal would need to take more time to achieve the same production output. This in itself would imply that the animal would need to divert proportionally more resources in maintaining itself for a longer period of time, and therefore the efficiency with which its food is being utilised would be reduced. However, studies that compared the performance of infected animals with that of uninfected animals that have been offered the same amount of food (usually called pair-fed animals), suggest that the former utilise the same amount of food less efficiently than the latter (Holmes, 1993). A frequent observation is that infected animals grow more slowly and deposit less protein and fat in their bodies than the uninfected pair-fed animals (Holmes, 1993; Escobar et al., 2004). This implies that infection per se is associated with other effects in feed utilisation, which will be detailed below.

2.2 The effects of infectious challenges on digestion, absorption and utilisation of nutrient resources

Due to their significance, the effects of infectious challenges on the digestion, absorption and utilisation of resources has been studied most extensively during gastrointestinal parasitism. Depending on the site of infection, digestion and absorption of nutrients may be significantly affected (Sandberg et al., 2007). In ruminant animals parasitized with gastrointestinal parasites, a reduction in nutrient digestion has been observed, especially when the parasites affect the organs of digestion. This is the case of parasitism with the abomasal parasites, *Ostertagia ostertagi* in cattle and *Teladorsagia circumcincta* in sheep, as the gastric glands of the abomasum are damaged (Holmes, 1993; Ceï et al., 2018). Similarly, whether the process of nutrient absorption is affected would depend on the site of gastrointestinal parasitism and its effect on organ integrity. Several gastrointestinal parasites in ruminants are associated with gastrointestinal damage, such as epithelial and mucus loss (Coop and Kyriazakis, 1999; Mavrot et al., 2015). In the case of blood-sucking parasites, such as *Haemonchus contortus*, blood and plasma loss is also the outcome of the infection. All these effects are associated with the loss of considerable quantities of protein into the digestive tract of the host animal (Holmes, 1993).

Similar observations have been reported in non-ruminant animals parasitized by gastrointestinal parasites. The apparent digestibility of protein was reduced during pathogen challenges with parasitic worms in pigs and was smaller for pathogens that affected mainly the stomach, compared with those affecting latter parts of the gastrointestinal tract (Hale et al., 1985; Midha et al., 2018) . For instance, in broilers infected with the small intestine coccidia *Eimeria acervulina*, the apparent ileal digestibility of every single amino acid in the food was reduced by ~5% (Rochell et al., 2016). As well as damaging parasitized enterocytes, *Eimeria* parasitism increases plasma protein leakage and mucogenesis, thus increasing endogenous amino acid flow.

Infectious challenges are expected to increase the (maintenance) requirements for nutrient resources through a variety of routes: (1) animals need to repair damage to its tissues or replenish lost fluids as a direct consequence of infection. (2) Fever, which accompanies several infections would increase energy expenditure and hence requirements. (3) Infected animals need to mount an immune response in order to cope with the infection and eventually overcome it. Hosts may respond with innate or acquired immunity, or a combination of these, depending on the type of challenge and the stage of a particular infection (Sandberg et al., 2007).

The Sandberg et al. (2007) investigations were the most comprehensive attempt to quantify such effects on nutrient resource requirements. It is difficult to make generalisations about these quantitative effects, given that different infectious challenges would increase the different sources of increased requirements to different extents, but some suggestions can be made. As far increases in energy requirements are concerned, it has been suggested that maintenance requirements to be 1.7–2.2 times as great in challenged as opposed to non-challenged animals. There appears to be highly specific pathogen differences, with the greatest energetic cost occurring for infectious challenges associated with fever, especially during the stages of acute infection (Sandberg et al., 2006). Otesile et al. (1991) challenged pigs with *Trypanosoma brucei* and found that they had a significant increase (1.7 times) in energy maintenance requirements than healthy controls.

In the case of increased protein requirements due to infection challenges, it has been estimated that protein maintenance animals challenged by a varied of pathogenic and non-pathogenic challenges varied from 1.3 times to 4 times that in the healthy. Webel et al. (1998) found that chicks challenged by a non-pathogenic antigen had increased lysine maintenance requirements, tended to have increased threonine maintenance requirements, but there was no effect for arginine requirements. Different effects on maintenance may suggest that amino acid requirements are affected to different extents and that this needs to be accounted for the changes in their utilisation during infectious challenges.

2.3 The effects of non-infectious challenges on digestion, absorption and utilisation of nutrient resources

Production diseases, which arise from the management of usually high-producing animals, are a good case to consider the effect of non-infectious challenges on digestion, absorption and utilisation of nutrient resources. They include the group of diseases usually referred to as 'metabolic diseases', such as rumen acidosis and ketosis in dairy cows, pregnancy toxaemia in ewes and ascites in broilers. Most of these conditions, at least in their subclinical form, may predispose animals to susceptibility to infectious challenges, and therefore, it is difficult to disassociate their consequences from them. For example, while it would be expected that the nutrient resource requirements which are associated with lameness would be very small, several metabolic diseases with significant resource requirements are a predisposing factor for lameness. Their subclinical forms are also very widespread, for example, sub-clinical ketosis was found to have an average prevalence of 24.1% in a global study of the issue in dairy herds (Brunner et al., 2019).

Sub-acute ruminal acidosis (SARA) in dairy cows is a good case in point for its effects on nutrient digestion and use. SARA is estimated to have an overall prevalence in dairy herds of 11–33% in studies that have investigated the issue (Kleen and Cannizzo, 2012). It arises from feeding of high-energy density diets to meet the energy requirements of high-yielding cows, which leads to reduced rumen pH and increased risk of acidosis. Ruminal acidosis can cause erratic fluctuations in feed intake, and low rumen pH causes the cow to go 'off-feed', which reduces the production of fermentation acids, allowing the pH to recover. Changes in the rumen environment lead to reduced digestion of fibrous ingredients and lowers the efficiency of microbial protein production in the rumen (Beauchemin, 2007), thus affecting directly digestion and absorption of nutrient resources. At the same time, low rumen pH leads to inflammatory changes both locally, including damage to the gastrointestinal tract wall, and systemically, associated with an acute phase response (Bertoni et al., 2008). This acute phase response may not only be associated with increased nutrient resource requirements, but also with significant changes in the energy and lipid metabolism in different body tissues. Due to the nature and the focus of the condition, and the difficulty in disassociating these effects, they have not been quantified separately.

Because most production diseases are associated with negative nutrient resource balance and the animal needs to sacrifice its body or tissue mastitis reserves for the sake of continuing the production of milk or eggs, there would be less nutrient resources available for the maintenance of ‘integrity’ functions, such as defences to pathogens. This would make the animal more vulnerable to challenges, previously easy to control. This explanation has been put forward for the occurrence of mastitis in high-yielding dairy cows (O’Rourke, 2009), which are less able to direct resources towards the functions of innate and acquired immunity.

2.4 Indirect consequences of health challenges on system inputs and outputs

In growing animals, the usual consequences of health challenges are increases in their mortality and decreases in their growth rate and feed efficiency. This is especially the case with endemic viral diseases, affecting non-vaccinated animals. For example, infection with the porcine reproductive and respiratory syndrome virus (PRRSv) resulted in an additional 11% increase in mortality among nursery pigs and 6% increase among growing pigs in the United States pig herds (Kliebenstein et al., 2004). The same reports suggest increased use of medication among PRRSv-affected herds, although the increase is not sufficiently quantified.

In reproducing animals, health challenges lead directly or indirectly to reproductive failure/fertility and culling. In herds endemically infected by PRRSv, there is a substantial increase in the percentage of abortions per sow year, and decreases in weaned pigs produced per sow year and number of farrowings per sow year (Valdes-Donoso et al., 2018). Similarly, it has long been established that there is a clear association between health and fertility for cows affected by conditions such as mastitis, lameness and ketosis (Bertoni et al., 2008). In all these cases, the percentage of animals which are prematurely culled or die from the conditions may be substantial.

Finally, health challenges may lead to product loss from affected animals. Such losses may be associated with the condemnation or discard of milk, and the partial or whole condemnation of carcasses from normal or emergency slaughter (Garcia et al., 2019). Specifically, during mastitis the condemnation of milk is associated with increased inflammatory cell content, which affects milk quality, and antibiotic residues in the milk due to treatment of infected udders. This is on top of the reduction in milk yield and any culling of cows.

Above, we developed a framework which enables to view the effects of health challenges on nutrient resource requirements, which in turn enables to quantify their effects on mass flows. The framework should allow us to review and account for the effect of health challenges on environmental impact, and this is done below.

3 Quantifying the environmental impact of health challenges

In this section, we review the literature published to date presenting quantitative results on the environmental impacts of health issues in livestock production systems. The life cycle assessment (LCA) framework is the widely accepted way to holistically assess the environmental impact of livestock systems (FAO, 2016b, 2016c, 2018), although there are no specific guidelines when applying the approach to health issues. While there have been a large number of environmental impact studies of livestock systems as reviewed by Poore and Nemecek (2018), a relatively small proportion of these focus on the implications of animal health issues for the environmental impacts of livestock production. These studies have begun to quantify the link between animal health issues and the environmental impacts of livestock systems, and they can broadly be grouped into two categories:

1. Studies that model the environmental impacts caused by the existence of a health issue.
2. Studies that investigate the potential of specific treatment strategies to mitigate a health issue and the potential implications for the environmental impacts of the production system.

Both approaches can be useful exercises when used appropriately. In the first category, approaches can be entirely hypothetical and take a broad view across multiple different diseases to understand where the greatest potential benefits for targeted treatment strategies lie, both in terms of environmental impact mitigation, and in traditional economic terms. Using the second approach, studies can provide a realistic picture of the real-world benefits in terms of impact mitigation that specific treatment or prevention strategies can have. In this section, we focus on studies that have taken the first approach.

Table 1 lists the studies found to date that have quantified the environmental impacts caused by specific health issues in livestock production systems. Almost all studies to date that have investigated the impact of health issues are on ruminant production systems, the exception being Li et al. (2015), who investigated the effect of vaccination for PRRSv on key sources of GHG emissions for pig production (see Section 4 for further details on this). Only two studies considered environmental impact categories beyond GHGs in relation to health issues (Chen et al., 2016; Hospido and Sonesson, 2005). The most wide-ranging and comprehensive study found was the ADAS (2015) report on the impact of endemic diseases and conditions for the GHGs and economic performance across the UK sectors of beef, dairy and dual purpose cattle systems. The ADAS study quantified both the GHGs caused by 10 important

Table 1 A summary of quantitative results reported in literature on the environmental impact of livestock health issues. Where a study addressed more than one disease, its results are reported separately in the table below

Study	Study type	Species (system)	Disease/s studied	Impact of health issue for GHGs (%)	Functional units and other methodological details	Other notes
(Skuce et al., 2016)	Modelling	Sheep	Gastrointestinal nematodes	+10	1 kg carcass weight	Theoretical calculation based on three levels of infection. +10% is based on going from 20% of flock infected to 0.
(Fox et al., 2018)	Experimental trial	Sheep (Lambs)	Parasitic worm infection (Teladorsagia circumcincta)	+33 methane emissions	Methane per dry matter intake	No overall GHG assessment.
(Skuce et al., 2016)	Modelling	Cattle (beef)	Neosporosis	+2.2–4.7	1 kg carcass weight	Theoretical calculation based on three levels of infection. Highest increase is based on going from 20% of flock infected to 0.
(Macleod et al., 2018)	Modelling	Cattle (dairy and beef)	Trypanosomiasis	+9	1 kg of edible protein at the farm gate	Milk and meat protein are equivalent in this calculation.
(Chen et al., 2016)	Modelling	Cattle (dairy)	Lameness	+8	1 kg of fat and protein-corrected milk (FPCM). FPCM milk = milk volume × (0.25 + 0.122 × fat% + 0.077 × protein%)	Study considered other impact categories, namely eutrophication potential, acidification potential and abiotic depletion.

(*Continued*)

Table 1 (*Continued*)

Study	Study type	Species (system)	Disease/s studied	Impact of health issue for GHGs (%)	Functional units and other methodological details	Other notes
(Mostert et al., 2018)	Modelling	Cattle (dairy)	Subclinical ketosis and related conditions	+2.3 per case	1 ton of FPCM milk	Calculation includes assumptions of probabilities for associated conditions including mastitis, metritis, displaced abomasum, lameness and clinical ketosis.
(Özkan et al., 2015)	Modelling	Cattle (dairy)	Mastitis	+2	1 L milk produced	
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Overall impact of disease on UK herd GHGs	+6 dairy and +6.6 beef	1000 L FPCM milk and 1 tonne edible carcass weight	The overall impact of all health issues considered for the UK cattle sector compared to theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Bovine viral diarrhoea (BVD)	+20 dairy and +130 beef	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Johne's disease	+25 dairy and +40% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Salmonella	+20 dairy and +30 beef	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.

(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Liver flukes	+10 dairy and +10 beef	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	IBR	+8 dairy and +20 beef	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Lameness	+7.5 dairy only	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Mastitis	+7 dairy only	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Infertility	+16 dairy and +21% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Calf pneumonia	+1 dairy and +4 beef	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Calf diarrhoea	<1 dairy and +4 beef	1000 L FPCM milk and 1 tonne edible carcass weight	Increase for cases where farms impacted by the condition compared to a theoretical healthy herd.

health issues in UK systems and the potential of associated treatments and prevention strategies to mitigate them.

The 10 diseases and conditions investigated by ADAS were: infectious bovine rhinotracheitis (IBR), bovine viral diarrhoea (BVD), calf pneumonia, calf diarrhoea, liver fluke, mastitis, lameness, infertility, paratuberculosis and salmonella (ADAS, 2015). Other health issues for cattle considered in literature to date include: subclinical ketosis (Mostert et al., 2018), trypanosomiasis (Macleod et al., 2018) and neosporosis disease (Skuce et al., 2016). The studies show a wide range in the GHG emissions attributable to different health issues, the most dramatic results including an estimated 130% increase in GHG emissions from beef farms affected by bovine viral diarrhoea (BVD), and an increase of 25% in GHGs for dairy farms impacted by Johne's disease (paratuberculosis) compared to a 'healthy farm' scenario (ADAS, 2015).

The underlying data behind these models are able to shed light on why certain health issues cause greater GHG emission increases than others. Previously in this chapter we listed various pathways through which health issues can negatively affect animal performance in ways likely to increase GHGs from livestock production, but the studies in Table 1 quantify this link directly. Table 2 (reproduced from ADAS (2015)) summarises the major assumptions used in that study regarding changes in dairy cow performance when affected by different health issues compared to a 'healthy herd'. For example, on average, BVD increases mortality from 2% to nearly 5%, increases levels of abortion/still birth rates and reduces conception rates (Gunn et al., 2004; Houe, 1999). In addition to the increased mortality risk, the issues with reduced productivity mean that on average culling rate increases from 17% to 20%. All of these changes are likely to cause an increase in the GHGs of the farming system by decreasing the productive outputs. As can be seen from Table 2, the presence of Johne's disease (+20%) and *Salmonella* (+16%) were deemed to result in the largest increases in GHGs per cow per year compared to a healthy herd scenario. In the ADAS report calculations, BVD only produced a 10% increase in GHGs per cow per year, but due to losses in productive outputs (particularly reduced milk yield) its overall impact on GHGs per 1000 litres of milk produced was similar to that of salmonella. The differences between the data for Johne's disease and salmonella/BVD demonstrate how different mechanisms can drive GHG increases from health conditions. The increase in GHGs from salmonella and BVD are driven by increase in mortality, decrease in milk yield (this is more dramatic for BVD) and a reduction in the calving rate. However, for Johne's disease it is a dramatic increase in the culling rate from 17% to 33% along with some losses in milk yield which drive the increase in GHGs. This demonstrates that how important management responses can be for determining the impact of health conditions on GHGs, and increased GHGs do not just emanate from direct impacts on animal performance.

While conditions such as BVD and Johne's disease have been identified as causing the highest increases in GHGs for UK cattle in beef and dairy systems respectively, the literature beyond the ADAS report has tended to focus on conditions that the industry considers the most important from an economic perspective. As mastitis and lameness have previously been identified as some of the most economically important diseases in dairy herds (ADAS, 2015), they are associated with some of the highest losses in cattle welfare (Bennett and IJpelaar, 2003), and mastitis is the most likely condition to cause an animal to be culled (Liang, 2013; Ózsvári, 2017). It is thus unsurprising that these health issues are the subject of multiple studies with respect to their environmental impacts. The increase in GHGs caused by widespread problems such as mastitis, lameness and subclinical ketosis are calculated to be in the range of 2–8% in several studies (ADAS, 2015; Chen et al., 2016; Hospido and Sonesson, 2005; Mostert et al., 2018; Özkan et al., 2015). As can be seen in Table 2, instances of mastitis are linked to increased mortality, while also decreasing lactation yield, with the complications associated with the condition leading farmers to increase the culling rate (Rollin et al., 2015). The condition also leads to milk being discarded, due to treatment of the condition and instances of raised somatic cell counts. All of these factors along with its very high prevalence in dairy herds (estimated at 37% of all cows over 1 year in the ADAS report), mean the condition inevitably has a large effect on animal performance in dairy herds and results in GHG increases of around 7% (ADAS, 2015). Both Chen et al. (2016) and the ADAS report attributed an increase of around 8% in GHGs to scenarios of increased lameness on farm. These increases are caused by reduced feed intake resulting in weight loss and reduction in milk production, and lameness experienced early in lactation is also associated with reduced fertility, which further increases GHG intensity of the milk produced (Collick et al., 1989; Lucey et al., 1986). Chen et al. (2016) also reported increases of around 10% in acidification, eutrophication and fossil resource depletion from dairy production due to lameness. They concluded that for lameness, the same mechanisms of reduced feed intake and milk production were driving the increase in all impact categories considered. The lack of consideration of impacts beyond GHGs in this area of study to date means it is difficult to state if this is the case for other health issues beyond lameness.

Another interesting case study is that of subclinical ketosis (SCK), the implications of which for GHGs was investigated in a detailed LCA study by Mostert et al. (2018). This study took into account the full impact of SCK on Dutch dairy herds including the likelihood of complications such as mastitis, metritis and lameness, as well as progression to clinical ketosis. While SCK is prevalent in up to 49% of European dairy herds causing significant economic losses, the study suggested that overall the impact of SCK in terms of increased

Table 2 A summary of the estimated impact of various health issues on livestock performance parameters and greenhouse gas (GHG) emissions in UK dairy systems (adapted from ADAS (2015)).

	Mortality (%)	Lactation yield (litres)	Cull rate (%)	Calving interval (days)	Productive life (lactations)	Calves per cow per year	GHG emissions per cow
Healthy	2.0	7831	17	368	6.1	0.89	6995
Industrial baseline	3.0	7539	26	362	3.9	0.86	7105
Bovine viral diarrhoea (BVD)	4.9	7204	20	451	5.0	0.67	7670
Calf pneumonia	2.0	7831	17	368	6.1	0.89	7039
Calf scour	2.0	7831	17	368	6.1	0.89	7003
Infectious bovine rhinotracheitis	4.0	7560	17	401	6.0	0.78	7326
Infertility	2.0	7194	20	449	5.2	0.73	7485
Lameness	2.0	7534	19	387	3.2	0.85	7245
Liver fluke	3.9	7804	17	376	6.0	0.87	7693
Mastitis	3.2	7766	19	368	5.2	0.89	7415
Paratuberculosis	2.0	7590	33	405	3.1	0.81	8423
Salmonella	5.0	7584	17	402	6.0	0.77	8104

GHGs is relatively small at 0.9% per case of SCK, increasing to 2.3% when predicted complications are accounted for (Mostert et al., 2018). Importantly, however, the Mostert study presented detailed data on exactly what caused the predicted increases in GHGs, which should serve as a template for other studies in this area. For cases of SCK only, with no further complications, 72% of the predicted increase in GHGs is caused by a prolonged calving interval with the rest caused by reduced milk production. When individual cows experience complications relating to SCK then the potential increases in GHGs increase and the source of these increases change. In those cases involving mastitis-displaced abomasum and clinical ketosis, the increased removal of heifers for culling was the second largest contributing factor to increased GHGs. Contrastingly, in cases involving lameness, reduced milk production was the largest contributing factor to increased GHGs followed by prolonged interval between calving. The Mostert et al. (2018) study predicted that individual cases of culled cows with SCK increased GHG emissions by around 20%, whereas any cases of cows which died on farm increased GHGs by 50% per case compared to healthy cows. This was because meat from culled cows was considered to be viable and replace other low-value meat products, thus off-setting the need to produce these, whereas meat from cows that died on farm was assumed to be discarded. While important queries may be raised about the validity of this methodological approach, the detail in such calculations opens up a potential future pathway in bringing environmental impact considerations into the existing economic models which optimise culling decisions in dairy herds based on economic outcomes (Liang, 2013).

4 A framework to evaluate the environmental impact of health interventions

A more interesting and challenging question than what impacts are caused by the existence of health issues, is how to quantify the potential of prevention and treatment strategies to mitigate environmental impacts in livestock systems. The added interest here is that rather than just stating the extra environmental burden caused by certain health conditions, researchers can use modelling to identify the most effective strategies that can reduce this. The challenges they face in doing so are actually similar to those faced by farmers, vets and economists when trying to establish which health interventions are actually cost-effective. As described by Rushton (2017) there are still huge issues with the availability of baseline level data on the prevalence of endemic diseases and welfare issues in livestock populations, even in OECD countries. This hampers our ability to understand how cost-effective health interventions are likely to be at the scale of a national or transnational population.

4.1 Studies that have modelled the environmental impact of health interventions

A key difference between quantifying the potential environmental impact mitigation from health interventions and the economic consequences of doing so is that the environmental impact of several interventions, for example, producing vaccines or medicines, is likely to be small in comparison to any significant projected benefits through improved animal performance. The relatively small environmental impact of interventions means there is unlikely to be any meaningful trade-off in terms of environmental impacts if a treatment or prevention strategy has been shown to be effective (ADAS, 2015). This completely contrasts with the economic modelling where there is often a fine balance between such costs and benefits. For example, vaccinations only become cost-effective when the risk from disease is deemed to be above a certain threshold (Linhares et al., 2015). In reality, economic and animal welfare considerations still drive decisions around whether to implement health interventions on farm. As such, the question of how any cost-effective interventions are in terms of environmental impact reduction is of great interest to researchers in this area looking to incorporate multiple objectives in their modelling to establish why particular health interventions should be prioritised.

This is reflected in work such as the ADAS (2015) report where marginal abatement cost curve (MACC) analysis was performed to identify the most cost-effective strategies to reduce GHGs in UK cattle through health interventions (ADAS, 2015). As such, it was modelled on the national scale and linked epidemiological, LCA and economic modelling. Their use of MACC analysis to relate the treatment/prevention of health issues, GHGs and economic in this way was innovative and to our knowledge has not been replicated elsewhere for livestock systems. However, the MACC methodology is known to have important limitations. For example, it is not able to properly rank cost-negative mitigation measures as traditional MACC methodology will tend to favour scenarios that actually produce lower emission savings (Taylor, 2012; Ward, 2014). More generally, the methodology is viewed as lacking transparency with respect to the calculations in some cases, with limited ability to interpret uncertainty in the underlying data and being unable to account for interactions between individual treatment options (Kesicki and Ekins, 2012). Despite these criticisms it will be important that economic considerations are integrated into future work on health issues and environmental impacts in livestock systems, whether using MACCs or other relevant methods to account for environmental externalities in economic models of livestock systems (e.g. Jongeneel et al., 2014).

Table 3 summarises the studies we found that assessed the impact of specific treatment and prevention strategies to reduce GHGs caused by health issues in animal production systems. Fewer studies have addressed the more difficult task of assessing the impact of treatment and prevention strategies, than those quantifying the impacts caused by health conditions discussed in Section 3. The majority of the studies were modelling exercises applying empirical evidence within an LCA modelling framework. However, some experimental studies, which directly measured GHG emissions were also identified (Fox et al., 2018; Houdijk et al., 2017; Li et al., 2015). The predicted benefits for GHGs from specific treatment/prevention strategies based on the evidence of their effectiveness are naturally more conservative than the theoretical reductions calculated based on eliminating health issues. This is because they need to be based on evidence that the predicted improvements to system performance can be achieved through these treatment and prevention strategies.

The shared challenges between modelling the potential environmental impact mitigation from health interventions and their economic consequences, combined with increased interest in understanding the potential environmental mitigation from health interventions, mean a guideline framework for researchers constructing such models would be an important resource.

4.2 Integrating epidemiological data in environmental impact assessment

Figure 1 sets out the important components of modelling the environmental impacts of health issues and health interventions in livestock systems. An essential component for understanding the potential of interventions to mitigate health issues is to model the expected changes to production parameters and animal health outcomes from any individual or combination of interventions. This includes mortality rates, fertility rates, the utilisation of feed and quality characteristics of products from the farming system. This is consistent with the frameworks currently used by LCAs to assess the consequences of management changes on the environmental impact of a livestock system. The level of data required for the epidemiological component of the exercise is entirely dependent on the scale at which researchers model on, and in many cases appropriate data may only be available at the farm or herd level, which can be very difficult to scale-up to model interventions at the regional or national level (Garner and Hamilton, 2011; Rushton, 2017). This is a problem for LCA models, too, which often set out to present the impact of health conditions at the national or regional level. Work to date modelling the

Table 3 A summary of quantitative results reported in literature on animal health issues and associated treatment/prevention strategies. Each reported outcome represents the potential mitigation of GHGs shown using the treatment/prevention strategies. Where a study addressed more than one disease, its results are reported separately in the table below.

Study	Study type	Species (System)	Disease/s studied	Health intervention/s	Reported GHGs outcome	Functional units and other methodological details	Other notes
(Houdijk et al., 2017)	Experimental trial	Sheep (Ewes)	Parasitic worm infection (*Teladorsagia circum- cincta*)	Anthelminthics	−14%	1 kg Live weight gain	Increases and decreases shown for different sources of GHG production.
(Kenyon et al., 2013)	Experimental trial	Sheep (Lambs)	Gastrointestinal nematodes	Anthelminthics (four strategies – 'monthly' (NST), 'strategic' (SPT), 'targeted' (TST) or based on 'clinical signs' (MT)	−9% for best treatment case compared to worst case	1 kg Live weight gain	All groups in trial treated with Anthelminthics just using different strategies.
(Li et al., 2015)	Experimental trial	Pigs	Porcine reproductive and respiratory syndrome virus (PRRSv)	Vaccination for PRRSv	+11% CO_2 +300% N_2O NH_3 CH_4 and H_2S all unchanged	Figures represent increase in emissions from manure storage when unvaccinated pigs infected with PRRSv	No overall GHG assessment.
(Skuce et al., 2016)	Modelling	Cattle (dairy)	Infectious bovine rhinotracheitis (IBR) disease		−1.5 to 3%	1 kg carcass weight	Reduction based on any one of control measures listed being implemented.

(Hospido and Sonesson, 2005)	Modelling	Cattle (dairy)	Mastitis	Scenarios for blanket and selective dry cow therapy	−2.5% GWP in 'improved herd' scenario	1 L of milk	Improved scenario was based on a reduction in discarded milk and culling. Higher reductions reported for other impact categories which included eutrophication, acidification and ozone depletion.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Bovine viral diarrhoea (BVD)	Vaccination, double fencing, identification of PI animal	−14% dairy and −50% beef	1 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Johne's disease	Vaccination, colostrum management and hygiene, buying policy, test and cull	−13% dairy and −21% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Salmonella	Vaccination, vector control, hygiene	−15% dairy and −13% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Liver flukes	Strategic treatment, grazing management	−7% dairy and −5% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	IBR	Vaccination, double fencing, identification of latently infected carrier animal	−6% dairy and −13% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.

(*Continued*)

Table 3 (*Continued*)

Study	Study type	Species (System)	Disease/s studied	Health intervention/s	Reported GHGs outcome	Functional units and other methodological details	Other notes
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Lameness	Change in cow 'hardiness', mobility management, cow comfort	−4% dairy only	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Mastitis	Milking routine, dry cow therapy, nutrition, housing and milking machine maintenance	−1% dairy only	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Infertility	Fixed time AI, tail paint/kamar and activity metres, nutrition	−10% dairy and −12% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Calf pneumonia	Vaccination, colostrum intake, buildings, stocking density and buying policy	−<1% dairy and −1% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.
(ADAS, 2015)	Modelling	Cattle (dairy and beef)	Calf diarrhoea	Housing and calf comfort, prophylactic therapy, vaccination and colostrum screening	−<1% dairy and −1% beef	1000 L FPCM milk and 1 tonne edible carcass weight	Values represent the impact of implementing all treatments in model compared to no treatment.

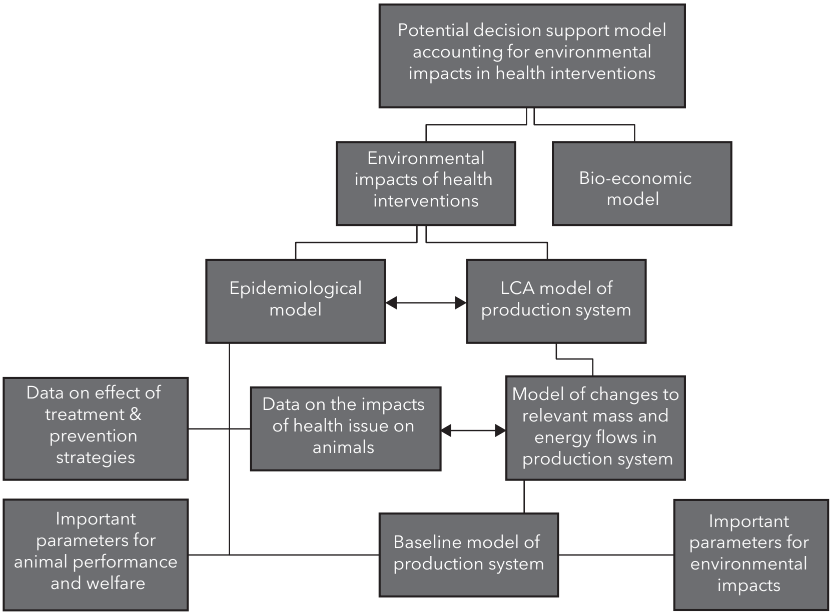

Figure 1 The important components for modelling the environmental impacts of health issues and health interventions in livestock systems through Life Cycle Assessment (LCA).

environmental impact of health interventions has acknowledged its limitations with regard to the robustness of the scenarios presented for animal health outcomes (e.g. ADAS, 2015). However, this may be an unfairly high standard to judge early work in this area, which can only work with the best data available to further our understanding of the potential for successful health interventions to reduce environmental impacts.

More challenging, when dealing with health issues, are the spatial and temporal scales that need to be taken into account to assess their effectiveness. Setting boundaries for the technical system being modelled is necessary in LCA. Commonly for LCA of livestock systems the model may be set up to represent a representative farming scenario within a region, without any precise definition of its location or spatial properties (McAuliffe et al., 2016). However, the effectiveness of many treatment and prevention strategies can only be considered at larger regional or national scales. In general, epidemic diseases affect multiple farms, and therefore have a strong spatial component. For example, it may be necessary to assume sufficient uptake of a preventative vaccine within a region to establish herd immunity without the need for extra controls on travelling animals, for example, in the case of bovine TB (Smith and Delahay, 2018). The same applies to endemic diseases whose transmission depends on a biological vector, such as trypanosomiasis. For this reason, several researchers have modelled the eradication of a disease as opposed to controlling a health challenge, as discussed above (Macleod et al., 2018; Skuce et al., 2016). This approach also comes with complexity, an example being the models of preventing IBR in cattle in both the ADAS (2015) report and later by Skuce et al. (2016). The latter study acknowledged that it may not be possible to achieve the eradication of the condition in the UK as has been shown to be possible elsewhere (Ackermann et al., 1990), without a full national programme of compulsory control including testing, culling vaccination and restriction of movement. As such, the implementation of control strategies on individual farms, such as vaccinations or double fencing, is predicted to have a reduced effect in disease reduction when introduced individually. In contrast, some treatment and prevention strategies can be pursued successfully in individual farms and can thus have 'isolated' consequences. For example, such is the case of hygiene measures: the washing of udders and general improvements to cleanliness of housing to reduce instances of mastitis (Lam et al., 2013). The challenges here are faced in all epidemiological modelling of transboundary diseases (FAO, 2016d): researchers need to justify why the scale at which they are modelling the treatment and prevention of health issues is appropriate and ensure that where possible they have considered that any issues they face with upscaling data from trials done at the farm level. They should also consider relevant interactions between different treatment strategies where possible.

Similarly, there are key temporal considerations in epidemiological modelling, with temporal scale being key to understand the effectiveness of prevention and treatment strategies (Onstad, 1992). For example, if one is interested in quantifying the environmental impact of a health challenge control over time, then the temporal effects on the epidemiology of the challenge will need to be taken into account. Currently, there is an increased interest in showing the reductions in environmental impact of a livestock sector achieved through management or breeding (Tallentire et al., 2018; Ottosen et al. 2020), and this exercise has analogies with what we are discussing here in relation to health challenge controls.

4.3 Identifying the impact of health issues and interventions on important mass and energy flows

Translating the outcomes of any epidemiological model of a health intervention into a model of the mass and energy flows for an animal production system is a significant challenge. One of the particular challenges here is that sensitive aspects of the LCA model may not be routinely recorded, even in experimental trials measuring the effectiveness of treatment and prevention strategies in reducing specific health conditions. For example, while aspects of animal performance such as feed intake, growth rate and milk or egg production would be routinely measured, the effect of health conditions on enteric methane production or the amount of volatile solids contained in manure would not be. While predictions of the environmental impact mitigation achieved from prevention and treatment strategies can be made just from traditional performance data, factors such as enteric methane and volatile solid excretion are extremely sensitive in models of environmental impacts in animal production (Opio et al., 2013). Most calculations relating GHGs and health issues in animal production use a fixed equation based on the energy and dry matter intake of animals to calculate enteric methane emissions. The methods either directly follow, or are derived from the tier 2 IPCC protocols for calculating methane emissions from livestock (IPCC, 2006). Several studies reference the fact that this is a sensitive assumption within their models which could be improved (Macleod et al., 2018; Mostert et al., 2018). Importantly, these emission factors and the predicted enteric methane emissions are not altered when considering the scenarios impacted by health conditions. This may actually not be true. Evidence of this can be seen from studies that have the relevant measurements in experiments (Fox et al., 2018; Houdijk et al., 2017). In the Houdijk et al. (2017) study, peri-parturient parasitism reduced feed intake by 9% and litter weight gain by 7% for rearing ewes, while also doubling maternal weight loss, and these were, at least partly, caused by parasite-induced anorexia. While net methane production was actually reduced, the methane yield per kg of digestible organic matter intake increased by 14%. Infection caused reduced feed intake depriving the animal of needed resources, reduced the efficiency with which feed was being used and increased the proportion of organic material being released as volatile organic compounds. The manure methane and nitrous oxide yields also increased 46% and 31% respectively per kg of digestible organic matter intake. These increased yields were a result of reduced nutrient absorption, which is a symptom of parasite infection (Coop and Kyriazakis, 1999; Shea-Donohue et al., 2017), and also contribute to the increased GHGs caused by untreated infection in this study.

These recorded increases in the yield of methane and nitrous oxide are important points for considering the environmental impact of health issues. Models that assume a constant relationship between feed intake and enteric methane emissions, as well as emissions from manure, may underestimate the increase in GHGs and other important emissions caused by health issues affecting the digestive system. To date these detailed experimental studies in relation to health issues and the production of GHGs have been conducted on sheep systems (Fox et al., 2018; Houdijk et al., 2017). However, similar findings could be reasonably predicted in dairy and beef systems for conditions involving parasitism and/or instances of diarrhoea. Increases in the methane and nitrous oxide yields per kg of digestible organic matter intake would increase the predicted increase in GHGs caused by such health issues produced by studies such as by ADAS (2015) on dairy and beef systems. Notably, Houdijk et al (2017) also found that release of respiratory CO_2 increased per kg intake of digestible organic matter by 17% and in the LCA results overall by 15%. CO_2 released this way is almost never taken into account in LCA models of livestock systems and certainly not modelled to increase in any of the other studies on health issues found in this review. These results suggest that the impact of some health issues on GHGs in livestock systems may be underestimated in many of the current LCA models produced. If possible, LCA models of health issues in livestock and potential mitigations should identify the relevant mechanisms within animals by which health issues may increase GHGs produced on farm from livestock systems, as well as accounting for expected changes to herd performance as is already typical.

Another important consideration in terms of mass and energy flows when modelling the environmental impact of health issues in livestock impact is any impact they may have on the quality of the output products. This is a different issue to some of the examples discussed earlier where milk may fail quality tests or for other reasons have to be discarded as a result of health issues for this is easily accounted for as waste within an LCA model. A relevant example in this case would be an alteration in carcass composition that reduced the quality of meat produced by sheep or beef cattle as a result of being challenged with gastrointestinal parasites (Holmes, 1993). Accounting for such issues is linked to a wider methodological challenge that researchers face when constructing LCA models of livestock systems that can account for the quality of the product produced. The key issue being the importance of the chosen functional unit in LCA modelling (Hospido et al., 2010).

The currently accepted convention, and standard way of representing functional unit in LCA of meat production systems is to use a variation on edible meat or carcass weight with no further properties describing the nutritional quality of the meat produced (e.g. ADAS, 2015; FAO, 2016c, 2018). Essentially its chemical composition and physical characteristics are usually assumed to be either unrelated to whatever treatments (changes to diet, health treatment, management changes) a livestock LCA has considered or it is acknowledged (not always explicitly) that the model was simply not able to take the relationship between these two things into account. This situation contrasts slightly with the standard functional unit used in dairy LCA of fat and protein-corrected milk (FPCM) (FAO, 2016a) using methods such as that set out by Bartl et al. (2011):

For conversion of kg milk to kg FPCM the yield was adjusted for energy to a standard milk with 4% fat, 3.2% protein and 4.8% lactose using the formula FPCM (kg/day) ¼ milk (kg/day) [0.038 fat (g/kg) þ 0.024 protein (g/kg) þ 0.017 lactose (g/kg)]/3.14 (Bartl et al., 2011).

A few studies of dairy systems build further on this to include either FPCM produced per land occupied, or to include the meat produced and sold from dairy systems in the functional unit, but the vast majority use a mass or volume measurement of FPCM (FAO, 2016a). More broadly in LCA of food systems there has been a trend towards developing nutritional functional units based on a set of nutritional properties for food products, which match guidelines for human dietary requirements (Saarinen et al., 2017). For LCA of livestock production systems McAuliffe et al. (2018) presented such a methodology based on using important nutritional properties for high-protein foods adapted from the methods of Saarinen et al. (2017) for Finnish food systems. To adopt such an approach requires confidently linking the consequences of production diseases for the chemical properties of livestock tissue. If such data is available for the health issues and treatments/prevention strategies being considered in LCA models, then it should be accounted for using an appropriate functional unit as discussed above, but to date this has not been the case for any studies of health issues in meat production systems.

4.4 Beyond health issues for ruminants and greenhouse gas emissions

Work to date on the environmental impacts of health issues in livestock has focussed almost exclusively on ruminant systems. We found only one study that specifically focussed on the environmental impact of health issues in non-ruminant systems. Li et al. (2015) assessed the implications of PRRSv infection on growth, dietary nutrient utilisation efficiency, manure output, as well as emissions of CO_2, CH_4, H_2S, N_2O and NH_3 gases from stored manure in both vaccinated and unvaccinated pigs. This study was able to show that in addition to the expected reduction in growth performance, exposure to PRRSv significantly increased CO_2 and N_2O released both directly from pigs and their manure when stored, with no observed impact on NH_3 or CH_4 emissions. Manure from infected pigs had a greater C:N ratio, and infection with PRRSv-increased manure output did not have an observed impact on the utilisation and retention of N in infected animals. These increased levels of organic matter excreted explained the increased CO_2 emissions from their manure. The increased C:N ratio was also observed to stimulate more fermentation and microbial activity during manure storage. Reaction routes as part of this increased microbial activity during storage were thought to cause the discrepancy between N_2O (increased) and NH_3 (no change) emissions from the manure of infected pigs.

Ultimately, the study was unable to demonstrate that prior vaccination reduced the negative impact of PRRSv on animal performance or GHG emissions (Li et al., 2015). While no overall GHG assessment was performed, the results of their work show that PRRSv caused an increase in the GHGs (increased CO_2 and N_2O) from pig production systems beyond the expected drops in animal performance. As with the case of parasite infection in sheep production discussed above, failure to take into account the link between infection and increase in on-farm GHG emissions may lead to researchers underestimating the impact of these conditions in LCA studies. Moreover, while their results were not fed into an LCA model, it was notable that neither NH_3 nor H_2S emissions from the pigs and during manure storage increased when animals were infected with PRRSv nor did infection have any detectable impact on nutrient utilisation. Nutrient utilisation efficiency and NH_3 emissions in particular, both in barn and during manure storage, are a major factor in determining the acidification and eutrophication caused by pig farming systems (Mackenzie et al., 2015; McAuliffe et al., 2016).

Most studies on the environmental impact of health issues (with exceptions, Chen et al., 2016; Hospido and Sonesson, 2005) did not consider other forms of environmental impact beyond GHGs, such as eutrophication, acidification and abiotic resource use. The focus on ruminant systems to date in this area is understandable as discussed above. However, when considering the environmental impacts of livestock production in broader terms beyond just GHGs, it becomes much more important to account for the role of non-ruminant production systems (de Vries and de Boer, 2010). Focussing on a single environmental impact does allow researchers to concentrate on translating the outputs of epidemiological models into fewer important mass flows. For example, LCA models which consider only GHGs will account solely for CH_4, N_2O, CO_2 and any hydrofluorocarbon emissions released during by the production system considered (Opio et al., 2013). Accounting for further impact categories such as acidification potential or water use, as recommended in most of the FAO technical guidelines on livestock LCA (FAO, 2016c, 2016b, 2018), would mean that researchers are more likely to capture potential trade-offs in the environmental impact benefits of health interventions. While each impact category added to the model increases uncertainty, as researchers have to establish the potential impact of health issues and treatment strategies on a greater number of physical flows in the system, it will be important to overcome these issues in future work in this area. As a case in point, the results from the Li et al. (2015) study are indicative that certain health conditions may have greater implications for some forms of environmental impact over others. Depending on the context that studies are carried out in, researchers may deem health issues that decrease nutrient utilisation efficiency, thus increasing NH_3 and other emissions are more problematic from an environmental impact perspective than those which do not in pig and poultry farming systems. For example, within the EU pig production represents around 25% of NH_3 emissions (Philippe et al., 2011) and EU has now defined standards which dictate limits for NH_3 emissions to air in housing as well as N and P excretions in manure (EU Science Hub, 2017). As such those looking to quantify which treatment and prevention strategies could yield the most important mitigation of environmental impacts in EU pig and poultry systems may wish to prioritise the reduction of nutrient excretion in their models. They would need to be able to identify the relevant mechanisms for health issues in pig and poultry systems in relation to nutrient utilisation and in barn emissions set out for PRRSv in the Li et al. (2015) study. The LCA models would also need to account for multiple impact categories in order to interpret these data into useful outputs for decision-making.

5 Conclusions

We reviewed important concepts for quantifying the relationship between health issues in livestock systems and their environmental impacts, as well as the studies published on this issue to date. In doing so we outlined a general framework and guidelines for constructing such models, highlighted a number of important methodological considerations for modelling in this area and outlined some significant gaps in current knowledge of this topic that should be addressed in future research. As this area of modelling requires the integration of epidemiological models with environmental impact models, there are unique temporal and spatial considerations to account for when modelling livestock health issues.

It is also important when integrating these two areas of modelling that the impact of health issues on sensitive mass flows within the animal and on farm, such as methane or ammonia emissions are taken into account. In most cases, researchers assume a constant relationship between the feed intake or energy intake of animals and on-farm emissions in their models of health issues and GHGs (Macleod et al., 2018; Mostert et al., 2018). However, while initial experimental work in this area to date suggests this may not always be the case, studies that have measured the relationships between on-farm emissions and health issues are sparse, presenting a challenge in developing effective models on this subject. Wherever possible they should be accounted for in models of the environmental impact of health issues, otherwise this will likely lead to inaccuracies in reporting the environmental impact of health issues in livestock. Likewise, no studies have thus far utilised relevant methods to account for the implications of health issues for product quality with respect to their environmental impacts. New methods being developed in this area for nutritional functional units in LCA studies of food systems (McAuliffe et al., 2018; Sonesson et al., 2017) should allow researchers to account for this in future where relevant data is available, for example, with respect to health challenges and product composition.

In most cases, the implications of health issues for environmental impacts beyond GHGs of livestock systems have not been considered or quantified to date. This contradicts several FAO guideline documents on how to quantify the environmental impact of livestock systems and represents a significant gap in our knowledge of the issue. Surprisingly few studies have considered the impact of health issues in pig and poultry production systems at all, with these sectors making up an ever-increasing proportion of livestock products consumed around the world, and this is an area that will warrant future exploration by researchers.

Ultimately, in order to actually be integrated into decision-making processes, environmental impact assessment models of health interventions will need to integrate economic considerations to produce recommendations for the most cost-effective mitigation measures. The ADAS (2015) report demonstrated the possibilities for this while modelling at a national scale. Work at this level could be used to justify funding or subsidies for particular health interventions at the national level on the combination of animal welfare and environmental grounds. However, there may also be scope for impactful work in this area to be done through farm level modelling. This could integrate health interventions and their potential benefits for environmental impacts into decision support tools as is being currently being developed in other areas of livestock husbandry such as feeding (Garcia-Launay et al., 2018; Mackenzie et al., 2016), breeding (Ottosen et al., 2020; Tallentire et al., 2018) and environmental management (Pexas et al., 2020; Ten Hoeve et al., 2014).

Chapter 5

Sustainable nitrogen management for housed livestock, manure storage and manure processing

Barbara Amon, Leibniz Institute for Agricultural Engineering and Bioeconomy (ATB), Germany and University of Zielona Góra, Poland; Lars Stouman Jensen, University of Copenhagen, Denmark; Karin Groenestein, Wageningen Livestock Research, The Netherlands; and Mark Sutton, UK Centre for Ecology & Hydrology (UKCEH), UK

1 Introduction

Nitrogen can take various forms (Fig. 1), including atmospheric di-nitrogen (N_2) and a wide range of reactive nitrogen (N_r) compounds, including all forms of nitrogen that are biologically, photochemically and radiatively active. Compounds of nitrogen that are reactive include ammonia (NH_3) and ammonium (NH_4^+), nitrous oxide (N_2O), nitrogen oxides (NO_x), nitrite (NO_2^-), nitrate (NO_3^-), nitric acid (HNO^-_3) and a wide range of organic nitrogen compounds (R-NH_2). Reactive forms of nitrogen are capable of cascading through the environment and causing an impact through smog, acid rain, biodiversity loss and so on as well as affecting climate (Butterbach-Bahl et al., 2011b). The design of abatement/mitigation measures requires a sound knowledge of the processes that influence formation and emission of all N_r compounds and N_2 into the environment, where nitrogen is lost to a wide range of atmospheric and aquatic pathways.

1.1 Ammonia

The principles of ammonia formation and its influencing factors are well known. Degradation of nitrogen-containing organic substance results in

http://dx.doi.org/10.19103/AS.2020.0077.08

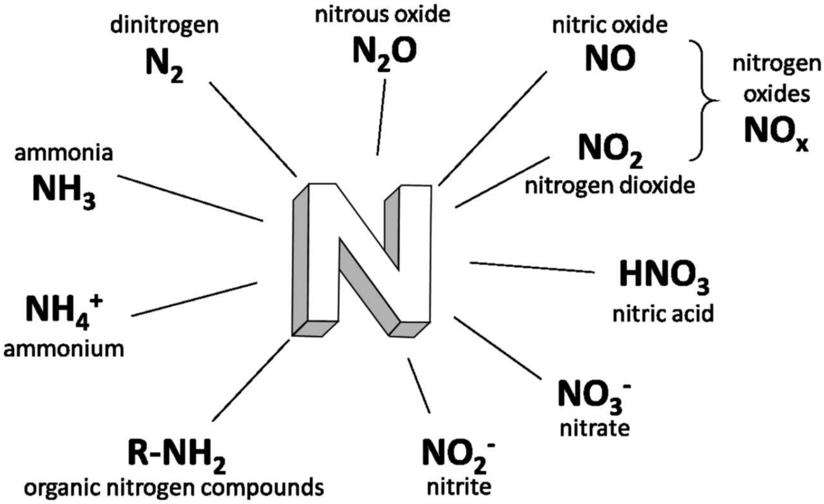

Figure 1 Major forms of nitrogen occurring in the environment. The sum of all forms except N_2 is often termed fixed or reactive nitrogen (Nr).

ammonium formation (NH4⁺). There is an equilibrium between ammonium and ammonia:

$$H_2O + NH_3 \rightleftharpoons OH^- + NH_4^+$$

The degree to which ammonia forms the ammonium ion depends on the pH of the solution. If the pH is low, the equilibrium shifts to the right: more ammonia molecules are converted into ammonium ions. If the pH is high, the equilibrium shifts to the left: the hydroxide ion abstracts a proton from the ammonium ion, generating ammonia.

Ammonia emissions are governed by the difference between solution and atmosphere NH_3 partial pressure. High NH_3 concentrations in the solution and low NH_3 concentrations in the surrounding atmosphere increase NH_3 emissions. According to Henry's Law, ammonia emissions are also temperature dependent with rising temperatures increasing emissions (Fig. 2). Denmead et al. (1982) give the following equation:

$$NH_{3(\text{solution})} = \left(NH_{3(\text{solution})} + NH_{4(\text{solution})}\right) \Big/ \left(1 + 10^{0.09018 + (2729.92/T) - \text{pH}}\right)$$

where

$NH_{3(solution)}$ = NH_3 concentration in the solution
$NH_{3(solution)} + NH_{4\,(solution)}$ = The sum NH_3 and NH_4^+ in the solution

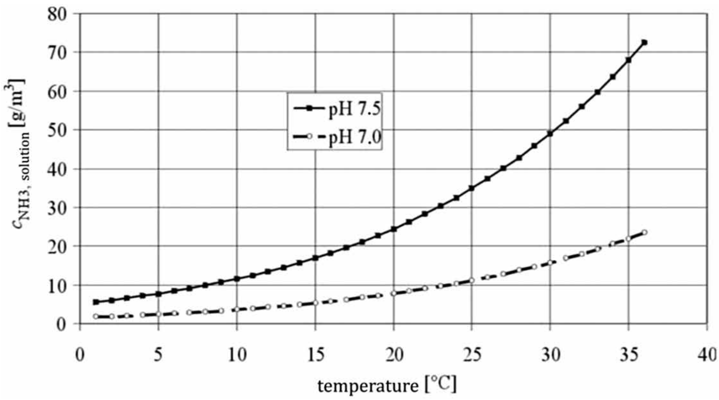

Figure 2 NH_3 concentration in the solution depending on temperature for pH 7.0 and pH 7.5 (Denmead at al., 1982).

T = Temperature in the solution [K]
pH = pH value in the solution

Ammonia emissions associated with livestock housing, manure storage, management and processing result from the degradation of urea by the ubiquitous enzyme urease which results in $NH4^+$ formation. Urea is mainly excreted in the urine and once it is hydrolysed it is much more prone to ammonia losses than organic nitrogen excreted in the faeces. In the case of poultry nitrogen is excreted largely in the form of uric acid, which hydrolyses like urea to produce ammonia. Where it is possible to dry excreta (e.g. in poultry litter), strategies may focus on reducing the hydrolysis rate of uric acid and urea. Once ammoniacal nitrogen (the sum of NH_3 + NH_4^+) is formed, strategies in animal housing and manure management focus on avoiding its volatilization to the atmosphere, for example, by reducing access to air, by reducing pH or by keeping the manure surface cool (cf. Fig. 2).

1.2 Nitrous oxide and di-nitrogen

The gases N_2O, NO_x and N_2 are formed both during the nitrification and the denitrification processes in the environment. The 'Leakage' model developed by Firestone and Davidson (1989) shows N_2O and NO_x losses as leakage flows during nitrification and denitrification (Fig. 3).

Nitrification oxidizes ammonia via nitrite to nitrate. This process is strictly aerobic. Autotrophic-nitrifying bacteria belong to the widespread group of nitrosomonas, nitrospira and nitrobacter, which are capable of growing on CO_2, O_2 and NH_4^+. Availability of NH_4^+ is mostly the limiting factor as CO_2 and O_2

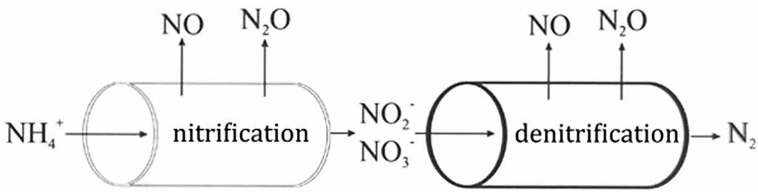

Figure 3 Leakage model for N_2O and NO_x losses during nitrification and denitrification (Firestone and Davidson, 1989).

are available in abundance. Low pH, lack of P and temperatures below 5°C or above 40°C lead to a reduction in nitrification activities. A water content of 60% of soil water-holding capacity is optimal for the nitrification process.

At low pH values, nitrification is carried out by bacteria and fungi. In contrast to the autotrophic nitrifiers, they need carbon sources for their growth. Their turnover rate is much lower compared to the autotrophic nitrifiers, but a substantial total turnover can still be achieved as a wider range of species have the ability for heterotrophic nitrification. N_2O production during nitrification is around 1%, NO_x production ranges between 1% and 4% of inputs N (Butterbach-Bahl et al., 2011a)

Denitrification reduces nitrate to N_2O, NO or N_2 when oxygen availability is low. NO_3^-, NO and N_2O serve as alternative electron acceptors when O_2 is lacking, and hence the denitrification occurs only under strictly anaerobic conditions. Molecular N_2 is the last part of the denitrification reaction chain and it is the only biological process that can turn reactive nitrogen into molecular N_2. Denitrifying bacteria are heterotrophic and facultative anaerobic. This means that they use O_2 as electron acceptor and switch to alternative electron acceptors (NO_3^-, NO and N_2O) when oxygen availability is low. Denitrifying bacteria are wide spread and show a high biodiversity.

Controlling factors for denitrification have been extensively investigated, mainly under lab conditions. Complex interactions exist between the various influencing factors which make a prediction of N_2O emissions difficult under practical conditions.

Denitrification is mainly governed by oxygen availability. Denitrification starts when the O_2 concentration decreases to below 5% (e.g. Hutchinson and Davidson, 1993). This may be the case in poorly aerated soils (e.g. high water content, in excess of 80% water-filled pore space), but also in soils where a high biological turnover consumes the oxygen faster than the supply. Easily degradable carbon sources and high nitrate concentrations also enhance the denitrification rate, while low temperature and low pH limit denitrification activity.

The relationship between N_2 and N_2O formation is mainly governed by the relationship between electron acceptor and reducing agent, and by the

O_2 concentration in the substrate. N_2 is only formed under strictly anaerobic conditions and a wide C: NO_3^- ratio. High nitrate concentrations increase the rate of N_2O production. These differences have effects in practice concerning N losses from housed livestock and manure storage, according to the extent of oxygen and carbon availability in different systems.

1.3 Nitrate and other nitrogen leaching and run-off

Diffuse pollution of groundwater and surface waters with N (and P) is a problem in many regions of the world, especially in areas with high livestock production. Animal manures contain substantial quantities of organic matter, N and P that if managed inappropriately may be lost from animal housing, manure storages or after field application.

Nitrogen and organic matter losses to aquatic systems mainly occur by leaching through the soil profile and through surface run-off when the infiltration capacity of the soil is exceeded. Point-source emissions can also be acutely damaging to local environments, for example, in the case of slurry store leakages. In surface waters, the losses cause problems with eutrophication and algal bloom, and in areas that rely on the use of groundwater, high nitrate concentrations can be a problem for the potable water quality. For drinking water the EU limit has been set at a nitrate (NO_3^-) concentration of 50 mg L^{-1} (EU Drinking Water Directive, 98/83/EC). Once leached to surface waters this N may also become a source of emissions of nitrous oxide, which is a potent greenhouse gas. In addition, significant loss of N resources is also an economic cost for the farmer, and N fertilizer production uses substantial amounts of fossil energy, causing global warming and other environmental emissions. Appropriate management and use of manures is therefore essential for minimizing nutrient leaching and the environmental impact of agriculture.

1.4 Consideration of nitrogen flows

Measures to reduce nitrogen losses from livestock feeding, housing and manure processing need to be seen in relation to other measures described in this guidance document. 'Manure management is a continuum from generation by livestock to storage and treatment and finally to land spreading' (Chadwick et al., 2011). This means that there is the potential for nitrogen, carbon and phosphorus losses at each stage of this continuum. A 'mass flow' approach has been used by Webb and Misselbrook (2004) to estimate NH_3 emissions from the manure management continuum. This approach allows effects of measures to reduce emissions and conserve manure N at one state to be considered as the manure passes to the next stage in the continuum. Similarly, other gaseous N losses, including N_2O, NO_x and N_2, may be assessed using a mass flow approach in a manner similar to that of Dämmgen and Hutchings (2008).

The importance of such a *whole system approach* is that effects of abatement methods at one stage are considered in downstream stages (Sommer et al., 2009, 2013), including losses of nitrogen to water through leaching and run-off.

1.5 Approach used to describe abatement measures

The following sections present the main management practices and abatement/mitigation measures that will influence N utilization and losses from housed livestock, manure storage, manure treatment and manure processing. Some measures will mitigate all forms of N loss, whereas others may mitigate a specific N loss pathway with either little impact or a negative impact on other N loss pathways. Enhanced abatement may be possible through the combined implementation of certain packages of measures. Linked management of nutrient cycles is required for effective environmental protection (Sutton et al., 2013)

The sections are based on information given in 'Options for Ammonia Mitigation: Guidance from the UNECE Task Force on Reactive Nitrogen' (Bittman et al., 2014), 'Best Available Techniques (BAT) Reference Document for the Intensive Rearing of Poultry or Pigs' (Santonja et al., 2017), 'Code for Good Agricultural Practice for Reducing Ammonia Emissions' (UNECE, 2015) and 'Framework Code for Good Agricultural Practice for Reducing Ammonia Emission' (Economic Commission for Europe, 2015). The information shall also be published as part of a Guidance Document on Integrated Sustainable Nitrogen Management developed by members of the Task Force on Reactive Nitrogen and submitted for adoption as UNECE document by the Executive Body of the UNECE.

2 Livestock feeding and housing

2.1 Livestock feeding

Ammonia emissions result from the degradation of urea by the ubiquitary enzyme urease which results in NH_4^+ formation. Urea is mainly excreted in the urine and once it is hydrolysed it is much more prone to ammonia losses than organic nitrogen excreted in the faeces. The crude protein content and composition of the animal diet is the main driver of urine excretion. Excess crude protein (CP) that is not needed by the animal is excreted and can easily be lost in the manure management chain. Adaptation of crude protein in the diet to the animals' needs is therefore the first and most efficient measure to mitigate nitrogen emissions. This measure reduces the loss of all N forms (Fig. 1) because it reduces the amount of excreted nitrogen. Groenestein et al. (2019) compared ammonia emissions related to nitrogen-use efficiency of livestock production in Europe. They come to the conclusion that expressing ammonia losses as a fraction of feed N would be preferable in expressing it per animal place as it give a clearer picture of the actual fraction of N in the feed that is lost to the environment.

Reduction of CP in animal feed is one of the most cost-effective ways of reducing N emissions throughout the entire manure management chain. For each per cent (absolute value) decrease in protein content of the animal feed, NH_3 emissions from animal housing, manure storage and the application of animal manure to land are decreased by 5–15% depending also on the pH of the urine and dung. Low-protein animal feeding also decreases N_2O emissions, and increases the efficiency of N use in animal production. Potential trade-offs with CH_4 emissions from enteric fermentation are not yet fully researched and need to be assessed. However, efficient N use is crucial for environmental-friendly milk production. Moreover, there are no animal health and animal welfare implications as long as the requirements for all amino acids are met. As there is much natural variation in nitrogen use efficiency (NUE) between individual animals, targeted breeding for better NUE can also be an option.

Low-protein animal feeding is most applicable to housed animals. It is less applicable for grassland-based systems with grazing animals, because grass is eaten by the animals in an early physiological growth stage and thus is typically high in degradable protein. It should be noted that grassland with leguminous species (e.g. clover and lucerne) also have a relatively high protein content, and so may be associated with provision of excess dietary N for livestock. Strategies to lower the protein content in herbage include: balanced N fertilization, grazing/harvesting the grassland at later physiological growth stage, and so on, and alteration of the ration of grassland-based systems, such as use of supplementary feeding with low-protein feeds.

2.1.1 Feeding strategies for dairy and beef cattle

Adapt protein intake in diet: Lowering CP of ruminant diets is an effective strategy for decreasing NH_3 loss. The following guidelines hold:

1 The average CP content of diets for dairy cattle should not exceed 15–16% in the dry matter (DM) (Broderick, 2003; Swensson, 2003). For beef cattle older than 6 months this could be further reduced to 12%;
2 Phase feeding can be applied in such a way that the CP content of dairy diets is gradually decreased from 16% of DM just before parturition and in early lactation to below 14% in late lactation and the main part of the dry period; and
3 Phase feeding can also be applied in beef cattle in such a way that the CP content of the diets is gradually decreased from 16% to 12% over time.

More information and associated costs can be found in the TFRN costs assessment (Chapter 3.4 'Low nitrogen feeding strategies in dairy cattle' in Reis et al., 2015).

In general, increasing the energy/protein ratio in the diet by using 'older' grass (higher sward surface height) or swathed forage cereal and/or supplementing grass by high energy feeds (e.g. maize silage) is a well-proven strategy to reduce levels of crude protein. However, for grassland-based ruminant production systems, the feasibility of these strategies may be limited, as older grass may reduce feeding quality, especially when conditions for growing high-energy feeds are poor (e.g. warm climates), and therefore such feeds have to be purchased. Hence, full use of the grass production would no longer be guaranteed. In the absence of other measures, such a strategy may also risk increasing methane emissions.

In many parts of the world, cattle production is grassland-based or partly grassland-based. In such systems, protein-rich grass and grass products form a significant proportion of the diet, and the target values for CP may be difficult to achieve, given the high CP content of grass from managed grasslands. The CP content of fresh grass in the grazing stage (2000–2500 kg DM/ha) is often in the range of 18–20% (or even higher, especially when legumes are present), whereas the CP content of grass silage is often between 16% and 18% and the CP content of hay is between 12% and 15% (e.g. Whitehead, 2000). In contrast, the CP content of maize silage is only in the range of 7–8%. Hence, grass-based diets often contain a surplus of protein and the magnitude of the resulting high N excretion strongly depends on the proportions of grass, grass silage and hay in the ration and the protein content of these feeds. The protein surplus and the resulting N excretion and N losses will be highest for grass-only summer rations (or grass-legume rations) with grazing of young, intensively fertilized grass or grass legume mixtures.

Urine excreted by grazing animals typically infiltrates into the soil. This means that NH_3 emissions per animal are reduced by extending the periods in which animal graze compared with the time spent with animals housed, where the excreta is collected, stored and applied to land. It should be noted that grazing of animals may increase other forms of N emissions (e.g. nitrate-N leaching and N_2O emissions). However, given the clear and well-quantified effect on NH_3 emissions, increasing the period that animals are grazing all day can be considered as a strategy to reduce emissions.

Increase productivity: Overall, increasing the productivity of dairy cattle in terms of milk or meat can decrease emissions per unit of animal production. Optimized productivity will also result in a reduction of enteric methane emissions. However, optimum productivity levels vary according to breed and region and must also consider that ruminants can only cope with a certain amount of concentrates and require sufficient roughage in their diet to stay healthy.

Increase longevity: Productivity can be increased though increasing milk production per year and through increasing the amount of milk production cycles per animal. Optimized diet and housing conditions enable a higher longevity of dairy cattle. Improving the longevity of dairy cattle also decreases the number of young cattle necessary for replacement. Reducing endemic disease and genetic gain through targeted breeding can also offer value.

2.1.2 Feeding strategies for pigs

Adapt protein intake in diet: Feeding measures in pig production include phase feeding, formulating diets based on digestible/available nutrients, using low-protein amino acid-supplemented diets and feed additives/supplements. Further techniques are currently being investigated (e.g. different feeds for males (boars and castrated males) and females) and might be additionally available in the future.

The crude protein (CP) content of the pig ration can be reduced if the amino acid supply is optimized through the addition of synthetic amino acids (e.g. lysine, methionine, threonine, tryptophan, typically limiting amino acids, which are too low in normal grain rations) or special feed components, using the best available information on 'ideal protein' combined with dietary supplementation. Lassaletta et al. (2019) performed a global analysis for pig systems that included the simulation of changes in CP. More information and associated costs can be found in the TFRN Costs Assessment (Chapter 3.2 'Low nitrogen feeding strategies in pigs', in Reis et al., 2015).

A CP reduction of 2–3% in the feed can be achieved, depending on the pig production category and the current starting point (Cahn et al., 1998). It has been shown that a decrease of 1% CP in the diet of finishing pigs results in a 10% lower total ammoniacal nitrogen (TAN) content of the pig slurry and 10% lower NH_3 emissions (Cahn et al., 1998). The inclusion of processed household and industry residues or wastes in the feed rations with a controlled energy/protein ratio is a complementary measure that reduces dependence on imported feedstuff. This measure also represents a reduction of upstream N_r emissions associated with feed production and downstream emissions associated with waste management (Lassaletta et al., 2019; zu Ermgassen et al., 2016).

2.1.3 Feeding strategies for poultry

Adapt protein intake in diet: For poultry, the potential for reducing N excretion through feeding measures is more limited than for pigs because the conversion efficiency currently achieved on average is already high and the variability within a flock of birds is greater. A CP reduction of 1–2% may be achieved depending on the species and the current starting point, but is already a well-proven measure for growers and finishers. Further applied nutrition research is currently being carried out in EU member states and North America and this may support further possible reductions in the future.

2.2 Livestock housing

When using measures to abate emission from livestock houses, it is important to minimize loss of the conserved nitrogen during downstream handling of the manure, in storage and spreading to maximize the benefit from the cost of abatement.

2.2.1 Cattle housing

Housing systems for cattle vary across the ECE region. While loose housing is most common, dairy cattle are still kept in tied stalls in some countries. In loose housing systems all or part of the excreta is collected in the form of slurry. In systems where solid manure is produced (such as straw-based systems), it may be removed from the house daily or it may remain there for up to the whole season, such as in deep litter stables. The system most commonly researched is the 'cubicle house' for dairy cows, where substantial NH_3 emissions arise from fouled slatted and/or solid floors and from manure in pits and channels beneath the slats/floor. There has been much less research to measure NO_x, N_2O and N_2 emissions from cattle housing, so recommendations in some cases have to be based on general principles, and are therefore subject to larger uncertainty than for NH_3 emissions from such systems.

Housed-cattle systems are generally set on stone or concrete bases, so direct nitrate leaching is not expected, unless there are cracked bases associated with poor maintenance. Run-off of N_r compounds from cattle housing systems may occur if ponded excreta is not correctly drained into storage tanks (e.g. associated with flooding events).

While 'hard standings' (typically concrete areas adjacent to dairies) provide a significant source of ammonia emissions outside of animal houses, in some parts of the UNECE region, cattle are kept in confined areas outside (e.g. feed lots), where N_r leaching, run-off and gaseous N losses may be substantial.

Animal welfare considerations tend to lead to an increase of soiled walking area per animal, increased ventilation and an overall increase in emissions. Changes in building design to meet the new animal welfare regulations in some countries (e.g. changing from tied stall to cubicle housing) will therefore increase NH_3 emissions unless abatement measures are introduced at the same time to combat this increase.

Solid versus slurry manure systems: Straw-based systems producing solid manure for cattle are not likely to emit less NH_3 in the animal houses than slurry-based systems. Further, N_2O, NO_x and N_2 losses due to (de)nitrification tend to be larger in litter-based systems than slurry-based systems (Webb et al., 2012; Groenestein and van Faassen, 1996).

While straw-based solid manure can emit less NH_3 than slurry after surface spreading on fields (e.g. Powell et al., 2008), slurry provides a greater opportunity for reduced emission application methods. Verification of any NH_3 emission reductions from using solid-manure versus slurry-based systems and from solid-liquid separation should consider all the stages of emission (housing, storage and land application).

2.2.2 Mitigation measures for cattle housing

Mitigation options for cattle housing can be grouped into the following types:

- Floor-based systems and related management techniques (including scrapers and cleaning robots);
- Litter-based systems (use of alternative organic material);
- Slurry management techniques at pit level;
- Indoor climate control techniques; and
- End-of-pipe techniques (hybrid ventilation + air cleaning techniques) and GHGs abatement/mitigation techniques.

Several pathways can be identified to further optimize existing and develop new abatement techniques. In this respect emission reduction techniques at animal housing level should aim to affect one or more of the following important key factors and/or driving forces of the nitrogen emission process:

- Draining capacity of the floor for direct transportation of urine to the manure storage;
- Residence time of open urine/manure sources;
- Emitting surface area of open urine/manure sources;
- Urease activity in urine puddles;
- Urine/manure pH and temperature (see Housing Measures 6 and 8);
- Indoor air temperature;
- Air velocities at emitting surfaces (urine puddles and manure surface in the pit);
- Air exchange between pit headspace and indoor air; and
- Exhaust of indoor air.

Immediate segregation of urine and faeces: A physical segregation (i.e. keeping separately) of faeces, which contain *urease*, and urine in the housing system reduces hydrolysis of urea, resulting in reduced emissions from both housing and manure spreading (Burton, 2007; Fangueiro et al., 2008a,b; Møller et al., 2007). Both acidification and alkalization of the in-house segregated urine reliably inhibits urea hydrolysis. The duration of the inactivation period can be adjusted by the dosage of acid or alkali addition

Verification of any NH_3 emission reductions from using solid-manure versus slurry-based systems and from solid-liquid separation should consider all the stages of emission (housing, storage and land application). Additional advantages of solid-liquid separation can also be expected during land-application, where urine (containing most of the available ammoniacal N) infiltrates more easily due to its lower dry-matter content than slurry, reducing NH_3 emissions. Although solid manure does not infiltrate, it mainly consists of organic N forms, which are much less liable to NH_3 emissions. Less is known about the consequences of solid-liquid separation on the emissions of N_2O, NO_x, N_2 and nitrate leaching, although substantial adverse effects are not expected.

Regular cleaning of floors in cattle houses by 'toothed scrapers': The 'grooved floor' system for dairy and beef cattle housing, employing 'toothed' scrapers running over a grooved floor, is a reliable technique to abate NH_3 emissions. Grooves should be equipped with perforations to allow drainage of urine. This results in a cleaner, low-emission floor surface with good traction for cattle to prevent slipping. Ammonia emission reduction ranges from 25% to 46% relative to the reference system (Smits, 1998; Swierstra et al., 2001). In the absence of measurement data, it is expected that use of the grooved floor system would have little impact on other N_r and N_2 losses since it is mainly directed to reduce immediate exposure to air of ammonium-rich excreta.

Regular cleaning of floors in cattle houses: Thorough cleaning of walking areas in dairy cattle houses by mechanical scrapers or robots has the potential to substantially reduce NH_3 emissions. The automatic cleaning should be performed at regular intervals (e.g. on an hourly basis) to achieve full benefits of the measure.

Frequent slurry removal: Regular removal of liquid manure from under the slats in the house to an outside store can substantially reduce NH_3 emissions by reducing the emitting surface and the slurry storage temperature. A reduced storage temperature will also result in a reduction of methane emissions.

Increase bedding material: Bedding material in animal housing can affect NH_3, N_2O, NO_x and N_2 emissions. The physical characteristics (urine absorbance capacity, bulk density) of bedding materials are of more importance than their chemical characteristics (pH, cation exchange capacity, carbon to nitrogen ratio) in determining NH_3 emissions from dairy barn floors and pig houses (Misselbrook and Powell, 2005; Powell et al., 2008; Gilhespy et al., 2009; Groenestein et al., 2007). However, further assessment is needed on the effect of bedding on emissions for specific systems while taking into account the whole manure management path. The approach can have a positive interaction with animal welfare measures.

Barn climatization to reduce indoor temperature and air flow: In houses with traditional slats (either non-sloping, 1% sloping, or grooved), optimal barn climatization with roof insulation (RI) and/or automatically controlled natural ventilation (ACNV) can achieve a moderate emission reduction (20%) of NH_3 due to the *decreased temperature* (especially in summer) and *reduced air velocities* (Braam et al., 1997a,b; Smits, 1998; Monteny, 2000). To the extent that such systems cool stored manure, emissions of methane will also be reduced.

Use of acid air scrubbers: Chemical or acid air scrubbers are effective in decreasing NH_3 emissions from force-ventilated pig housing. However, they cannot yet be generally implemented in cattle housing because these are mostly naturally ventilated across the ECE region. Also, there are few data for scrubbers on cattle (Ellen et al., 2008). In any situations where cattle are housed with forced-ventilation, this measure can be considered as Category 1. Recent developments consider combining targeted ventilation of naturally ventilated barns with air scrubbers. More research and development are needed here.

Floor type: Different improved floor types based on slats or solid, profiled concrete elements have been tested. These designs combine emission reduction from the floor (increased run-off of urine) and from the pit (reduction of air exchange by rubber flaps in the floor slots). The emission abatement efficiency depends on the specific technical characteristics of the system.

Increased grazing: Decreasing the amount of animal excrement in animal housing systems through increased grazing is an effective measure to decrease NH_3 emissions. Total annual emissions (including housing, storage and spreading) from dairy systems may decrease by up to 50% with nearly all-day grazing, as compared with animals that are fully confined. While increased grazing is a reliable NH_3 emission reduction measure for dairy cows, the amount of emission reduction depends on the daily grazing time and the cleanliness of the house and holding area. In some cases grazing may also contribute to increased run-off and leaching of NO_3^- and other N_r compounds, as well as N_2O and NO_x emissions. Grazing can also be associated with increased pathogen mobilization.

2.2.3 Pig housing

Designs to reduce NH_3 emissions from pig housing systems have been described in detail in Economic Commission for Europe (2015) and in the IPPC document on Best Available Techniques (BAT) (Santonja et al., 2017). These apply the following main elements:

- Reducing manure surfaces such as soiled floors, using channels for slurry holding surfaces and using sloped walls. Partly slatted floors (~50% area), generally emit less NH_3, particularly if the slats are metal- or plastic-coated rather than concrete, allowing the manure to fall rapidly and completely into the pit below. Emissions from the non-slatted areas are reduced by inclined, smooth surfaces, by locating the feeding and watering facilities to minimize fouling of these areas, and by good climate control in the building;
- Removing the slurry from the pit frequently to an external slurry store with vacuum or gravity removal systems or by flushing systems at least twice a week;
- Additional treatment, such as liquid/solid separation; provided that the storage of the separated fractions maintains low emissions;
- Circulating groundwater or other cooling agents in floating heat exchangers or walls of slurry pits to cool the surface of the manure in the under-floor pit to at least below 12°C. Constraints include costs and need to locate a source of groundwater away from the source of drinking water;
- Changing the chemical/physical properties of the manure, such as decreasing pH;
- Using surfaces which are smooth and easy to clean (see above);
- Treatment of exhaust air by acid scrubbers or biotrickling filters;
- Lowering the indoor temperature and ventilation rate, taking into account animal welfare and production considerations; and
- Reducing airflow over the manure surface.

For a given floor slat width, manure drains from concrete slats less efficiently than from steel- and plastic-covered slats and this is associated with greater emissions of NH_3. Note that steel slats are not allowed in some countries for animal welfare reasons. Cross-media effects have been taken into account in defining BAT for the various housing designs. For example, frequent flushing of slurry (normally once in the morning and once in the evening) causes nuisance odour events. Flushing slurry also consumes energy unless manually operated passive systems are used.

Use of straw litter in pig housing is expected to increase due to concern for the welfare of the pigs. In conjunction with (automatically controlled) naturally ventilated housing systems, straw allows the animals to self-regulate their temperature with less ventilation and heating, reducing energy consumption. In systems with litter, the pen is sometimes divided into solid areas with litter and slatted dunging areas. However, pigs do not always use these areas in the desired way, using the littered area to dung and the slatted area to cool off in warm weather. Generally, pens should be designed to accommodate desired excreting behaviour of pigs to minimize fouling of solid floors. However, this is more difficult in regions with a warm climate. Note that integrated evaluation of straw use should consider (a) the added cost of the straw and mucking out the pens, (b) the possible increased emissions from storage and application of manure with straw and (c) the benefit of adding organic matter from straw to the soil.

2.2.4 Mitigation measures for pig housing

The reference system, used commonly in Europe, is a fully slatted floor with a deep manure pit underneath and mechanical ventilation; emission ranges from 2.4 kg NH_3 to 3.2 kg NH_3 per finisher pig place per year. Since growers/finishers are always housed in a group, most systems used for group housing of sows are applicable to growers. Emissions from different abatement/mitigation approaches are compared with this reference system in terms of the emission reduction amount (Bittman et al., 2014). Most data are available for NH_3, with little data concerning effects on N_2O, NO_x, N_2 and nitrate leaching. The underlying principles are largely similar for these losses as for cattle housing systems, recognizing the different housing needs of pigs and the particular characteristics of pig excreta.

Acidification of slurry: Reductions in NH_3 emissions can be achieved by acidifying slurry to shift the chemical balance from the gaseous NH_3 to the ionic and soluble NH_4^+. The manure (especially the liquid fraction) is collected into a tank with acidified liquid (usually using sulphuric acid, but organic acids can be used as well, though at higher cost) maintaining a pH of less than 6 (Bittman et al., 2014; Fangueiro et al., 2015). In pig housing systems, emission reduction of 60% or more have been observed (Kai et al., 2008). The measure is not anticipated to affect other N_r or N_2 losses. Acidification of slurry is anticipated to be effective for both cattle and pig slurry, though measurements have so far concentrated on investigating pig slurry. One study (Petersen et al., 2012) showed acidification of cattle slurry to pH 5.5 reduced the NH_3 emissions by more than 90% and at the same time reduced emissions of the GHG CH_4 by 67–87%. Attention should be given to monitoring soil pH and metal content if acidified slurry is to be used in agriculture. In-house acidification will reduce NH_3 emissions throughout the manure management chain. Furthermore, slurry acidified with sulphuric acid is not suitable as the sole feedstock for biogas production (but can be used as a smaller proportion).

Reduce emitting surface: Ammonia emissions can be reduced by 25% by decreasing the surface area of the emitting floor through frequent and complete vacuum-assisted drainage of slurry from the floor of the pit. Where this is possible, this technique has no cost. Partly slatted floors covering 50% of floor area generally emit 15–20% less NH_3, particularly if the slats are metal or plastic-coated which is less sticky for manure than concrete. Decreasing the risk of emissions from the solid part of the floor can be achieved by: (a) using an inclined (or convex), smoothly finished surface, (b) by appropriate siting of the feeding and watering facilities to minimize fouling of the solid areas and (c) by good climate control (Aarnink et al., 1996; Guingand and Courboulay, 2007; Ye et al., 2008a,b). Further reduction of the emitting area can be achieved by making both the partly slatted area and the pit underneath smaller. With the smaller slatted area, the risk of greater fouling of the solid area can be mitigated by installing a small second slatted area with a water canal underneath at the other side of the pen where the pigs tend to eat and drink. The canal is filled with about 2 cm of water to dilute any manure that might eventually drop into it. This slatted area will have low emissions because any manure dropped here will be diluted. This combined manure-canal and water-canal system can reduce NH_3 emissions by 40–50% depending on the size of the water canal. This approach is not expected to have a significant effect on emissions of N_2 or other N_r compounds.

Reducing the emitting surface area by having one or two slanted pit walls, in combination with partly slatted floors and frequent manure removal, can reduce emissions by up to 65%. Reducing the emitting surface area with shallow V-shaped gutters (maximum 60 cm wide, 20 cm deep) can reduce emission in pig houses by 40–65%, depending on the pig category and the presence of partly slatted floors. The gutters should be flushed twice a day with the liquid (thin) fraction of the slurry rather than water; flushing with water dilutes the manure and increases the cost of transporting and applying it in the field.

Increase bedding material (solid manure housing): Bedding material in animal housing can affect NH_3, N_2O, NO_x and N_2 emissions. The physical characteristics (urine absorbance capacity, bulk density) of bedding materials are of more importance than their chemical characteristics (pH, cation exchange capacity, carbon to nitrogen ratio) in determining NH_3 emissions from dairy barn floors (Misselbrook and Powell, 2005; Powell et al., 2008; Gilhespy et al., 2009). However, further assessment is needed on the effect of bedding on emissions for specific systems while taking into account the whole manure management path. The approach can have a positive interaction with animal welfare measures. However, approaches benefiting animal welfare can also be operated as slurry-based systems, with only little straw supply.

Regular cleaning of floors: Cleaning of floors in pig houses by mechanical scrapers or robots has the potential to substantially reduce NH_3 emissions. The automatic cleaning should be performed at regular intervals to achieve full benefits of the measure (Amon et al., 2007). It is worth mentioning that in warm countries (e.g. Mediterranean region), for sanitary reasons, floor cleaning is done more frequently with consequences in the slurry composition, which may reach up to 98% water.

Frequent slurry removal: Regular removal of slurry from under the slats in the house to an outside store can substantially reduce NH_3 emissions by reducing the emitting surface and the slurry storage temperature. A reduced storage temperature will also result in a reduction of methane (Amon et al., 2007).

Barn climatization to reduce indoor temperature and air flow: Surface cooling of manure with fans using a closed heat exchange system is a technique with a reduction efficiency of 45–75% depending on animal category and surface of cooling fins. This technique is most economical if the collected heat can be exchanged to warm other facilities such as weaner houses (Huynh et al., 2004). In slurry systems this technique can often be retrofitted into existing buildings. However, this system is not applicable when straw bedding is used or when the feed contains a lot of roughage. This is because a layer of floating residue may develop on top of the slurry.

Use of acid air scrubbers: Treatment of exhaust air by acid scrubbers (mainly using sulphuric acid) or biotrickling filters has proven to be practical and effective for large-scale operations in Denmark, Germany, France and the Netherlands (e.g. Melse and Ogink, 2005; Guingand, 2009). This is most economical when installed in new houses, because retrofitting in existing housing requires costly modification of ventilation systems. Acid scrubbers have demonstrated NH_3 removal efficiencies of more than 90%, depending on their pH-set values. Scrubbers and biotrickling filters also reduce odour and particulate matter by 75% and 70%, respectively (Guingand, 2009). Further information is needed on the suitability of these systems in South and Central Europe. Operational costs of both acid scrubbers and trickling filters are especially dependent on the extra energy use for water recirculation and to overcome increased back pressure on the fans. Optimization methods are available to minimize costs (Melse et al., 2012) and costs will be lower for large operations. The approach may also contribute to reducing N_2O and NO_x emissions, but more research is needed here.

Use of biological air scrubbers: Biological air scrubbers operate with bacteria that remove ammonia and odours from the exhaust air. Ammonia captured in biological air scrubbers typically undergoes nitrification and denitrification associated with increased emissions of N_2O, NO_x and N_2. Recovery of the collected N_r in bio-scrubbers may help offset this increase by reducing the need for fresh N fixation and production of chemical fertilizers.

2.2.5 Poultry housing

Designs to reduce NH_3 emissions from poultry housing systems have been described in detail in Economic Commission for Europe (2015) and in the document on BAT under the EU Industrial Emissions Directive (Santonja et al., 2017), and applying the following principles:

- Reducing the open surface area of emitting manure;
- Removing the manure frequently from the poultry house to an external slurry store (e.g. with belt removal systems);
- Quickly drying the manure to reduce hydrolysis of uric acid to ammonia;
- Using surfaces which are smooth and easy to clean;
- Treatment of exhaust air by acid scrubbers or biotrickling filters (i.e. biological air scrubbers); and
- Lowering the indoor temperature and ventilation as animal welfare and/or production allow, reducing microbial processes that mobilize N_r losses.

Many of the measures listed for cattle and pigs are also applicable for poultry systems, especially reduction of emitting surface, barn climatization to reduce indoor temperature and air flow), and acid air scrubbers. This section therefore focusses on additional considerations for poultry housing. Further information can be found in European Commission (2015), in the IPPC BREF document (Santonja et al., 2017) and in the UNECE Ammonia Guidance Document (Bittman et al., 2014).

Where poultry houses are disconnected from the ground (e.g. concrete base), emission reduction measures for NH_3 are not directly expected to affect nitrate and other N_r leaching and run-off. For smaller farms, which are not required to comply with national legislation (e.g. BAT) for layers, and for free-range poultry, pathways to the soil can also be anticipated. In such cases, NH_3 emission reduction including rapid drying and dry storage of poultry litter may also have benefits to reduce N_r leaching. In addition, expert observations have shown that downward pointing air exhausts onto porous ground surfaces surrounding poultry houses can lead to localized increases of N_r leaching and run-off into ground waters. Reduction of NH_3 emissions (and N_r-containing dusts) can therefore also contribute to reducing such hotspots of N_r leaching and run-off.

2.2.6 Mitigation measures for housing systems for laying hens

A wide range of regulations and minimum standards for protecting laying hens exist across the UNECE region. For example, in the EU, regulations apply under Council Directive 1999/74/EC. This Directive has prohibited the use of conventional cage systems since 2012. Instead, only enriched cages (also called 'furniture cages'), or non-cage systems, such as litter (or deep litter) housing systems or aviary systems, are allowed.

Rapid drying of poultry litter: Ammonia emissions from battery deep-pit or channel systems can be lowered by reducing the moisture content of the manure by ventilating the manure pit. The collection of manure on belts and the subsequent removal of manure to covered storage outside the building can also reduce NH_3 emissions, particularly if the manure has been dried on the belts through forced ventilation. The manure should be dried to 60–70% DM to minimize the subsequent formation of NH_3. Manure collected from the belts into intensively ventilated drying tunnels, inside or outside the building, can reach 60–80% DM content in less than 48 h, but in this case exposure to air is increased, risking an increase in NH_3 emissions. Weekly removal from the manure belts to covered storages reduces emissions by 50% compared with bi-weekly removal. In general, emission from laying hen houses with manure belts will depend on: (a) the length of time that the manure is present on the belts, (b) the drying systems, (c) the poultry breed, (d) the ventilation rate at the belt (low rate = high emissions) and (e) the feed composition. Aviary systems with manure belts for frequent collection and removal of manure to closed storages reduce emission by more than 70% compared with the deep litter housing system. While the primary drying poultry litter has been on reducing NH_3 emissions, keeping excreted N in the form of uric acid can be expected also to reduce N_2O, NO_x and N_2, since this will also reduce nitrification and denitrification. Dried poultry litter will therefore have a higher fertilizer value for farmers, which should be compensated by using reduced doses during land application, as compared with decomposed poultry litter.

Use of acid or biological air scrubbers: Treatment of exhaust air by acid or biological scrubbers (=biotrickling filters) has been successfully employed in several countries (Melse and Ogink, 2005; Ritz et al., 2006; Patterson and Adrizal, 2005; Melse et al., 2012). Hahne et al. (2016) in Germany counted 179 installed air scrubbers in poultry installations and 1012 scrubbers installed in pig houses, respectively. The main difference from pig systems is that poultry houses (especially with dried litter) typically emit a much larger amount of dust. Acid or biological scrubbers remove 70–90% of NH_3, and also remove fine dust and odour. To deal with the high dust loads, multistage air scrubbers with pre-filtering of coarse particles have been developed (Ogink and Bosma, 2007; Melse et al., 2008).

2.2.7 Mitigation measures for housing systems for broilers

To minimize NH_3 emission in broiler housing, it is important to keep the litter dry. Litter moisture and emissions are influenced by:

- Drinking-water design and function (leakage and spills);
- Animal weight and density, and duration of the growing period;
- Ventilation rate, use of in-house air purification and ambient weather;
- Use of floor insulation;
- Type and amount of litter; and
- Feed.

Reducing spillage of water from the drinking system: A simple way to reduce spillage of water from the drinking system is using a 'nipple drinkers' instead of 'bell drinkers'. This approach should be integrated into wider systems designed to keep poultry litter dry.

Air scrubber technologies to remove NH_3 from ventilation air are highly effective, but not currently widely implemented because of high installation and running costs. Packed-bed filters and acid scrubbers currently available in the Netherlands and Germany remove 70–90% of NH_3 from exhaust air. Comprehensive measuring of air scrubbers is done by the German Agricultural Association (DLG, 2020) based on a scientific standard testing frame. As with such systems for laying poultry, questions about long-term reliability due to high dust loads need to be further clarified. Various multi-pollutant scrubbers have been developed to also remove odour and particulate matter (PM_{10} and $PM_{2.5}$) from the exhaust air (Zhao et al., 2011; Ritz et al., 2006; Patterson and Adrizal, 2005). Implementation of both acid scrubbers and biological air scrubbers for broiler housing is largely similar to that for laying hens

3 Manure storage, treatment and processing

3.1 Principles of emissions from manure storage, treatment and processing

For livestock agriculture to become sustainable, an optimal and efficient use of manure nutrients and organic matter is essential. However, manure nitrogen may be easily lost via gaseous emissions (NH_3, N_2O, NO_x and N_2) and leaching of nitrate (NO_3^-) and other N_r compounds. Besides nitrogen losses, animal and manure emissions of methane (CH_4) to the atmosphere must be reduced as far as possible, to limit climate change impacts.

Significant N losses may occur during storage of urine, faeces or mixtures (slurries and farmyard manures/deep litters), and simple treatment (e.g. solid-liquid separation) or more advanced processing (e.g. anaerobic digestion, ultrafiltration) may enable more appropriate manure management with lower N losses.

The *treatment of manures* typically involves a one-step operation to improve the properties of the manure. Expected effects include the improvement of the fluid properties (by adding water or by separating solids), the stabilization of volatile nutrients (by acidification) or a reduction in odour nuisance (e.g. aeration). Single-stage treatment of manures is typically applied on farms in the proximity of livestock buildings. The mass and ingredients of manures are not or only slightly changed by treatment systems.

The *processing of manures* generally describes more complex and multi-step processes, which are used specifically to produce new products, for example,, higher nutrient content, less water content, free of undesirable odours and hygienically safe. In most cases, manure processing is used to produce marketable products that can be used as fertilizers and soil conditioners, as well as secondary raw materials (e.g. fibres). Manure processing technologies may either be located on farms or operated as central/decentral plants.

Manure treatment and processing always come at a cost, both in economic, energy and environmental terms, so the simplest option fulfilling the goal(s) should always be the priority option: (1) direct land application, (2) simple treatment second, (3) advanced processing (with (1) first, according to local limitations, including those related to pollution). Simple treatment and advanced processing are most relevant when conditions (e.g. high regional livestock density, large manure N surplus relative to local crop demand) favour overall environmental benefits from treatment or processing. Such systems should be designed with awareness of the need to avoid pollution swapping (e.g. reducing ammonia loss, but increasing nitrate leaching somewhere else and vice versa).

Animal slurry composition is typically not ideal with regard to low emission handling and crop fertilizing properties. In particular, the high DM and carbon content pose several problems during slurry storage, application and crop utilization (Table 1). This points to the opportunity for increased development of systems to collect and store urine and dung separately, or to apply manure treatment by solid-liquid separation.

High slurry DM tends to result in crust formation on the slurry surface and/or to sedimentation on the bottom of the slurry tank. In order to achieve an even distribution of nutrients in the slurry, slurry must be mixed/homogenized prior to application. Homogenization of slurry with high DM content is energy-consuming and increases NH_3 emissions as a larger volume of the slurry comes in close contact with the atmosphere.

Slurry contains considerable amounts of easily degradable carbon that serves as substrate for microbes. During slurry storage a continuous degradation of organic matter can be observed. Degradation intensity is strongly dependent on the slurry DM content. Amon et al. (1995) investigated changes in slurry composition over a 200-day storage period for stored cattle, beef and pig slurry. Degradation of organic matter was found to be significantly greater with higher slurry DM content. Such slurry degradation will include mineralization to form of ammonium (NH_4^+) from organic matter. This points to the opportunity for increasing the immediate fertilizer value of the slurry, provided that storage is covered, thereby avoiding NH_3 emissions and benefiting from increased slurry NH_4^+ content.

As conditions in slurry are anaerobic, degradation of organic matter is always dominated by anaerobic pathways. This means, that both CH_4 and CO_2 are formed as end-products of the degradation process. It is thus to be assumed that high DM slurry bears a greater risk for CH_4 emissions, contributing

Table 1 Challenges and benefits resulting from slurry high dry matter and carbon content, low nutrient content

	Problems
Storage	• natural crust formation and sedimentation of solids, giving heterogeneous concentration of nutrients • high energy consumption per unit of nutrient for pumping and mixing • potentially higher emissions of NH_3, N_2O, N_2, CH_4 and odour
Field application	• high potential risk of NH_3 losses due to slow infiltration • high technical effort required (at high economic cost) for even and low emission application • suffering of crop plants due to scorching by broadcasted slurry
Crop utilization	• less effective crop uptake of slurry N than from mineral fertilizer • increased temporary N immobilisation in the soil, increasing risk of lower crop N effect • higher risk of denitrification and subsequent N_2O and N_2 emissions • crop N effect less predictable/more variable than from mineral fertilizer
	Benefits
Storage	• natural crust formation may serve as a natural barrier, inhibiting NH_3 transport to the atmosphere; furthermore, the crust may have significant capacity for CH_4 oxidation, due to its partial aerobic conditions and high microbial activity
Field/soil	• high dry matter and carbon content contributes to maintenance of soil organic matter content and biologically active soil

significantly to climate change. This also points to the opportunity for CH_4 and CO_2 recovery, for example, linked to anaerobic digestion for production of biogas.

Environmental-friendly slurry application in the field requires that the slurry is more evenly applied near or below the soil surface. It is much more complicated to fulfil this requirement when the slurry has a higher DM content, causing a higher viscosity and less easy flow through band spreading hoses. Following application of slurry, NH_3 emissions can be substantial and are found to increase with an increase in slurry DM content, due to slower soil infiltration (Sommer et al., 2013; Bittman et al., 2014). This emphasizes the importance of maintaining low DM contents of slurries. By reducing NH_3 and other nitrogen losses, available N resources on farms are increased, decreasing the need for additional N to be bought as manufactured inorganic fertilizer.

The N availability to plants is difficult to calculate with high DM slurry, because a high DM content drives increased microbial immobilization right after application. The more narrow the C/N-ratio, and the higher NH_4-N content, the more slurry N is potentially available to plants, whereas with a wide C/N-ratio,

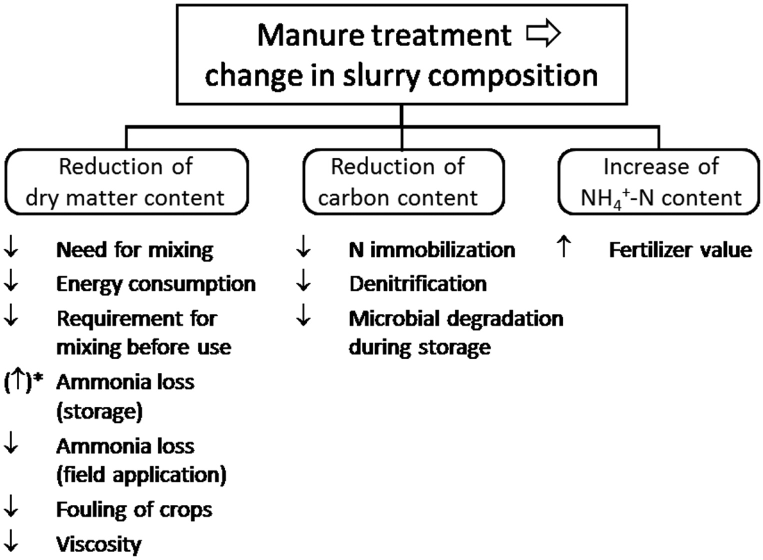

Figure 4 Effect of changes in slurry composition achieved by manure treatment. Arrows indicate decrease (↓) or increase (↑) in the listed property. * If depending on natural crusting of manure to reduce emissions rather than other types of cover.

part of the slurry N is immobilized in the soil N pool and becomes available only at a later and often unpredictable or even too late stage, causing increased risk of nitrate leaching. In addition, an increase in slurry DM and subsequent soil N content has the potential to increase rates of nitrification and denitrification, increasing subsequent N_2O, NO_x and N_2 losses (e.g. Dosch, 1996). It may thus be beneficial to reduce slurry DM and carbon content at an early stage of manure management. This leads to several manure treatment options that can be evaluated in relation to the requirements listed in Fig. 4.

In line with the objectives of the EU Circular Economy Action Plan,[1] there is an opportunity to encourage the use of recycled nutrients that can replace nutrients otherwise obtained from primary raw materials. The main challenge is to use recycled nutrient resources that have an equal or better environmental performance than the primary nutrient resources they replace. Efforts are ongoing across the EU to develop manure-processing technologies that allow manure to be turned into a safe and agronomically valuable resource that could be more widely used.[2]

Techniques for simple manure treatment can be classified as physical, chemical or biological (Fig. 5, Bernal et al., 2015). Furthermore, a number of

2 https://ec.europa.eu/jrc/en/research-topic/waste-and-recycling

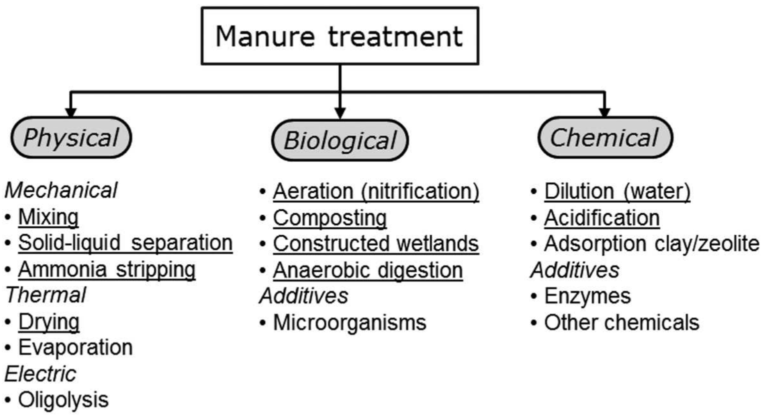

Figure 5 Options for simple manure treatment. Options underlined are in some regions commonly applied in full scale on commercial farms (mainly pig farms); other options are applied either rarely or only in experimental/pilot scale – these are not dealt with further here, pending the availability of proof-of-concept and documentation.

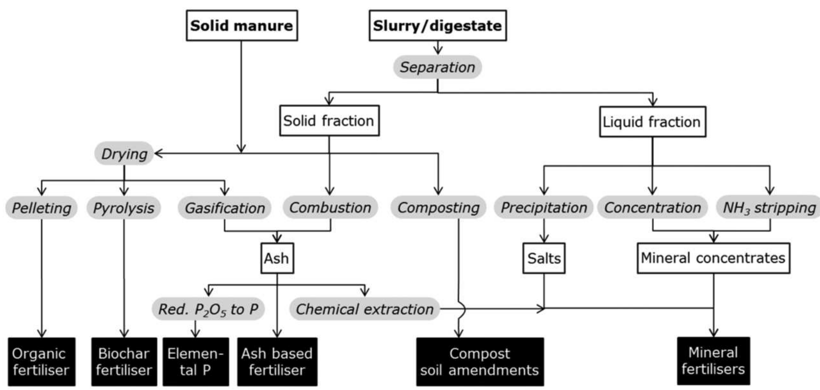

Figure 6 Options for combining simple treatment with more advanced processing of manures to recover and upgrade nutrient and energy, resulting in widely different bio-based fertilizers (modified from Jensen, 2013). Only a few are yet applied in full commercial scale; other are still in experimental/pilot stage (and are therefore not dealt with further here).

different options/technologies are available for further and more advanced processing of raw or treated manures for recovering and upgrading nutrients and organic matter from different manure types (Fig. 6). For slurries or other liquid manures, such as digestate from anaerobic digestion of manure and other bio-waste, all treatment steps start with mechanical separation into (a) a *solid fraction* which is relatively rich in organic N and P, and (b) a *liquid fraction*, with low P, but relatively high mineral N and K contents. Different simple techniques can be combined with each other. This allows a wide variety of by-products to be combined, resulting in highly variable distribution of organic nitrogen, ammoniacal nitrogen, phosphorus, carbon and other nutrients, which must be taken into account when managing the different fractions.

There may be additional possible treatments of the liquid phase. In order to save water without increasing the amount of nitrogen supplied to the soil, and to favour the circular economy of water, it is common to carry out successive treatments of the liquid phase, so that the resulting product can be used in fertigation. For example, in the south of Spain wetlands are being constructed to allow the reuse of water for irrigation, in areas of scarce availability. In addition to nitrogen, many other characteristics have an influence in the decision of choosing a procedure, such as the contribution of organic matter, the formation of methane and other GHGs, the presence of other nutrients, type of agricultural systems, salinity, weather and, very important in the countries of southern Europe, the water footprint.

Each of these processing pathways and resulting products (Fig. 6) has certain advantages and disadvantages, and the net environmental benefits/impacts and economic costs/profits differ greatly. A number of factors must be considered when prioritizing the processing options (Jensen, 2013):

- The primary aim should be nutrient recycling, mainly N and P; N is consumed in the largest quantities, is expensive and has impacts on energy consumption and GHG emissions, while P is a scarce and non-renewable resource, with the highest price.
- Splitting N and P into different fractions is generally beneficial, as this enables more flexible and balanced fertilization in accordance with the needs of many crops.
- The technology or combination of technologies applied should preferably also produce energy or consume relatively little energy, so net energy production should be taken into account for both environmental and economic reasons.
- Local solutions should be preferred, avoiding too high transport cost and impacts; regional or more central solutions are therefore only justified if the economy of scale via higher efficiency outweighs the negative impacts of transporting the manure to a common facility.
- The quality of end-products and byproducts is assessed differently depending on the perspective of the user. For instance, a manure combustion ash, where the majority of the N has been lost, will not be appreciated by an organic farmer, while a compost is highly appreciated for its soil ameliorating effect and slow release of N, even if some N has been lost in the process.
- Biochars and compost may be valued highly by orchard and vineyard producers for its effects on soil-water-holding capacity and nutrient

retention, whereas conventional crop production farmers may value mineral concentrates and salts more highly. Production of recovered, bio-based fertilizer products should not be supply-driven (trying to solve a waste problem), but rather demand-driven (bio-based fertilizers that the farmers want).

3.2 Mitigation measures for manure storage, treatment and processing

3.2.1 Covered storage of slurry (natural crust)

Where slurries have a high DM content, these may form a natural crust during storage, which is associated with substantially reduced ammonia emission (Bittman et al., 2014). There is large agreement that crusting impacts the gas release in many ways: enhanced resistance to mass transfer (Olesen and Sommer, 1993), oxidation of NH_3 (Nielsen et al., 2010) and CH_4 (Petersen et al., 2005) and formation of N_2O related to nitrification and denitrification occurring in liquid-air interfaces near air-filled pores present in crusts (Petersen and Miller, 2006). NH_3 and CH_4 may be consumed due to microbial activity in the crust leading to an emission reduction (Petersen and Ambus, 2006; Nielsen et al., 2010) while N_2O production may be enhanced (VanderZaag et al., 2009). A comprehensive assessment of the current knowledge on the effect of natural crusts can be found in Kupper et al. (2020). The reference is taken as uncovered storage, including on an impermeable surface, which explains the benefit for nitrate leaching.

3.2.2 Covered storage of manure (solid cover)

A wide range of options are available for covered manure storage using solid covers, including use of metal tanks with solid lids, floating covers on lagoons and use of slurry bags, most of which are associated with negligible ammonia emission if well operated. Further details of such systems are provided by Bittman et al. (2014). Less focus has been given to ensuring that solid manure (e.g. farmyard manure and poultry manure) are covered, for example, through use of plastic sheeting. The reference is taken as uncovered storage, including on an impermeable surface, which explains the benefit for nitrate leaching.

3.2.3 Covered storage of manure (dispersed coverings)

Ammonia emissions can be significantly reduced when covering solid organic fertilizers with dispersed coverings such as peat, clay, zeolite and phosphogypsum. The basis of the approach is to prevent contact of NH_3 emitting surfaces with the air, especially when covering them with ammonium absorbing substances. Lukin et al. (2014) found that total NH_3 emissions from poultry manure amounted to 5.9% when it was covered with peat, 4.7% when it was covered with loam, 1.3% when it was covered with zeolites and 16.9% when it was covered with phosphogypsum. These values are relative to NH_3 emissions in the reference variant with no covering. Use of these simple materials to cover piles of organic fertilizers thereby substantially reduces NH_3 emissions into the atmosphere (Lukin et al., 2014). Protocols are needed to specify minimum thickness of each type of covering material. Further testing is needed to assess the effect on N_2O, NO and N_2 emissions. Unless an impermeable base is used, the approach risks significant nitrate leaching. In combination with an impermeable base, it can reduce both N_r emissions to air and leaching losses to water.

3.2.4 Storage of solid manure under dry conditions

Simply storing manure in a dry place, out of the rain, can also reduce nitrogen emissions from a range of N_r compounds and N_2. This is even more important for dried poultry litter, where keeping manure dry and out of the rain helps to avoid hydrolysis of uric acid to form ammonia. However, poultry litter is hydroscopic and will emit some ammonia when in humid atmospheres, even when kept free of rain (e.g. Elliot and Collins, 1982). Keeping solid manure dry during storage minimizes mineralization and denitrification which can give rise to N_2O, NO_x and N_2 emissions, as well as reducing nitrate and other N_r leaching.

3.2.5 Storage of manure on a solid concrete base with walls

Investments in this approach have been motivated out of the need to reduce nitrate leaching and other N_r leaching by avoiding run-off and infiltration into the soil. The approach has the benefit of being low-cost, but risks substantial NH_3 emissions, while also being ineffective at avoiding nitrification and denitrification, which contribute to N_2O, NO_x and N_2 emissions. The approach is preferable to open-field storage of solid manure on a permeable surface. Storage of solid manure on concrete areas is considered good agricultural practice for nitrate pollution, but makes no contribution to reducing NH_3 emissions.

3.2.6 Slurry mixing

Slurry mixing in the storage is one of the most commonly applied manure treatment technologies. Slurry is thereby homogenized, typically shortly prior to field application, in order to achieve a more homogenous distribution of nutrients across the field(s) to which the volume of the slurry storage is applied. Apart from this, mixing does not offer any additional benefits compared to untreated slurry. Neither DM nor carbon content is reduced, and the C/N-ratio is not altered. No significant changes in N_2O or CH_4 emissions are expected, but NH_3 may tend to increase, depending on the extent and timing of mixing (mixing will tend to increases pH by promoting CO_2 loss from slurry), so mixing should only be done shortly before field application.

3.2.7 Adsorption of slurry ammonium

Slurry additives can act on a chemical, physical or biological basis. Clay/zeolite mineral additives have been shown to adsorb NH_4-N and can thus potentially reduce NH_3 losses. However, this can only be achieved effectively with high amount of additives, for example, 25 kg of zeolite per m^3 slurry have been shown necessary to adsorb 55% of NH_4-N (Kocatürk-Schumacher et al., 2017, 2019). On most commercial farms it is neither logistically possible nor economically profitable to add such high amounts of slurry additives. Addition of biochar may also reduce NH_3 emissions from stored manure.

3.2.8 Slurry acidification during storage

An obvious way to minimize ammonia emissions from stored slurry is to decrease pH by addition of strong acids or other acidifying substances. This can also be done in the animal house (Housing Measure 8). Care must be taken that the low pH is maintained to get the full benefit of this measure. Slurry with a sufficiently reduced pH will also emit less methane. This solution has been used commercially since 2010 in countries such as Denmark (by 2018, around 15–20% of all slurry applied in Denmark was acidified; Birkmose, pers. comm.), and its high efficiency for minimizing NH_3 emissions has been documented in many studies (see review by Fangueiro et al., 2015, with emission reductions by >80% possible). It is most typical to acidify slurry using sulphuric acid (cheapest industrial acid; also, the sulphate added serves as a relevant plant nutrient source), though use of other acids is also possible. Acidification also reduces methane formation very effectively, by up to 67–87% (Petersen, 2018). Reduced nitrification and denitrification decrease the potential for N_2O and N_2 emission, though further studies are required to demonstrate efficiency for this. In one novel variant of this method, electricity is used to produce a plasma, which oxidizes N_2 to NO and thence to nitrogen dioxide (NO_2), which converts in slurry to produce nitric acid (HNO_3). In this way, slurry acidification is achieved while augmenting the nutrient value of the manure (Graves et al., 2019). More research is needed to assess this option fully.

Costs for in-house acidification systems can be higher than acidification during field application (Manure Measure 9), but are counteracted by additional benefits including improved in-house air quality benefiting animal and staff, which may influence productivity, retention of more slurry

N throughout the manure management chain, and associated savings in fertilizer costs.

3.2.9 Slurry aeration

Slurry aeration introduces oxygen rapidly into the slurry in order to allow aerobic microbes to develop. Oxidation of organic matter to CO_2 and H_2O increases, and thus CH_4-production and emission is reduced. Odorous compounds are degraded. Slurry DM content decreases. Thus, less mixing is needed and technical properties of slurry are often improved. However, successful aeration requires 200 m^{-3} oxygen per t of slurry (Burton, 1998).

Slurry aeration increases NH_3 emissions and energy consumption. The potential for NO_x emissions is also expected to increase, as increased oxygen availability promotes nitrification, while subsequently higher levels of nitrate availability may increase other oxidized N_r losses and denitrification. The extent of these increases has so far been quantified only in few studies (Amon et al., 2006) and more research is necessary to allow a complete evaluation. In the present context, an increase in denitrification to form N_2 is considered a waste of available N_r resources.

3.2.10 Mechanical solid-liquid separation of slurry fractions

During slurry separation, solids and liquids are mechanically separated from each other. This results in two fractions: a liquid slurry fraction, with relatively low DM content compared with the slurry, and a solid fraction that can be stored in heaps. Energy consumption for slurry separation is relatively low, but depends on the technology used for separation. DM content in the liquid fraction is reduced by 40–45%, and vice versa for the solid. Carbon content in the liquid is typically reduced by 45–50%, with the C/N-ratio of the liquid decreasing from about 10:1 to about 5:1 (Amon et al., 1995; Sommer et al., 2013). As carbon is removed from the slurry, microbial degradation of organic matter during slurry storage is reduced. However, the opposite may be the case for the solid fraction, depending on storage conditions.

The removal of solids reduces crust formation and sedimentation of the liquid fraction compared to raw slurry. Thus, less-intensive mixing is necessary to homogenize the slurry prior to application. Efforts for low-emission application techniques are also reduced as separated slurry has a lower viscosity and flows more easily through band spreading hoses (Owusu-Twuma et al., 2017). Slurries with very low DM content can be spread with simple nozzle-beam-dischargers that can be operated on slopes >10%, which is not possible with other band-spreading techniques. Furthermore, separated slurry liquid fraction has a low viscosity and infiltrates rapidly into the soil. Thus, plants get less dirty, and ammonia emissions after liquid fraction spreading are typically reduced.

A substantial reduction of ammonia emissions by slurry separation is therefore possible for the liquid phase, especially following land application (e.g. Amon et al., 2006).

The liquid fraction of separated slurry has a narrow C/N-ratio which reduces the potential for microbial N immobilization in the soil and the potential for N_2O emissions. Crop N availability of the liquid fraction is therefore more predictable and can be better calculated in order to match nutrient requirements of crops to actual fertilization. Dosch (1996) investigated fertilization with untreated and separated slurries and found significantly higher denitrification rates with untreated slurry. Separated slurry liquid fraction on the other hand resulted in significantly higher crop yield. However, the solid fraction needs to be handled with care during storage to avoid elevated ammonia emissions. Furthermore, the solid fraction may become a source of methane emissions, if not properly treated. Alternatively, if the solid fraction is used as feedstock for biogas production, this methane potential may be recovered and utilized as renewable energy source. After application, the solid fraction serves mainly as soil improvement and slow release N fertilizer.

Slurry separation fulfils most requirements of appropriate manure treatment. Costs could be further reduced if the technology was more widespread and more separators were on the market and available to farmers. As the fertilizer value of the liquid fraction from separated slurry is improved, mineral N fertilizer input can be reduced. The slurry liquid fraction can be applied at the soil surface in a growing crop with very simple low-cost slurry band spreaders with a high uptake efficiency and fertilizer replacement value. The main caveat of the method is the difficulty of appropriate storage, handling and utilization of the solid fraction; this needs to be low emission, in order not to compromise benefits of the liquid fraction. An alternative is to use the solid fraction as a feedstock in nutrient anaerobic digestion with nutrient recovery.

3.2.11 Anaerobic digestion

Anaerobic digestion of animal manures is mainly implemented for bio-energy production reasons. Improvement of manure quality is therefore typically considered to be a 'by-product' of anaerobic digestion. However, when combined with nutrient recovery methods (Fig. 6), nutrient management can be considered as fully integrated as a key goal in implementation of anaerobic digestion.

Biogas production from animal manures through anaerobic digestion aims at maximizing the bio-methane yield. Where no biogas recovery system is available, unintended anaerobic degradation of organic substances into methane during manure storage should be limited as far as possible, to prevent emission to the atmosphere of this strong GHG. This also maximizes the resource availability for subsequent biogas production when facilities are available. Under these circumstances (including heating of the manure to promote digestion) methane production is enhanced, allowing its collection and use (e.g. in combined heat and power production). Anaerobic digestion not only reduces methane emissions from subsequent storage of the manure digestate, but the energy produced typically substitutes consumption of use of fossil energy. Both effects reduce anthropogenic GHGs.

Anaerobic digestion reduces manure carbon and DM content by about 50% (Amon and Boxberger, 2000). NH_4^+ content and pH in digested slurry are higher than in untreated slurry. Thus, potential for ammonia emissions during subsequent slurry storage are increased. Digested slurry therefore has to be stored in covered slurry stores. These should be connected to the gas-bearing system of the biogas plant, because methane is still formed after the main digestion phase has taken place in the heated digester.

Due to the reduced DM content, biogas slurry can infiltrate more rapidly into the soil, which tends to reduce ammonia emissions after slurry application. However, the increased NH_4^+ content and pH give rise to higher potential for ammonia loss especially after surface application. It is therefore strongly recommended to apply biogas slurry with low-emission techniques near or below the soil surface (e.g. band application or injection).

The combined implementation of anaerobic digestion (reducing DM content, increased NH_4^+ and pH) and low-emission land-spreading application (e.g. trailing hose, injection) considerably reduces ammonia emissions. In addition, N immobilization and N_2O losses are likely to be smaller than from untreated slurry, due to the removal of easily degradable organic substances during the anaerobic digestion process. Energy consumption for pumping and mixing is considerably reduced due to the reduced DM content. When combined with appropriate methods for low-emission land-spreading of the digestate, anaerobic digestion therefore has multiple benefits. In addition, it provides the opportunity for further processing for more advanced forms of nutrient recovery, including nutrient precipitation, concentration and ammonia stripping (Fig. 6).

3.2.12 Manure composting

Composting of manure is done in order to create a stable and odourless bio-based fertilizer product, with lower moisture content, while containing most of the initial nutrients, free of pathogens and seeds (Jensen, 2013). Composting significantly reduces mass (as a result of water evaporation and volatile solids decomposition to release CO_2) and hence transport costs. However, it is difficult to avoid some loss of manure N in the form of NH_3 and the process also emits greenhouse gases, with potential for increased N_2O and CH_4 emissions, in addition to NO_x and N_2 (Chowdhury et al., 2014). The N fertilizer value of composts is often significantly lower than the N-rich manure components it is made from, which is largely a result of associated NH_3 and N_2 emissions (Jensen, 2013). Composting on porous soil surfaces may also be associated with significant leachate, including NH_4^+, NO_3^- and other N_r compounds. Composting is typically a low-cost technology, but implies space requirements and energy consumption. Overall, it can therefore not usually be recommended to mitigate nitrogen losses, but may be preferred on other criteria (e.g. volume and weight reduction, compost product stability, reduced odour, improved marketability and soil amelioration).

3.2.13 Nutrient recovery by drying and pelletizing of manure solids

Drying and pelletizing of solid manures, slurry or digestate solids can be done to create a more stable and odourless bio-based fertilizer product. Drying is energy-intensive and thereby relatively expensive, unless excess energy (e.g. from the combined heat and power plant engine on a biogas plant) is freely or cheaply available. Increased ammonia loss is inevitable in the process, unless exhaust filtering or scrubbing and recovery is applied, or the solids are acidified prior to drying. Drying is usually combined with a pelletizing process to facilitate handling. The pelleted material can be marketed as an organic matter and P-rich soil amendment; if acidified prior to drying, the resulting product may also be rich in plant available N (Pantelopoulos et al., 2017).

3.2.14 Nutrient recovery by combustion, gasification or pyrolysis

Combustion, thermal gasification or pyrolysis of manure and digestate solids can be used to generate a net energy output for heat and/or electricity production. However, at present the method leads to a more or less complete loss of the manure N, which is converted into gaseous N_2, as well as NO_x and NH_3. Available advanced technologies (e.g. selective non-catalytic reduction) focus on denitrifying these N_r gases to N_2. Until systems are implemented to minimize N_2 formation and recover the N_r gases, this measure cannot be considered appropriate for abating overall N loss.

At the same time, the approach produces ash or biochar residuals. These ashes contain the non-volatile nutrients, concentrated relative to the solids. They can be used as an ash-based, P- and K-rich soil amendment or bio-based fertilizer. The availability of the remaining nutrients in the ash is generally much lower than for the raw manure, whereas for biochar it is in-between ash and raw manure. Organic compounds in the biochar that are produced are very recalcitrant to biological decay and have a very large specific surface area, being potentially charged. This means that such biochar may be used for soil amendment, ameliorating soil pH and organic matter positively.

3.2.15 Nutrient recovery by precipitation of nitrogen salts

Struvite ($MgNH_4PO_4{\cdot}6H_2O$) can be precipitated from liquid manures, provided that the appropriate conditions are present (pH ~9, a molar ratio 1:1:1 of Mg^{2+}:NH_4^+:PO_4^{3-}, conducive physical settling conditions). As such the precipitation of struvite is a method for removal and recovery of both N and P from liquid manures. The method has been developed for wastewater treatment, where P removal can easily reach more than 70% and it is commercially available for sewage treatment plants, although not yet widely applied. For manures, the struvite technique is particularly relevant for anaerobically digested slurries and the liquid fraction from digestate separation; hence, it has been the subject of massive research in the past decade and quite high removal efficiencies have been achieved (56–93%; see further review in Jensen, 2013). However, it only works for the N already present as NH_4^+ and further development is needed for appropriate application to liquid manures and digestates. So far, only a few commercial-scale plants are in operation worldwide. The main advantage of struvite is its high concentration and similarity in physical-chemical properties to conventional mineral N fertilizer.

3.2.16 Nutrient recovery by concentration of nitrogen salts and solutions

Mineral concentrates are highly nutrient-rich solutions that may be obtained via ultrafiltration, evaporation or reverse osmosis of the liquid fraction from separation of slurry or digestate. These mineral concentrates (the retentate) may be directly applied to agricultural land and the byproduct water low in nutrients (the permeate) may be directly discharged to surface waters or the sewage system. The greatest experience with these technologies in Europe are from the livestock regions of the Netherlands and Belgium, where a number of centralized and large-scale manure processing plants utilizing a range of technologies in combination (e.g. anaerobic digestion, solid-liquid separation, ultrafiltration/reverse osmosis/solids drying). Provided that the losses can be kept to a minimum, the mineral fertilizer replacement value of the mineral concentrates can be relatively high, as they resemble commercial liquid fertilizers, with nearly all the nutrients in a mineral, plant-available form. However, to avoid gaseous NH_3 losses this may require prior acidification or injection of the concentrate into the soil (Jensen, 2013). As these technologies are still under investigation, the UNECE Categories are currently uncertain (i.e. Category 3, pending further assessment).

3.2.17 Nutrient recovery by ammonia stripping

Air stripping of NH_3 is a process whereby the liquid fraction after manure separation is brought into contact with air, upon which NH_3 evaporates and is carried away by the gas. Instead of ambient air, 'steam stripping', can be used where steam is replaces use of air as the ammonia carrier. Since evaporation occurs from the liquid surface, it is advantageous to ensure that the liquid has a large surface area. This can be achieved in a stripping column with structured packing, where it spreads over the packing material in a thin film and therefore has a considerably larger surface. The mass transport also increases with the concentration of $NH_{3(aq)}$ in the liquid phase, hence, if pH and/or temperature is increased, an increasing part of total ammoniacal nitrogen is in $NH_{3(aq)}$ form and the mass transport of NH_3 increases (Sommer et al., 2013). Altogether this makes the technology relatively energy demanding and costly, though cheap/free surplus energy from, for example, a biogas- combined heat and power plant may reduce energy costs. Alternatively, using selectively permeable membrane contact systems at lower temperatures may offer a cheaper solution, if membrane fouling can be avoided. Ammonia released from an NH_3 stripping column or from a manure drying facility can be collected using wet scrubbing with an acid solution, typically sulphuric acid to make ammonium sulphate (most common), but also has been reported with nitric acid to make ammonium nitrate. Both compounds can serve as raw materials for mineral fertilizers, and thus provides opportunity for circular economy development as part of the fertilizer industry's commitment to include recovered and recycled N_r. In general, this is a well-known and generally effective technology. The main barriers are the relatively low N scrubber-liquid concentrations achievable (and thus high logistic costs), and the quality requirements for introduction of the scrubber-liquid into the raw materials market for the fertilizer industry. Actual developments are working on process improvement through applying sulphur or nitrate instead of an acid and on developing a system with CO_2 to generate ammonium carbonate which can also be used as fertilizer and bring C back into the soil. The ammonia-low liquid fraction is then used to flush the manure channel to reduce NH_3 and CH_4 emissions in the house.

4 Best practices and priority measures

Best practices and priorities for the selection of abatement/mitigation measures must be based on the following criteria: (i) implementability; (ii) effectiveness; (iii) impact on environmental emissions; (iv) secondary effects; (v) controllability; and (vi) cost efficiency. Based on these criteria, we suggest the following priority measures:

4.1 Livestock feeding

The following priorities through livestock feeding help to reduce nitrogen losses:

- Avoid N surplus from the very beginning of the manure management continuum;
- Adjust animal diet to animal performance (in line with existing guidance in the UNECE Ammonia Framework Code);
- Adapt animal diet to shift N excretion from urine to faecal excreta;
- Dairy cattle:
    - Reduction of crude protein content in the diet;
    - Adapt diet and dairy production system to site specific conditions;
    - Increase milk yield with moderate level of concentrates;
    - Increase production cycles per cow.
- Pigs:
    - Reduction of crude protein content in the diet;
    - Multiphase feeding;
    - More use of food wastes (inc. from processing and retail) as a way to reduce upstream and downstream emissions.

4.2 Livestock housing

The following priorities help to reduce nitrogen losses from livestock housing:

- Reduction of indoor temperature;
- Reduction of emitting surfaces, reduction of soiled areas;
- Reduction of air flow over soiled surfaces;
- Use of additives (e.g. acidification);
- Frequent removal of slurry to an outside store; and
- In the longer term: smart barns with optimized ventilation (open housing) or ventilation air scrubbing (closed housing), immediate segregation of urine and faeces components, in-house acidification of slurry (pigs and cattle).

4.3 Manure storage, treatment and processing

The following priorities help to reduce nitrogen loses and to mobilize nitrogen recovery and reuse from manure storage, treatment and processing:

- Store solid manures outside the barn on a solid concrete base in a dry/covered location;
- Ensure tight slurry stores, and cover either by a solid cover, or by ensuring sufficient natural crust formation;

- Use manure treatment where relevant to:
  - Homogenize nutrient content for more even field spreading to ensure that all available nutrient resources are used effectively for crop growth;
  - Reduce slurry DM content, for example, by solid-liquid separation, to enhance soil infiltration and limit NH_3 loss;
  - Increase slurry NH_4^+ content to maximize crop N availability;
  - Lower pH by acidification to reduce NH_3 volatilisation and enhance fertilizer value; and
  - Apply manure treatment methods to enable combined energy and nutrient recovery, that is, anaerobic digestion, where relevant.

The use of manure advanced processing for N recapture and production of value-added nutrient products from recycled manure N resources should be focused on situations where other effective options are not available. Examples of such advanced processing technologies are high-tech separation by filtration, reverse osmosis and NH_3 scrubbing, drying of manure and digestate solids for organic fertilizer production.

Production of recovered, bio-based fertilizer products should not be supply-driven (trying to solve a waste problem), but rather demand-driven (bio-based fertilizers the farmers want).

5 Conclusion and future trends in research

It is clear that manure management impacts quantities of N_r emissions (NH_3, direct and indirect N_2O emissions, NO_x emissions, NO_3^- leaching) and N_2 emissions, as well as emissions of CH_4 and CO_2. This applies at each stage of the manure management continuum (Chadwick et al., 2011). Since production of these gases, as well as of leachable N_r, is of microbial origin, the DM content and temperature of manure and soil are key factors for farm manure management decisions that influence the magnitude of N and GHG losses. There remains a degree of uncertainty in emission rates of N and GHGs from different stages of manure management, and researchers continue to investigate interactions of the management and environmental factors that control emissions. Some specific approaches to reducing N and greenhouse gas emissions from livestock housing and manure storage include optimizing diet formulation, low-emission housing technologies, manure processing and nutrient recovery. The technologies include air scrubbers, covered manure storage, slurry separation and anaerobic digestion, nitrogen concentration and stripping methods.

Existing legislation across the UNECE region offers opportunities to find 'win–win' scenarios, with benefits in reducing multiple forms of pollution. An example is the EU Nitrates Directive (91/676/EEC), which has led to development of Nitrate Vulnerable Zone action plans to prevent application of animal manure, slurry and poultry manure (with high available N content) in autumn, a practice which reduces N losses, as well as direct and indirect N_2O losses. Care is needed to ensure that legislation does not lead to potential 'pollution swapping' (e.g. unadjusted use of slurry injection to reduce NH_3 emissions at the expense of an increase in N_2O emissions, with no modification of N inputs). A core principle is that measures that reduce one form of N loss need to either be accompanied by a reduction of fresh nitrogen inputs, or be accompanied by an increase in harvested products, to maintain mass consistency. In this way, what may first seem a trade-off at the field-scale, can be seen at the landscape and regional scale as an opportunity to move towards a more circular system with lower overall N losses.

The nature of the N cycle and its interaction with the C, P and other nutrient cycles demands a holistic approach to addressing N and GHG emissions and mitigation research at a process level of understanding. Systems-based modelling must play a key role in integrating the complexity of management and environmental controls on emissions. Progress has been made to this end (Sommer et al., 2009), with some studies producing whole farm models encompassing livestock production (del Prado et al., 2010).

Concepts for best practices to reduce adverse environmental impacts depend on the following integrated concepts:

- Relationship between nitrogen and GHG emissions;
- Influence of climate change on nitrogen emissions;
- Interaction between abatement/mitigation and adaptation measures;
- Interaction between nitrogen emissions and animal welfare;
- Integrated assessment of the whole manure management continuum;
- Integrated assessment considering the three pillars of sustainability: economy, environment, society;
- Interaction between consumer demand and nitrogen emissions;
- Development of region-specific concepts for sustainable intensification;
- Modelling of livestock production at regional, national and global scale; and
- Economic impact of both the cost of the techniques and the benefit to the farmer of reducing emissions and retaining nitrogen as a fertilizer.

Concepts to reduce adverse environmental impacts depend on the *understanding at a process level* of the following:

- Assessment of emissions from naturally ventilated barns;
- Assessment of emissions from new, animal friendly housing systems;

- Development of abatement/mitigation measures especially for naturally ventilated dairy barns (e.g. targeted ventilation and air scrubber, manure acidification);
- Interaction between climate change and heat stress/animal behaviour/emissions;
- Interaction between low protein diets and N and GHG emissions;
- Interactions between N and GHG emissions during housing, storage and application to field;
- Life-cycle assessment: for example, grass-based dairy feeding versus low protein dairy feeding;
- Feed and manure additives for improved N use efficiency; and
- Manure treatment for higher N use efficiency (increase of nutrient availability, decrease of emissions) and potential of processing to recover manure N into bio-based fertilizers in a circular economy.

Concepts to reduce adverse environmental impacts depend on the development of *flexible concepts* for environmental improvement:

- Climate and site-specific conditions vary across the UNECE region and globally;
- All three columns of sustainability must be considered: economic, environmental and social sustainability;
- Conflicts of interest must be addressed; and
- Targeted approaches according the needs of different regions.

Concepts to reduce adverse environmental impacts depend on *effective communication and interaction*:

- Establishing networks to exchange manure management information, connect people, and forge partnerships;
- Launching an on-line knowledge hub – on best practices for livestock housing and manure management; and
- Establishing a roster of experts to provide targeted technical assistance and training, analysis and practical implementation and policy support, relying heavily on co-financing and in-kind resources from partners.

The development of best practice concepts is challenging. Climate and site-specific conditions are highly variable. It is essential to consider the three columns of sustainability: economy, environment and society and to address synergies and potential conflicts of interest. This inevitably leads to the conclusion that there will be no 'one size fits all solution'. Best-practice concepts provide the basis to guide on the development of flexible measures targeted for each specific region and context.

Chapter 6

Developments in anaerobic digestion to optimize the use of livestock manure

Mingxue Gao, Danmeng Wang, Chunlan Mao, Yongzhong Feng, Zhiyuan Zhu, Xiaojiao Wang, Guangxin Ren and Gaihe Yang, Northwest A&F University, China

1 Introduction

For thousands of years, agricultural production has provided humans with the food needed for survival. However, the fact that agriculture can provide energy has received less attention, starting with burning firewood and crop straw to produce heat and energy. Non-renewable energy sources such as oil and coal are declining, which means alternative energy sources such as biomass energy are urgently needed. As a renewable resource, biomass energy is also environmental-friendly.

Anaerobic digestion (AD) is an important method for converting biomass into bioenergy. AD can use a range of substrates including kitchen waste, crop straw, energy crops, municipal solid waste, sewage sludge and livestock manure. Although biogas production from livestock and poultry manure cannot achieve zero carbon emissions, it does not produce the level of carbon

http://dx.doi.org/10.19103/AS.2020.0077.09

emissions produced by fossil fuels. Livestock manure is still a widely used biomass material for production of bioenergy.

The production of biogas through AD of livestock manure is a complex process. It involves a variety of complex physiological and biochemical metabolic pathways, the essence of which is the material and energy metabolism of microorganisms under anaerobic conditions. AD is typically into three stages according to the utilization and transformation of organic matter (Fig. 1):

- hydrolysis;
- acidogenesis; and
- methanogenesis.

In the hydrolysis step, macromolecular organic matters (fat, carbohydrate, protein, etc.) are hydrolyzed into small molecules such as monosaccharides, amino acids, fatty acids and so on by the action of extracellular enzymes. Then the small molecule organic compounds are converted to a volatile organic acid, ethanol and so on by the acidified bacteria. H_2, CO_2 and acetic acid are then formed under the action of hydrogenic bacteria and acetogenic bacteria during this acidogenesis step. Finally, the methanogenic bacteria synthesize methane using acetic acid, H_2, CO_2 and so on in the methanogenesis stage.

It can be seen from the above that the AD process can produce a variety of substances, including H_2, CH_4, alcohol, lower fatty acids and so on. These substances can also be reused as biofuels, biodiesel, biogas, power generation and so on. The production of bioenergy by AD is thus very clean and efficient. There are many kinds of substrates in AD. Livestock and poultry manure is one of the commonly used raw materials, but a large amount can cause pollution, a key issue to address in its effective use.

The purpose of this chapter is to discuss developments in AD to optimize the use of livestock manure, particularly the use of livestock in the production of biogas. It also discusses the use of biogas slurry and residues. The chapter shows how AD can play an important role in promoting circular agriculture. It includes a case study on the use of AD in practice in Henan Province, China.

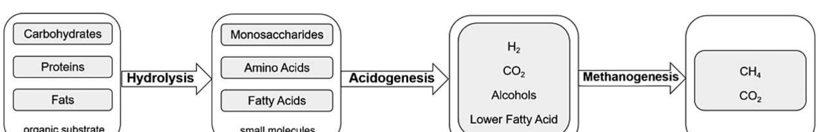

Figure 1 Steps of anaerobic digestion process.

2 Livestock manure: quantities and risks

Since ancient times, pigs, cattle, sheep and poultry have been kept by humans. However, it has not been possible to measure the amount of that feces produced by these livestock species exactly. Fortunately, the numbers of livestock and poultry raised in various countries and regions are now more accurately counted, so that the amount of manure can be estimated. Numbers of livestock in countries and regions are counted by the Food and Agriculture Organization of the United Nations (FAO), and can be found through its database (http://www.fao.org/home/en/; accessed November 10, 2019). A method for estimating the amount of manure by the quantity of livestock and poultry has been proposed using the following formula that is as follows (Gao and Li, 2015):

$$M_i = \sum_{i}^{n} Q_i \cdot d_i \cdot m_i \tag{1}$$

where Q_i is the total number of livestock, d_i is the excretion coefficient (the daily excretion of each animal) and m_i is the animal slaughter period.

This formula has been used to estimate the quantity of livestock manure produced in China (Lin et al., 2012; Li et al., 2010; Liu et al., 2005) (Fig. 2). The estimate for 2017 is up to 4 trillion tons of livestock manure that is produced

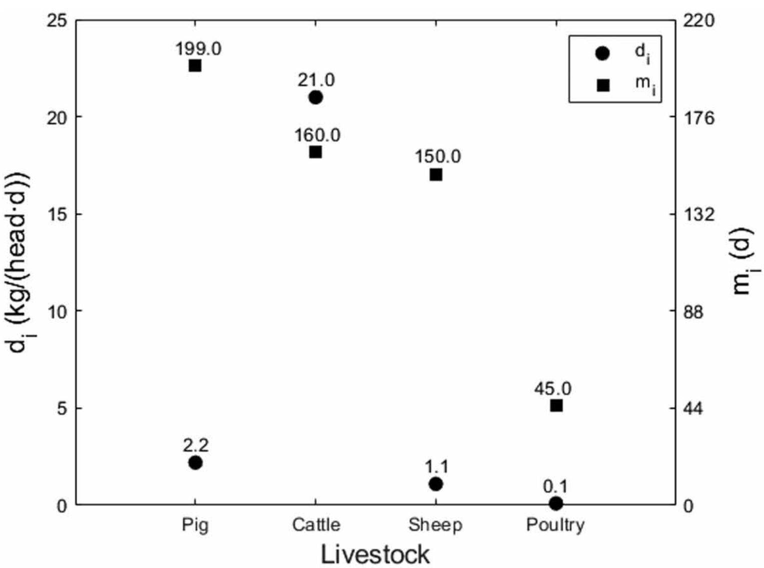

Figure 2 The estimated parameters of livestock manure quantity (Note: d_i is the excretion coefficient; m_i is the animal slaughter period).

in China. If such large amounts of manure were directly discharged without proper treatment, they would cause a huge pollution risk.

The first pollution consequence is air pollution. Livestock and poultry manure contain harmful gases such as hydrogen sulfide and amine, which can produce methyl mercaptan, dimethyl sulfide, methyl sulfide, dimethylamine and a variety of low-grade fatty acids or other odorous gases. If not treated in time, they cause a relatively low oxygen content in the air and increase the degree of turbidity (Liu et al., 2010). Moreover, greenhouse gases from livestock manure are also an important factor in global climate change. In addition to emitting CH_4, it is estimated that N_2O produced by livestock manure accounts for 30–50% of global agricultural N_2O emissions (Oenema et al., 2005). These harmful gases are caused by the unique environment of the feces and the large amount of microbial activity. It is striking that since the pre-industrial era, the concentration of CH_4 in the atmosphere has increased by 2.5 times and the concentration of N_2O has increased by about 20% (IPCC, 2006). Although this situation is caused by many factors, the treatment of livestock manure is a significant issue in controlling greenhouse gas (GHG) emissions (https://www.ipcc.ch/; accessed November 6, 2019).

The second consequence is water pollution. The effects of pollution of livestock and poultry manure to water bodies can be divided into three types:

- the release of acid gas into the air and then precipitation in the form of acid rain;
- direct discharge of pollution into surface water which flows into rivers and lakes; and
- entry into groundwater by osmosis.

Manure contains a lot of nitrogen and phosphorus. Once manure enters a water body and the quantity exceeds the water's purification ability, it causes algae to multiply in the water, and aquatic animals die of oxygen deficiency. Physical and chemical water properties will change followed by microbial composition, which finally makes the water toxic (Hooda et al., 2000).

The third consequence is soil pollution. Heavy metals are ingested through feed during livestock and poultry farming. Most are not used but excreted. When these manures are used as fertilizers, heavy metals including copper, zinc, cadmium, chromium, lead, mercury and arsenic will accumulate in the soil and crops, posing a potential risk to soil and human health (Feng et al., 2018b). In addition, when excessive sodium and potassium are in the feces, it will decrease soil micropores, destroy soil structure and reduce plant growth if applied directly to the soil. In addition, animal antibiotics are commonly used to treat and prevent animal diseases. Excessive antibiotics cannot be completely absorbed in animals but are excreted, accumulating in the soil and posing a significant environmental risk (Pu et al., 2018).

Finally, pollution from livestock also causes harm to human health. Air quality is reduced and the odor causes potentially fatal diseases of the respiratory system. Unclean drinking water systems are associated with waterborne disease outbreaks (Oun et al., 2014). Moreover, there are many pathogens in feces and, if humans eat plants grown in contaminated land, they are also likely to get sick. Thus, livestock manure can directly or indirectly affect human health. In summary, the large amount of livestock manure produced and unsuitable handling creates enormous environmental and health risks. Rational use of livestock and poultry manure to reduce these hazards and turn them into useful products is an important area of research.

3 The biogas potential of livestock manure

The biogas potential of a region refers to the amount of biogas produced by the waste in the region under appropriate conditions. Since not all waste is used for AD, and production conditions are not always optimal, biogas potential is an estimate under ideal conditions. Nevertheless, it is of great significance as a guide to the development of biogas production in a particular area.

Different types of animal manure have different capacities to produce biogas. The difference between them is called the biogas conversion coefficient of manure. Many studies have shown that livestock manure has moderate biogas potential (Nasir et al., 2012). Many factors involved in production processes also affect the production of biogas from livestock manure. Previous studies have suggested the following livestock manure biogas conversion parameter and formula for estimating manure biogas potential (MBP) (Yao, 1988; Zhang et al., 2012) (Fig. 3). Eq. (2) is one of the methods to calculate the biogas potential.

$$\mathrm{MBP} = \mathrm{M_i} \cdot \mathrm{b_i} \tag{2}$$

where M_i is the amount of livestock manure produced (kg) from livestock i, and b_i is the livestock manure biogas conversion parameter.

This method is a simple calculation but subjected to a high potential level of error. In order to make up for the shortcomings of this method, some scholars have proposed a new method to improve biogas potential estimation. Biogas production is affected by the total solids (TS) of livestock manure because the presence of manure and urine in the excrement means it cannot be used entirely to produce methane. The total solid coefficients (TSC) of the feces can be further calculated by Eq. (3) (Zhang et al., 2019):

$$\mathrm{TSC}(\%) = \frac{\mathrm{F_i} \cdot \mathrm{F_s} + \mathrm{U_i} \cdot \mathrm{U_s}}{\mathrm{F_i} + \mathrm{U_i}} \tag{3}$$

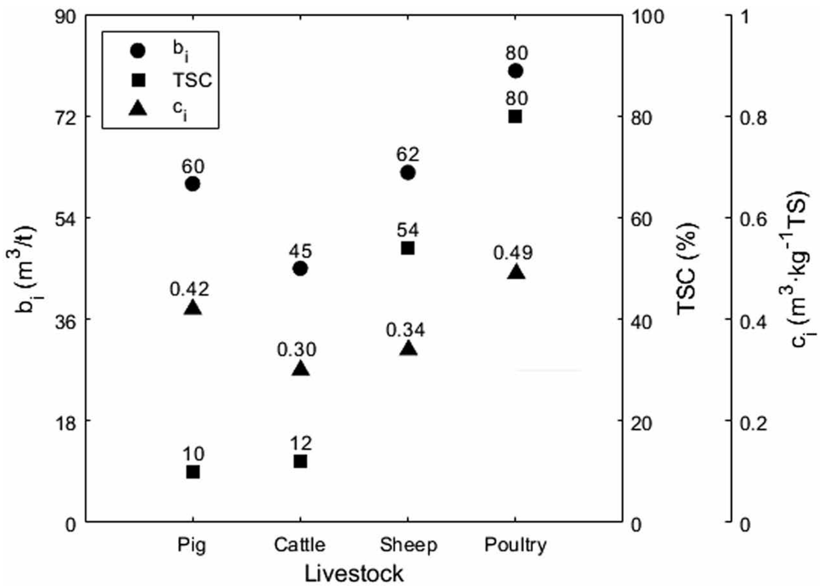

Figure 3 The estimated parameters of livestock manure biogas potential (Note: b_i is the livestock manure biogas conversion parameter. TSC is the total solid coefficients of livestock manure. c_i is raw biogas production rate per kg of dry matter).

where F_i represents the daily output of feces, F_s represents the total solid of the feces, U_i is the daily yield of urine and U_s is the urine's total solid.

Eq. (4) is used to calculate the biogas potential:

$$MBP = TSC \cdot M_i \cdot c_i \quad (4)$$

where M_i is the amount of livestock manure, c_i is the raw biogas production rate per kg of dry matter ($m^3 \cdot kg^{-1}$TS).

For reference, the TSC and c_i of some livestock have been listed in Fig. 3. It should be noted that, if the statistical data of animals is used to directly estimate the potential (where the amount of manure used for gasification, returning to the field and other industrial production has not been removed), the estimated value is relatively large.

4 Anaerobic mono-digestion and co-digestion

Depending on the different feeding modes of the substrate, the AD of biogas is divided into two types:

- anaerobic mono-digestion; and
- anaerobic co-digestion.

These are discussed in the following sections.

4.1 Anaerobic mono-digestion

At present a diverse range of livestock manure can be used in anaerobic mono-digestion raw material, in which feces from swine, cattle and chicken are richer. In addition, there are some AD that uses the droppings of ducks, sheep and rabbits (Song et al., 2010). The growth characteristics of cattle mean a large amount of excretion. Its abundance makes cattle manure one of the most commonly used raw materials for AD. Fodder is excreted after being digested through the rumen, and so cattle manure is rich in microorganisms, making cow dung a good raw material for AD. However, the content of cellulose and hemicellulose in cattle dung is high, and microorganisms are difficult to decompose and utilize, so there is still much space for improvement of biogas production from this source.

Swine manure is also a good AD substrate, with rich organic matter and high biogas yield. But the rapid hydrolysis caused by the large amount of carbohydrates can also have a negative effect. The accumulation of volatile fatty acids (VFA) in the system leads to acidification, imbalance of microbial growth and even digestion failure. Swine manure also contains ammonia, which is prone to ammonia inhibition. Chicken manure contains ammonia nitrogen which interferes with digestion because ammonia poisoning affects the performance of reactor. However, chicken feed is mainly based on grains and protein, and chicken manure has high nutrient content and high utilization value.

As this suggests, the performance of different manures in anaerobic mono-digestion varies because of their different characteristics. Gao and Li (2015) found methane yields for swine, cattle and chicken manure of 410, 270, 377 mL CH_4/g VS respectively, at initial volatile solid loading (VSL) of 8 g VS/L. Due to the variable presence of nutrients, anaerobic manure mono-digestion often faces problems such as poor stability, long lag time and low yield. However, anaerobic co-digestion can balance the carbon-nitrogen ratio (C/N) of the system to make microorganisms grow. It can also supplement the trace elements needed for microorganism growth and metabolism which further improves the fermentation effect.

4.2 Anaerobic co-digestion

Single manure substrate fermentation often suffers from C/N imbalance. A high C/N ratio results in a low protein dissolution rate. The total ammonia nitrogen (TAN) and free ammonia nitrogen (FA) concentrations are both low (Xue et al., 2019). However, an excessively high C/N ratio is not sufficient to maintain cell biomass, resulting in a reduction of biogas production. Substrates with a low

C/N ratio increase ammonia inhibition, which is noxious to methanogens and decreases underutilization of carbon sources (Mao et al., 2015). Optimizing the substrate C/N ratio by mixing suitable raw materials thus plays an important role in the AD process. The optimal C/N ratio for AD is between 20 and 35, with the most commonly used ratio at 25 (Yen and Brune, 2007; Zhang et al., 2013; Punal et al., 2000). It is worth mentioning that, whether anaerobic mono- or co-digestion is used, the optimal pH in systems is in the range of 6.8–7.4, because pH can directly affect microbial activity.

Mixing raw materials is an effective way to reduce the negative impact of anaerobic mono-digestion and expand the production of biogas. The mixing of raw materials for AD is not limited to feces, which can also extend to other substances like municipal solid waste, food waste, sewage sludge and crop straw. Through the mixing of substrates, nutrients such as C and N in the digestion system can be balanced, the microbial community in reactor can be enriched and the methane conversion efficiency of the organic substance can be improved. Studies have shown that the synergistic effect of mixed fermentation has a positive effect on the production of biogas.

Co-digestion of dairy manure, chicken manure and wheat straw performed better in methane production than digestion using a single substrate, with a maximum potential of CH_4 production predicted to be 394 mL/g VS (Wang et al., 2013). A synergistic effect was found when corn straw and chicken manure was mixed in proportions of 3:1, regardless of pretreatment (Feng et al., 2018a). The co-digestion of pig manure and dry maize straw is superior to the mono-digestion of pig manure, improving the C/N ration and enhancing the buffer capacity of the system (Song et al., 2016). When dairy manure was co-digested with food wastes, the highest cumulative biogas yield reached 459.4 mL/g VS (Batool et al., 2020). Livestock manure can also be co-digested with a variety of organic matter, such as the *Pennisetum* hybrid (Lianhua et al., 2020), mango leaves (Abudi et al., 2020) and animal carcasses (Tapparo et al., 2020). As these examples show, in general, mixed fermentation is better than single fermentation.

5 Factors affecting the efficiency of anaerobic digestion

There are many factors affecting AD which can be divided into the following categories:

- Substrate regulation;
- Raw material pretreatment;
- Process control; and
- Accelerators.

These are discussed in the following sections.

5.1 Substrate regulation

Each kind of animal excrement has unique physicochemical characteristics. Substrate regulation includes factors such as substrate concentration, C/N ratio and inoculum substrate ratio. The digestion system can be affected by changing these conditions. The fact that different livestock and poultry manures produce different biogas yields is one example of the way substrate properties and their combinations influence AD. The effect of inoculum on AD is also multifaceted. It can increase the number of microorganisms and ensure a suitable pH, but also accelerates the start of fermentation and shorten the lag phase. Selecting the proportion of inoculation to match the properties of the raw materials is important for optimizing AD.

5.2 Raw material pretreatment

The importance of pretreatment in substrate regulation needs to be emphasized. Low biodegradability usually occurs because the substrate contains something which is difficult to degrade, for example, the undigested plant fiber in cow dung (Sawatdeenarunat et al., 2016). Pretreatment of the substrate before fermentation is a good solution to this problem (Mosier et al., 2005). Different pretreatments have different effects on substrates.

Physical pretreatment mainly consists of mechanical pulverization and grinding to change the external morphology or internal structure of the raw material in order to improve biodegradability and biogas production (Elliott and Mahmood, 2012; Carrere et al., 2010). Larger granules of substrate reduce the degradation rate of chemical oxygen demand (COD) in the fermentation process, thereby reducing biogas production (Esposito et al., 2011). Chemical pretreatment mainly uses chemical reagents such as acid, alkali or oxidizing agent. Alkali reagents like ammonium hydroxide and sodium hydroxide are often used as alkaline pretreatment. Wahid et al. (2020) have shown that mixing wheat straw, solid cattle manure and solid slaughterhouse carcass material can improve anaerobic biodegradability after alkali and ultrasonic pretreatment. Acetic acid and organic acids provide the desired organic acid components to some microorganisms. Hydrogen peroxide and especially ozone are common oxidants, which avoid excessive accumulation of intermediate products in the digestion process and eliminate pathogens (Kianmehr et al., 2010). However, oxidant pretreatment is relatively costly. Other pretreatments include thermal pretreatment (Kaar and Holtzapple, 1998) and biological pretreatment (Zhong et al., 2011). All pretreatment methods have advantages and disadvantages. Various factors such as likely costs and benefits need to be considered, after which a single pretreatment can be chosen or combined to achieve the desired effect.

5.3 Process control

Digestion temperature, pH, hydraulic retention time (HRT) and organic loading rate (OLR) are all factors that can be regulated during the fermentation process. Some of these factors are discussed in more detail below. In addition, factors such as the type of reactor (Fig. 4), management, construction time and power generation equipment will impact the generation and utilization of biogas.

The usual temperature for thermophilic AD is 55°C and 35°C for mesophilic digestion. Compared to mesophilic AD, thermophilic AD has a fast response speed and high carrying capacity, resulting in higher yield. But it also has shortcomings, including lower system stability, acidification, more polluting discharge, higher net energy input and more investment, given the temperature requirements (Bowen et al., 2014). In actual production, many biogas digesters on farms depend on seasonal temperature without additional heating, reducing process stability and gas production due to ambient temperature changes.

pH directly affects the digestion process. The growth rate of microorganisms is very sensitive to changes in pH. The relative abundance of microorganism species is 6 when pH is 4.0 and increases to 14 when pH rises to 7.0 (Fang and Liu, 2002). Suitable pH ranges for methanogenic and acidogenic microorganisms are different. At pH 6.5–8.2, the efficiency of methanogenesis is optimal with the best pH at 7.0 (Lee et al., 2009). Methanogen growth slowed down visibly when the pH is less than 6.6

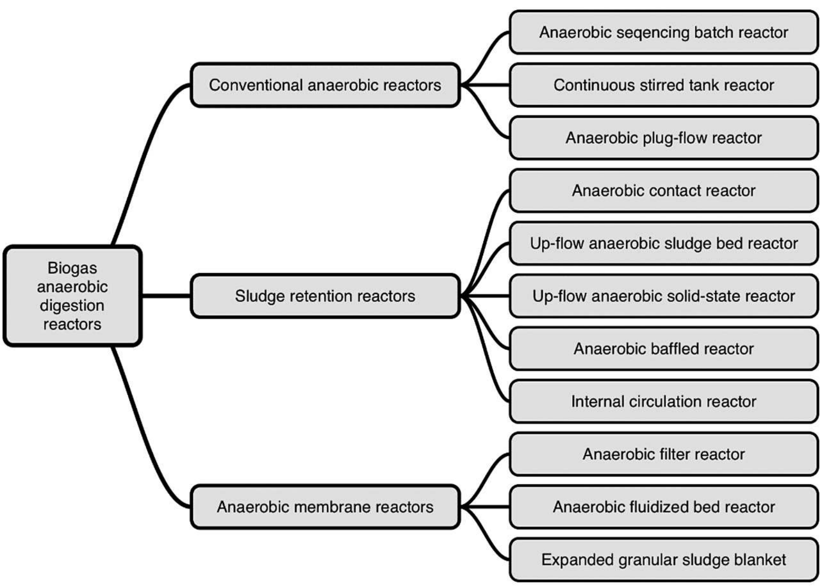

Figure 4 Types of biogas anaerobic digestion reactors.

(Zhang et al., 2009b). For acidogenesis, 5.5–6.5 is the most suitable pH range (Kim et al., 2003). Separating AD into a two-stage process is the preferred mode of operation with separate hydrolysis/acidification and acetogenesis/methanogenesis stages.

The time required for the decomposition of organic matter is defined as the retention time. Decomposition is affected by microbial growth rate, the process temperature, OLR and the matrix substance (Aboudi et al., 2015). The quantity of volatile solids in the digester is represented by OLR. Biogas production will improve to some extent with higher OLR (Mao et al., 2015).

5.4 Accelerators

AD additives can be divided into inhibitors and accelerators. Artificial inhibitors are not generally used in most biogas production processes, and so this section focuses on the use of accelerators. Accelerators can be further subdivided into biological accelerators and inorganic chemical accelerators.

Biological accelerators include several kinds of fungal microbial agents, which are mainly used for the treatment process of lignocellulosic biomass (Zheng et al., 2014). These include rumen fungi and protozoa (Zheng et al., 2019; Yildirim et al., 2017). Other biological accelerators include functional enzymes, for example, extracted from 3-day cultures of *T. harzianum* (Enzyme T) and *Aspergillus* spp. to improve methane yield (Zhao et al., 2018). But the cost of enzyme preparation is high, limiting its use.

Inorganic chemical accelerators are widely used, including acids, bases, inorganic salts and elements such as N, P, K and S. These substances are essential nutrients for the growth and metabolism of microorganisms that can be directly utilized in the AD process with significant effects (Weiland, 2010). However, inappropriate doses of these elements may result in reduced system stability. Trace elements such as Fe, Ni, Mg and Ca can also promote biochemical reactions (Demirel and Scherer, 2011). However, if too acidic or alkaline, and not utilized by microorganismss, these accelerators may affect the stability of the process.

6 Products from biogas digestate

During the AD process, livestock and poultry manure are decomposed through the action of microorganisms into biogas slurry containing proteins, amino acids and other water-soluble substances. Substances that cannot be completely decomposed and other impurities are deposited at the bottom of the reactor by gravity and become biogas residue after drying. The effluent of many biogas digesters is a solid-liquid mixture referred to as biogas digestate.

6.1 Digestate value-added products

The components of biogas slurry are complex, including nutrients such as N, P and K, as well as trace elements like Fe, Zn, Mn and Mo, which can be utilized by animals and plants. Microorganisms, antibiotics, enzymes and other unknown substances may also be present in the slurry. This means that the reuse value of biogas slurry is very high. In addition, the use of digestate to produce value-added products can reduce odor by up to 80% and make positive changes in odor composition (Weiland, 2010). The AD process is also able to partially inactivate weed seeds, bacteria, viruses, fungi and parasites in feedstock from livestock manure, improving safety (Mata-Alvarez et al., 2000).

Biogas slurry and biogas residue can be used directly or processed to produce value-added products such as biogas fertilizers and soil improvers (Nkoa, 2014; Edwards and Daniel, 1992) and animal feed (Zhang et al., 2008). Because biogas digestate can contain plant hormones including heteroauxin, gibberellins (GA4, GA19, GA53), plant growth agents can be produced (Huo et al., 2011). Biogas residue can also produce bedding materials for animal housing.

Biogas digestate is widely used as a base fertilizer, foliar fertilizer, top dressing and in soilless cultivation. As an example, the recommended application rate of biogas slurry on coastal-reclaimed farmland is 480 and 9.00–11.25 m^3 ha^{-1} for rice and wheat, respectively (Tang et al., 2019). The optimal proportion of chemical fertilizer nitrogen substitution by biogas slurry was 70% with a biogas slurry application rate of 278.56×10^3 kg hm^{-2} (Wang et al., 2018). Digestate as a fertilizer has a positive function on plant biomass (Barbosa et al., 2014). Digestate promotes the activities of various enzymes such as nitrate reductase and glutamine synthetase (Jabeen and Ahmad, 2017). It has also been shown to improve yield (Holm and Heinsoo, 2013, 2014). The use of digestate also promotes recycling (Tampio et al., 2016). Indirect effects include promotion of soil microbial activity (Hupfauf et al., 2016). Biogas fertilizer also changes soil composition through processes such as ammonia and nitrogen oxide emissions (Nkoa, 2014), nitrate leaching potential (Riva et al., 2016), transformation of organic carbon and GHG emissions (Knudsen et al., 2014), as well as leaching and precipitation of phosphorus. These cause changes in elements such as Mg, Fe, Mn and so on (Zirkler et al., 2014). Biogas digestate also increases pH, electrical conductivity, air porosity and bulk density (Meng et al., 2018). In addition to biogas fertilizer, biogas slurry can also promote germination and seedling by soaking of seeds (Ni et al., 2015).

Biogas slurry can also be used for aquaculture and livestock feed. Biogas residue as an alternative feed saves feed costs and improves digestion without affecting pork quality (Zhang et al., 2009a). In aquaculture, biogas digestate nutrients can be eaten by fish or promote the growth of plankton as a source of nutrition.

6.2 Disadvantages of biogas digestate

There are some shortcomings in using biogas digestate. Harmful substances such as heavy metals may still be present in biogas fertilizer and will still contaminate the soil (Duan et al., 2012). The bioavailability of heavy metals in AD is an important criterion to predict the ecological risk of heavy metals, which is determined by the form of each metal (Thanh et al., 2016). AD operational parameters (pH, redox potential and VFAs concentration) determine bioavailability (Knoop et al., 2017). Heavy metals are not biodegradable and can accumulate to potentially toxic concentrations as digestion proceeds (Chen et al., 2014). In the process of AD, S^{2-}, CO_3^{2-}, PO_4^{3-} and so on will cause reactions and precipitation will change the solubility and availability of heavy metals (Insam et al., 2015). The toxic effects of heavy metals depend on their solubility and availability (Choong et al., 2016). Vegetables and grains produced after irrigation with heavy metals such as zinc, lead and cadmium are harmful to human health (Bian et al., 2015). Although the maximum allowable concentrations of heavy metals in the digestate are currently set in many countries, they still present an environmental risk (Gusiatin and Kulikowska, 2014). However, proper management can reduce this risk.

7 Ecological agriculture models for biogas utilization

Agriculture needs to reduce its environmental impact by adopting ecological principles such as reducing waste and creating circular, more self-sufficient systems which recycle waste into useful by-products such as fertilizer and biogas which can then be fed back into the system. This section introduces four typical ecological agriculture models: ecological farms, ecological orchards, ecological greenhouses and 'five supporting' mode.

7.1 Ecological farms

Ecological farms are a widely used model. They can be divided into two types:

- Small-scale household farms; and
- Large-scale 'engineering' farms.

The household ecological farm consists of a single household or several neighboring households on a small scale. Processes are simple: human feces and livestock manure are added to a fermentation tank to produce biogas for human. The 'engineering' type is mainly for farms that cultivate animals and crops on a large scale. Biogas digesters are constructed to eliminate agricultural waste such as straw and manure. Equipment and capacity of biogas digester are usually well developed. Biogas is not only used for heating but also for generating electricity which can be used on the farm with any surplus supplied into the local power grid to generate additional value too.

7.2 The ecological orchard and other three-in-one models

The ecological orchard model is one example of a circular agricultural system. The three-in-one model (Fig. 5) combines animals, microorganisms and plants. First, animals can eat plant stalks, weeds, fruits and so on to grow. Secondly, biogas is produced by AD when animal manure is fed to biogas digesters to produce biogas for heat and power. Thirdly, biogas slurry can be applied to the plants as organic fertilizer to stimulate plant growth, and biogas residue can also be used as animal feed. This creates a circular, more self-sufficient system with fewer inputs and outputs. Plants can be orchard trees, arable crops, vegetables, tea and so on. Animals can be livestock, poultry and aquatic species. Typical examples of this three-in-one model are the 'biogas-rice-duck', 'chicken-biogas-fruit' and 'pig-biogas-fish' models (Chen, 1997; Yang et al., 2018; Yang et al., 2012). Successful models of this type save feed and energy costs, increase the variety and quantity of products produced, and can also improve product quality while reducing environmental impact.

7.3 Ecological greenhouse: the four-in-one model

Temperature is a key limiting factor for the production of biogas. Both ecological farms and ecological orchard models can use their own production of biogas as an energy source for heating. However, in some areas, the winter is cold and low temperatures prevent the fermentation tank from operating properly (Pham et al., 2014). Adding thermal insulation can be expensive. For the circular agriculture model to operate properly and economically, a four-in-one model has emerged. This model has a greenhouse in addition to biogas digesters and provides an effective ecological cycle from livestock feeding to

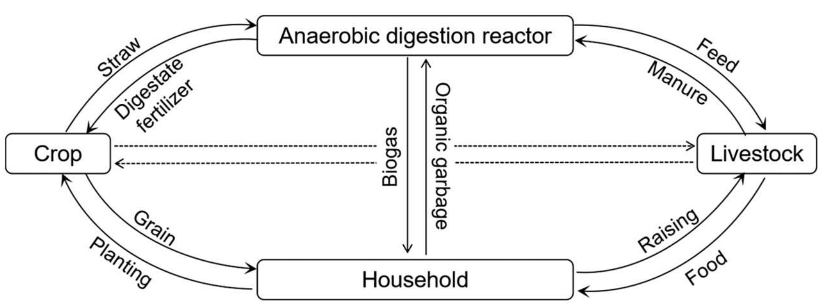

Figure 5 Eco-agriculture model of biogas anaerobic digestion.

vegetable production, resulting in a higher conversion efficiency in nutrient cycles and energy flows (Qi et al., 2005). An example is combined pig and vegetable greenhouse production, by combining a plastic solar greenhouse, an underground 6–10 m^3 biogas digester, a pigsty of about 10–20 m^2 and toilet facilities, parallel to the vegetable greenhouse. This forms an energy ecosystem (Fig. 6).

This model has the following advantages:

1 Due to the presence of the greenhouse, the biogas digesters are warmed up by the solar energy, solving the problem of gas production in cold winter temperatures.
2 The temperature of the pigsty can also be increased by 3–5°C in winter, providing suitable growth conditions for pigs.
3 The toilet (for human personnel) and pigsty provide sufficient fermentation feed for the biogas tank.
4 The pigs exhale a large amount of CO_2, and increase CO_2 concentration in the greenhouse by a factor of 4–5 which can greatly improve vegetable growth conditions in the greenhouse, and increase yield and quality.

7.4 Five-in-one model

The four-in-one model has improved ecological agricultural production in cold areas, but what kind of ecological agricultural model should be developed in areas of water shortage? As an example, the northwestern region of China has sufficient sunshine and a large temperature variation between day and night

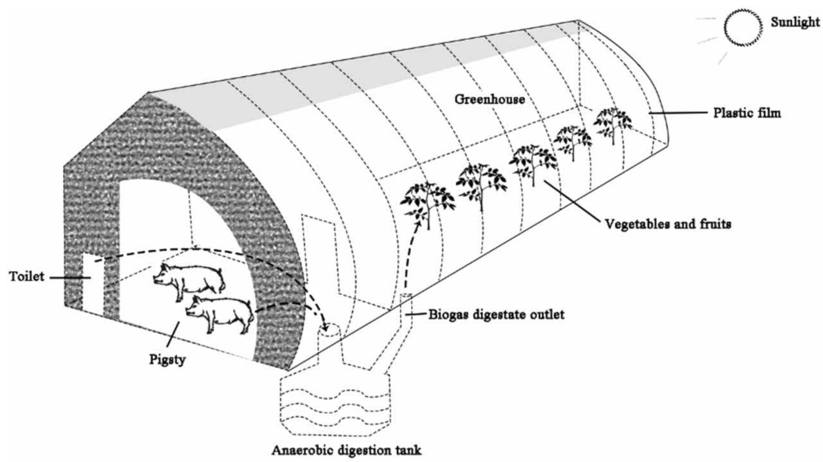

Figure 6 Structure of ‘four-in-one’ eco-agriculture model.

which could favor planting high-quality fruit and cash crops. However, the regional climate is arid and semi-arid climates with problems such as drought and soil erosion due to lack of water. The five-in-one model incorporates the components of the four-in-one system but adds water storage capacity (to capture the available natural precipitation) to enable drip irrigation (Qiu et al., 2001; Wu et al., 2015). The biogas slurry can, for example, be applied to the roots of fruit trees using drip irrigation. As with the four-in-one model, each component supports the others.

8 Case study: biogas production in Henan Province, China

China is a country with abundant resources and well-developed agriculture, including the production of large volumes of agricultural, forestry and domestic waste as well as sewage sludge. Bio-gasification is a promising way of recycling this large amount of waste. Henan is the country's major agricultural province. In 2014, the output of major cereal and meat products in Henan Province reached 55.227 million tons and 69.91 million tons, respectively, as recorded by the Henan Statistical Yearbook (http://www.ha.stats.gov.cn/hntj/lib/tjnj/2015/indexch.htm; accessed November 8th 2019). Henan Province also has a large number of biogas projects combining the development of biogas and agriculture.

8.1 Biogas potential of Henan Province

The 2014 China Statistical Yearbook shows the number of pigs, cattle, sheep, chickens and ducks raised in Henan Province during the year. The total number of these animals reached 959.62 million. The amount of cattle manure and pig manure produced is 88.77 million ton and 61.68million ton, respectively, sheep manure is 11.12 million ton and poultry is 4.05 million ton, respectively. Figure 7 shows the numbers of sheep, cattle, pigs and poultry, the volume of manure and MBP. It can be seen that biogas potential and fecal volume do not increase with the number of animals in a linear way. Although poultry is the largest group, accounting for 84% of the total, the biogas potential is the smallest, accounting for only 4% at 324 million m^3. Biogas potential also corresponds to the kinds of manure produced: the MBP of cattle, pig, sheep and poultry reached 3.99 billion m^3, 3.70 billion m^3, 0.68 billion m^3 and 0.32 billion m^3, respectively. This shows that agricultural waste resources have great potential to supply energy via biogas. However, the biogas production of current biogas projects is far below the potential value (Gao et al., 2019). This may be due to geographical conditions, technical equipment, management methods, and policy and economic constraints. However, this estimate shows the biogas potential of agricultural waste.

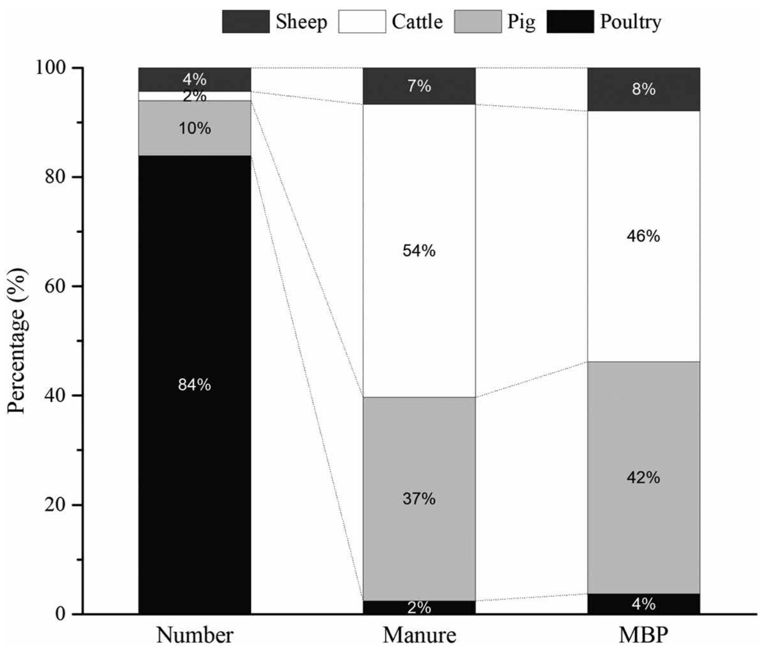

Figure 7 Livestock number, manure and MBP volume of Henan Province in 2014.

8.2 Eco-agriculture model

Henan Province has pioneered an eco-agriculture model called '100 mu-1000 heads ecological quadrant' (mu is a unit of area of about 0.0667 ha). It consists of a 3 mu livestock production line and 100 mu of farmland as a unit with 1000 pigs produced. Pig manure is digested and turned into organic fertilizer to use on the farmland, and the feed grain is processed into organic grain in situ. Such a 'pig-fertilizer-grain' recycling production line has the characteristics of low investment, rapid results and environmental benefits. It not only solves the problem of pollution in pig production, but also helps farmers out of poverty.

There are a number of requirements needed to develop this model. First, the government must improve policies related to biogas. Good policy guidelines can lead, supervise, guarantee, promote and support high-quality and sustainable production of biogas locally. High-quality biogas projects are economically and ecologically beneficial while supplying large amounts of bioenergy. Policies are an effective guarantee to achieve these benefits. The types of policies should include guidance, incentives, research, measure to promote markets, as well as standards governing constructive and operation (Feng et al., 2012).

Second, biogas companies must be responsive to policies and regional conditions, particularly in developing technologies that match local conditions. A key aspect is the intelligent control technology to improve the gas production rate of AD. By continuously monitoring and adjusting the actual fermentation environment, it is possible to find the best substrate and conditions for AD. Selecting a fermentation device to suit local conditions can improve resource utilization and biogas production efficiency. There is also a need for supporting infrastructure and maintenance capabilities to support biogas power generation, including skills training (Gao et al., 2019b).

Finally, each region needs to adapt biogas production to local resources and conditions. As an example, it might select crops which benefit most from local conditions while selecting livestock with the greatest regional market potential. Establishing successful, long-running biogas engineering enterprises are the path to promote large-scale, professional development of biogas. Circular agriculture and ecological agriculture models provide the basis for fully utilizing biogas resources, for example, by integration with solar greenhouses and water-saving irrigation systems, and combining biogas production with crop and aquaculture production to achieve sustainable biogas production. These models provide a path toward a sustainable future for agriculture.

9 Summary and future trends

Livestock and poultry manure is a huge potential problem which exposes the environment to pollution and other risks. However, as an organic substance, livestock manure has huge biogas potential in the production of clean energy in the face of energy shortages and environmental change. Developments in biogas production technology have improved the utilization of animal manure through AD, increasing the economic and environmental benefits. However, at present biogas production from animal manure is below its potential. Areas for further study include:

1. Establishing a more accurate biogas estimation method, for combining various wastes with actual research data.
2. Innovating high-efficiency, low-cost biogas production technology and equipment.
3. Developing a variety of eco-agricultural models suitable for different regions to find more efficient ways of using animal manure.
4. Developing evaluation methods to determine the most scientific and effective way to use manure in different areas.

Advances in these and other areas offer the opportunity for a bright future for this sector.

Nutrition

Chapter 7

The impact of improving feed efficiency on the environmental impact of livestock production

James K. Drackley, University of Illinois at Urbana-Champaign, USA; and Christopher K. Reynolds, University of Reading, UK

1 Introduction

As ruminants, cattle are marvellous bioreactors that, through symbiotic rumen fermentation, convert cellulosic plant biomass and other organic materials inedible to humans into high-quality animal proteins for human nutrition. Nevertheless, the conversion is of course not 100% efficient, and so varying quantities of waste products such as carbon dioxide (CO_2), methane (CH_4), and reactive nitrogenous compounds are emitted. As such, producers of ruminant livestock must strive to maximise output for each unit of input, both to enhance enterprise profitability and to minimise the environmental impacts of dairy and meat production. A key metric of this system efficiency is feed conversion efficiency (FCE), which for milk production is usually defined as energy-corrected

http://dx.doi.org/10.19103/AS.2020.0077.10

milk divided by feed dry matter intake (DMI) and for meat production is live weight gain divided by feed DMI. FCE per se also has a genetic component, which can be measured by residual feed intake (RFI). RFI is defined as the actual intake minus the feed intake expected to meet requirements for milk production, growth, reproduction and maintenance (Koch et al., 1963).

FCE has been widely used in beef production, as well as in pork and poultry production, to monitor the efficiency of feed utilization for growth. The dairy industry also recognizes the importance of the metric in management systems, but in addition to milk yield, there is also a need to account for body tissue loss and gain in calculating the efficiency of a lactating dairy cow (VandeHaar, 1998). Maximising the output of saleable product per unit of resource input is a standard principle of all manufacturing industries that relate directly to profitability. Another way of stating this relationship is that producers must minimise their unit cost of product and optimise their total unit output (Colman et al., 2011).

Relative to the reduction of greenhouse gases and contaminants of water, the simple concept is that the more carbon and nitrogen (N) in feedstuffs captured in the product, the less carbon and N are available for conversion into waste products (e.g. CO_2, CH_4 or urea N). By this principle, increasing milk or meat output from the same feed input requires changes in digestibility or postabsorptive nutrient metabolism with the result that less greenhouse gases and other waste products are produced per unit of milk or meat. The same principles apply to phosphorus and other nutrients that may become pollutants when they escape the animal through feaces or urine. This chapter will focus on the efficiency of milk production by dairy cattle related to nutrition and genetics focussing on how improving FCE can decrease the greenhouse gas burden of milk production and how FCE can be improved.

2 Greenhouse gases and dairy production

In the United States during 2008, the dairy sector's contribution to greenhouse gas emissions was estimated to be 134 Tg CO_2 equivalents, which equated to 1.9% of the total U.S. output (Thoma et al., 2013). Of this, CH_4, nitrous oxide (N_2O), and CO_2 contributed 44%, 13%, and 41%, respectively, of total emissions of the sector (Thoma et al., 2013). Emissions of CH_4 attributed to the dairy sector are primarily enteric emissions arising from digestive tract fermentation and stored manure, whereas N_2O emissions are largely attributable to N fertiliser application for the production of feedstuffs and manure application to farm land, including direct deposition by grazing livestock (Uweze et al., 2020; Rotz, 2018). In contrast, direct emissions of CO_2 arising from rumen fermentation and animal metabolism are not considered, as these emissions are a consequence of the digestion and metabolism of plant material incorporating atmospheric

CO_2 captured by photosynthesis. These estimates of the contribution of dairy production systems to global greenhouse gas emissions have been revisited recently because of the shorter half-life of CH_4 relative to CO_2. Methane from ruminants is also derived from the digestion of plant material, and over time CH_4 in the atmosphere is converted to CO_2, which reduces the long-term global warming effect of enteric CH_4 (Cain et al., 2019). In light of these considerations, dairy's contributions to CO_2 and N_2O emissions through fossil fuel consumption, fertilizer production and use, as well as manure management, are a greater concern for global warming in the longer term.

While the dairy sector is a small contributor relative to other industries such as oil and gas, the industry faces pressure to decrease greenhouse gas output. From the viewpoint of dairy producers, this pressure should not be viewed necessarily as burdensome because methane amounts to a 3.8–7.4% (5.6% on average) loss of gross energy intake from feeds (Kebreab et al., 2008). Mitigating greenhouse gas emissions should help not only the environment but also the financial bottom line of dairy production, unless the costs of mitigation become excessive. This is true especially if the feed energy not emitted as methane is captured as additional milk or body tissue (Reynolds et al., 2011). However, in most studies to date decreases in methane emission resulting from feeding methane inhibitory compounds such as 3-nitrooxypropanol (Reynolds et al., 2014; Hristov et al., 2015) or nitrate (Olijhoek et al., 2016) have not been associated with increases in milk energy yield or body energy balance. In this case, a part of the energy not emitted as methane is emitted as hydrogen, but the fate of the remainder of the methane energy not emitted is not certain (Olijhoek et al., 2016). In contrast, dietary strategies such as supplemental fat consistently decrease methane per kg feed DMI and often increase milk yield (Beauchemin and Grainger, 2011), but in this case, the effects on milk yield are through mechanisms independent from the effects on methane emission.

An issue with striving to decrease methane emissions is a decrease relative to what – in other words, what is the denominator of the equation? A reduction in total methane produced by the dairy sector will be difficult to achieve without reductions in animal numbers or effective mitigation strategies (e.g., methane-inhibiting feed supplements). Reductions in methane formation per unit of feed dry matter consumed (methane yield) may require shifts in the microbial community's overall metabolism or methanogenic enzyme inhibition through feed additives such as nitrate (Olijhoek et al., 2016) or 3-nitrooxypropanol (Hristov et al., 2015) as discussed above. Reductions in methane yield can also be achieved by feeding supplemental fat, which provides dietary energy that is not fermented in the rumen to yield hydrogen for methane synthesis (Grainger and Beauchemin, 2011). In contrast, decreases in methane production per unit of milk produced (methane intensity) are possible by boosting production efficiency (milk per unit of feed DMI). Much of this benefit arises from a dilution of the greenhouse gas production associated with the maintenance intake of the animal (Knapp et al., 2014). Cows require a certain amount of feed nutrients to maintain critical life functions even in the absence of milk production; think of it as the 'overhead' digestion and metabolism needed to sustain the basic functions of cows. Increasing the amount of milk produced per unit of additional feed intake thus serves to dilute the amount of maintenance greenhouse gas production over a larger number of milk production units. Other ways that improving feed efficiency may decrease methane output per unit of milk produced relate to increasing rates of nutrient passage through the rumen, shifting site of digestion to the intestine, feeding supplemental fat, or reducing heat production by the animal by alterations in metabolism that result in greater milk yield (discussed in a later section).

3 Origin of methane and reactive nitrogen excretions

In ruminants, enteric methane is mostly produced by the reduction of CO_2 in the rumen and hindgut. Greenhouse gas (primarily methane) output by dairy cattle represents 24.2% of enteric emissions from livestock (USEPA, 2021). The majority of methane production (ca. 85%) occurs in the reticulorumen of cattle, with normally only 13% being produced in the lower gut and rectal emissions constituting only 2–3% of total animal emissions (Murray et al., 1976; Munoz et al., 2012). Thus, factors relating to feed quality, feed consumption, feed degradation, and ruminal metabolism are paramount for the determination of methane output by dairy cattle.

The rich and extensive microbiota in the rumen constantly degrades complex carbohydrates in the diet (cellulose, hemicellulose, pectin, and starch) and metabolizes the constituent monosaccharides to the principal short-chain or volatile fatty acids (VFA), which are acetate, propionate, and butyrate. Conversion of monosaccharides to VFA generates ATP that can be used to drive nucleic acid and protein biosynthesis, that is, the principal components of new microbial cells. Degradation of feed protein and nonprotein N, including urea N recycled to the rumen, provides substrates (NH_3, amino acids, peptides) for microbial amino acid and protein synthesis. Ammonia N not captured as microbial protein is absorbed, converted to urea N in the liver, and either recycled to the gastrointestinal tract or excreted in the urine. Urea recycled to the rumen and hindgut is degraded by microbial urease to CO_2 and NH_3, and the NH_3 is either used for microbial protein synthesis or is reabsorbed. Any microbial protein synthesized in the hindgut is excreted as faeces, and microbial protein can account for more than 50% of faecal non-ammonia N of lactating dairy cattle (Larsen et al., 2001). Urea N in urine is very reactive and can be quickly volatilised as NH_3, especially when urine is mixed with faeces containing microbial urease. Faecal protein N is less reactive than urinary urea N, but as noted above, can contribute to N_2O and nitrate losses to the environment, depending on manure management practice.

Methane production serves a critical role within the microbial community. Production of acetate from fibre fermentation is associated with the co-production of CO_2 and H_2. The partial pressure of H_2 must be kept very low in the rumen to avoid poisoning the fermentation, and the primary means of doing so is the conversion of H_2 and CO_2 to CH_4 and H_2O (Hungate, 1966). The organisms responsible belong to the Archaea, but changes in Archaeal populations correlate only weakly with methane production (Tapio et al., 2017). Rather, methane production is related more to the populations of hydrogen-producing bacteria (Wallace et al., 2017). Production of propionate is not associated with the production of CO_2 or H_2; in fact, propionate uses hydrogen reducing equivalents in its synthesis. Although butyrate production also produces CO_2, it uses hydrogen reducing equivalents, so methane formation is not necessary (Hungate, 1966).

A fundamental relationship exists then in the fermentative breakdown of dietary components within the rumen, which can be appreciated by writing a simplified (non-chemically balanced) equation for rumen fermentation:

$$\text{dietary C and N} \rightarrow \text{microbial biomass} + \text{VFA} + CO_2 + CH_4 + H_2O + NH_3 + \text{heat} \quad (1)$$

From the standpoint of microbial growth efficiency, microbes strive to maximise biomass growth at a minimum VFA production, thus capturing as much of the starting feed substrate in new microbial cells as possible. The mixed rumen microbial population is able to generate 3–4 moles of ATP per mole of glucose fermented, which contrasts with simple monoculture fermentations that may generate only 2 moles of ATP (Hungate, 1966). Therefore, as rumen nutritionists, we understand that maximising microbial efficiency in the rumen ultimately leads to improved efficiency of milk production. Another way to think of this relationship is that the more dietary C and N we can keep in VFA and microbial protein, the less CH_4 and NO_2 are released into the environment. Similarly, the more efficiently dietary protein can be converted to milk protein through microbial protein synthesis and the metabolism of absorbed amino acids, the less excess N is excreted in urine and faeces. This idea forms the basis for why improving FCE decreases methane loss and the total greenhouse gas emissions attributable to dairy production.

4 Feed conversion efficiency

Improvements in milk production over the last several decades provide a clear demonstration of the benefits of improved FCE. Increases in FCE have arisen from increases in milk production, which dilutes the proportion of feed used for maintenance (VandeHaar and St-Pierre, 2006). Milk production has increased from intense genetic selection, improved nutrition and cow health, and other advances in modern management techniques. The improved FCE has benefited dairy producers' profitability, decreased the environmental impact of milk production, reduced the amount of land required for milk production, and decreased the greenhouse gas emission per unit of milk produced (Knapp et al., 2014). Continued gains in FCE by these methods will diminish, however, because the effect diminishes with each increment of dilution of maintenance (VandeHaar, 1998; Reynolds et al., 2011; VandeHaar et al., 2016).

Many environmental factors also affect FCE, including nutrition. Diet digestibility, or more specifically forage digestibility, is a major component of FCE. Dietary protein and carbohydrate balance, supplemental fats and various additives may also impact FCE through effects on digestive function and milk energy yield. Other factors include the stage of lactation, body reserve changes, physical activity, mastitis or other diseases, acidosis and heat and cold stress. From a dairy system standpoint, the total FCE of the farm unit is impacted by numerous factors, including calving interval, days dry, age of first calving, reproductive efficiency, periparturient health disorders, and death loss in calves and heifers. These latter factors centre on the effects of decreased productive days of life for those animals that are not producing milk, or not producing large amounts of milk, but continue to consume the feed.

Herd and Arthur (2009) reviewed the biological basis for differences in RFI for beef cattle. Possible components included feed intake, digestion, metabolism associated with fat and protein deposition, physical activity, thermoregulation, and other components of basal metabolism. As reviewed by Reynolds et al. (2011), digestible energy is the most variable proportion of gross energy intake in ruminants. It accounted for 86% of the variation in dietary net energy for lactation in dairy cattle in the calorimetry studies on which the initial NEmilk system for energy requirements of lactating dairy cows in the USA was based (Moe et al., 1972). This largely reflects differences in forage quality and the digestibility of fibre, which is affected by forage maturity at harvest and processing during conservation and feeding, as well as associative effects of other diet components that impact the rate and extent of fibrolytic activity in the rumen.

Beever and Drackley (2013) calculated methane production per kilogram of milk production as a function of increasing milk production efficiency and found a negative relationship between the two (Fig. 1). That this theoretical calculation was borne out in practice was demonstrated by an analysis of 323 measurements of methane emission by lactating dairy cows at the University of Reading (Fig. 2). When expressed on the basis of MJ of methane emitted per MJ of milk energy production, there was a reduction in methane emission

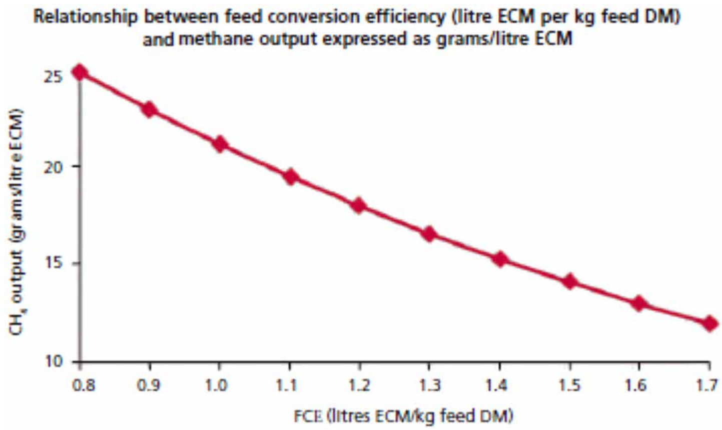

Figure 1 Theoretical relationship between methane output (g/L ECM) and FCE (L ECM/kg DM). Reprinted from Beever and Drackley (2013) with permission.

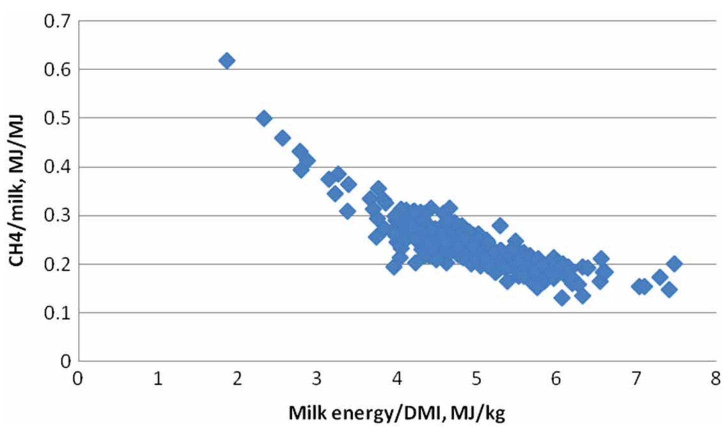

Figure 2 Methane energy/milk energy (MJ/day) as a function of milk energy (MJ/day) per unit feed dry matter intake (kg/day) where $y = 0.833*\exp^{(-0.259*x)}$. Individual observations (n = 323) for cows fed various dietary treatments in experiments conducted at the University of Reading with correction for the random effect of experiment on the intercept.

per unit milk energy yield with increasing FCE, expressed as milk energy per kg feed DMI (MJ/kg). An exponential decay curve provided the best fit of the data after correction for the effect of experiment, clearly showing the higher methane 'overhead' of lower-yielding cows and the dilution of maintenance greenhouse gas 'costs' with higher milk yield and FCE. Similar relationships between increased milk yield per se and reduced methane emission per unit milk yield have been noted previously (Reynolds et al., 2011).

5 Nutritional practices to enhance feed conversion efficiency and decrease CH_4 excretion

Because methane formation occurs from microbial fermentation of dietary constituents, it follows that nutrition of the ruminant impacts FCE and methane production (Table 1). The most important aspect of nutrition is feed intake, represented in ruminants as DMI. A meta-analysis of methane measurements from growing and lactating cattle (Mills et al., 2009) revealed that feed DMI was the primary predictor of methane emission (Reynolds et al., 2011). The effect of DMI is explained by the increasing provision of fermentable substrates, although the use of digestible energy only marginally improved the prediction (Mills et al., 2009).

A commonly used equation to estimate methane production (Moe and Tyrrell, 1979) is as follows:

$$\begin{aligned}\text{methane production, MJ/d} = {} & 1.837 + 1.142\,(\text{digested soluble residue, kg/d}) \\ & + 2.142\,(\text{digested hemicellulose, kg/d}) \\ & + 5.828\,(\text{digested cellulose, kg/d}).\end{aligned} \tag{2}$$

Since this early work of Moe and Tyrrell (1979), there have been numerous subsequent meta-analyses of measurements of methane emission relative to

Table 1 Feeding management variables and effects on methane (CH_4/ECM), dry matter intake (DMI), energy-corrected milk (ECM), and feed conversion efficiency (FCE). Modified from Knapp et al. (2014)

Feeding alteration	CH_4/ECM	DMI	ECM	FCE
Increased DMI	Decrease	Increase	Increase	Increase or no change
Increased forage quality	Decrease	Increase	Increase	Increase
Decreased forage particle size	No change	Increase	Increase or no change	No change
Grain processing	Decrease	No change	Increase or no change	Increase or no change
Increased concentrate feeding	Decrease	Increase	Increase	Increase or no change
Rumen pH <5.5	Decrease	No change or decrease	Decrease	Decrease
Brown midrib corn	Decrease	Increase	Increase	Increase or no change
Fat feeding	Decrease	Decrease or no change	Increase	Increase

diet intake and composition, which have largely confirmed the overriding role of intake of digestible structural and nonstructural carbohydrates, as well as lipids (see below), in determining methane emission and yield. For example, a recent global analysis of 3183 individual observations concluded that prediction models should include diet intake, digestibility, and concentrations of structural and nonstructural carbohydrates and ether extract for greatest accuracy (Benaouda et al., 2019).

According to Equation 2, increments of digested soluble residue, largely comprising starch and sugars, will increase methane to a lesser extent than digested hemicellulose or cellulose from forages. In turn, digested hemicellulose has a much smaller effect than digested cellulose. This is consistent with the fact that starch fermentation yields a greater proportion of propionate compared to fibre fermentation (Hungate, 1966). Increasing concentrate supplementation in the diet increases digestible energy, usually increases FCE, and decreases methane output per unit of milk produced, as predicted by the analysis in Fig. 2 and by the diluting effect of greater productivity on methane production per unit of milk yield. Concentrates containing cereal grains rich in starch will increase the metabolisable energy available to the animal, usually increasing milk yield unless excessive amounts are fed that cause acidosis (Van Soest, 1994).

In contrast, increasing the digestibility of forages, which will usually increase FCE by boosting milk yield, might not reliably change methane production per unit of milk produced because of the increase of fermented cellulose and hemicellulose. However, in practice, improving forage digestibility usually increases FCE and, by increasing milk production, the yield of methane per unit of ECM decreases due to the dilution of the maintenance concept. Variations in concentrations of cellulose, hemicellulose, and starch, as well as their digestibility, interact with differences in DMI that can make it difficult to predict the resulting methane production from differences in FCE (Reynolds et al., 2010; Livingstone et al., 2015). For example, diets higher in maize silage contained more starch and less NDF than diets higher in grass silage, and resulted in greater DMI and milk yields, but FCE was greater for the diets high in grass silage. However, methane intensity was greater for the high grass silage diets (Hammond et al., 2016).

Forage digestibility can be increased in several ways. Harvesting at younger maturity increases digestibility because of greater concentrations of nonstructural carbohydrates, such as sugars and fructans, along with lower lignification of plant cell walls (Van Soest, 1994). Some genetic variants have greater digestibility. For example, the stover from the *bm-3* or brown midrib genetic variant of maize and sorghum is more highly digested than typical varieties (Oba and Allen, 2000). Cellulose, hemicellulose, and NDF were less digestible in diets containing 40% (DM) maize silage and 10% alfalfa silage than in diets containing 10% maize silage and 40% alfalfa silage (Ruppert et al., 2003). Finally, grass forage is typically more digestible than legumes, such as alfalfa, although the rate of fermentation is faster for legumes (Van Soest, 1994).

Processing forages can have contradictory effects on methane yield. Fine grinding or pelleting of forage increases the surface area available for fibrolytic microbiota to attach for fermentation, but the small particle size increases its passage from the rumen (Russell and Hespell, 1981), thus limiting the digested dry matter and so limiting methane formation (Moss et al., 2000). Such effects could decrease methane by 20–40% per unit of DM at high intakes, although at restricted intakes the effects are less (Johnson and Johnson, 1995). However, this also decreases potential energy delivery to the animal, which might decrease milk production, although compensatory hindgut digestion can recover some of the lost energy (Van Soest, 1994). With fine grinding of the forage and the resulting faster passage, however, the animal will likely eat more (Van Soest, 1994), which would tend to increase methane production.

Grains can be processed by grinding, rolling, and steam flaking, all of which increase surface area for digestion and decrease particle size. Grain processing can decrease the amount of starch that passes to the small intestine. Digestion in the small intestine should be more efficient energetically, but results have not borne this out in practice (Huntington et al., 2006). The effect of processing on ruminal degradation of starch varies among cereals and depends on the processing methods used (Svihus et al., 2005). Extensive rolling of barley maximised ruminal and postruminal digestion of starch (Yang et al., 2001). More extreme processing tends to increase total VFA concentration in the rumen, with a greater proportion of propionate that would decrease methane formation. Grinding maize grain increased starch digestibility in the total tract compared with rolling (Knowlton et al., 1998), but ground maize resulted in greater methane production (Wilkerson et al., 1997). Steam flaking maize grain resulted in greater FCE than grinding, regardless of particle size of grind (Ahmadi et al., 2020). However, finely ground maize can produce results similar to steam-flaked maize (Mathew et al., 2011). Heat treatment through pelleting, flaking, extruding, and toasting can change the ruminal degradation rates of protein and carbohydrates and decrease the acetate:propionate ratio in the rumen (Van Nevel and Demeyer, 1996). However, the relationship between such treatments and CH_4 emissions depends on the feed, composition of the total diet, and intake (Knapp et al., 2014).

Supplemental fats and oils are often added to diets for dairy cattle to increase the energy density of diets for high milk production (Palmquist and Jenkins, 2017). According to meta-analyses (Rabiee et al., 2012; Hu et al., 2017), fats usually maintain or decrease DMI while increasing milk yield and milk energy output. Consequently, supplemental fat sources often increase FCE and, as expected, decrease methane output per unit of milk energy (Ruppert et al., 2003; Kliem et al., 2019). The effect of lipids on methane production is dependent on the source, fatty acid profile, inclusion rate, form of lipid, and diet composition (Beauchemin et al., 2008). Lipid sources replace fermentable substrates, and the unsaturated fatty acids provide an alternate sink for hydrogen disposal. Unsaturated fatty acids also directly impact fibre-fermenting microbiota and methanogens in the rumen (Czerkawski et al., 1966; Blaxter and Czerkawski, 1966). In practice, however, changes in methane production are not always observed. Nevertheless, a meta-analysis conducted by Knapp et al. (2014) found that increasing fat content of the diet decreased methane per unit of ECM, and that the type of lipid source affected the response. Free vegetable oils and endogenous lipids resulted in a greater reduction of methane per unit of ECM than did inert fats or seed lipids. Some seeds, vegetable oils, and medium-chain fatty acids (such as those found in coconut oil; Hristov et al., 2009) further decrease methane, but often at the expense of DMI, which could be detrimental to productivity and reproduction over the long term (Reynolds et al., 2011; Knapp et al., 2014).

In addition to 3-nitrooxypropanol and nitrate mentioned previously, a variety of potential nutritional additives have been tested for their ability to improve FCE and decrease methane losses, including ionophores, yeasts, certain seaweeds, and plant bioactive compounds with antimicrobial or digestive effects, such as tannins and essential oils (Beauchemin et al., 2008; McAllister and Newbold, 2008). These compounds have had varying efficacies, especially in the longer term, perhaps due to differences in dose rate and adaptation of the rumen microbes (Beauchemin et al., 2008). Although some have shown potential to decrease methane excretion, for these approaches to be widely adopted their effects will need to be consistent, sustained, without deleterious effects on feed intake, production, FCE or product quality, economic to adopt, and sustainable (Reynolds et al., 2011).

6 Nutritional practices to increase milk protein efficiency and decrease N_2O excretion

In ruminant production systems, enteric CH_4 production is the greatest contributor to greenhouse gas emissions, followed by CH_4 from manure and in beef feedlot systems, N_2O from pen surfaces, and N_2O emissions from soils (Montes et al., 2013). Improving the efficiency of dietary N use by increasing N incorporation into milk protein and decreasing N losses in faeces and urine will have positive effects on N_2O excretion and environmental contamination with N (Uwizeye et al., 2020). Many of the same principles discussed to this point relative to increasing FCE will have beneficial effects on increasing efficiency of dietary N use. From an environmental standpoint, animal practices to decrease urinary N loss have the biggest impact because urinary N is more susceptible to leaching and volatile losses than faecal N and contributes directly to N_2O loss from livestock facility surfaces (Dijkstra et al., 2013a; Montes et al., 2013).

The main driver of N losses from cattle is N consumed in feed. Dairy cows secrete in milk an average of 21–33% of consumed N (Calsamiglia et al., 2010), with almost all the remaining N excreted in faeces and urine. In agreement, Reed et al. (2015) calculated an average total manure N excretion of 69% of N intake from a large database. Dijkstra et al. (2013b) calculated the theoretical upper limit of dietary N incorporation into milk protein to be 43% at maximal milk secretion for a cow weighing 650 kg and producing 40 kg/day of fat and protein corrected milk.

Huhtanen and Hristov (2009) concluded from a meta-analysis that dietary crude protein (CP) concentration is the most important dietary factor influencing milk N efficiency, with ruminal degradation of CP being of lesser importance. Differences in amount and, to a smaller extent, digestibility of N in feed affect not only the total amount excreted but also the partitioning of N among milk, urine, and faeces (Castillo et al., 2001; Kebreab et al., 2002). Partitioning of manure N excretion into faecal and urinary N excretion is important because differences in N intake largely affect urinary N output, which is of greater importance to reduce environmental impact (Dijkstra et al., 2013a).

The carbohydrate portion of the diet may impact the efficiency of dietary N use through differences in the amount or efficiency of N capture in the rumen. Ruminants must have sufficient ruminally degradable protein to maximise fermentation with the amount of fermentable carbohydrates supplied. Wilkinson and Garnsworthy (2017) showed that replacing dietary grazed grass or grass silage with corn silage at similar milk yield increased N efficiency and reduced the C footprint. Grazed grass is particularly problematic in terms of urinary N loss because of the high soluble CP content of the grass and concurrent lower content of rapidly fermentable carbohydrates (Hristov et al., 2013).

Dairy producers have often overfed dietary protein in the mistaken assumption that it would boost milk production (Broderick, 2018). Broderick (2003) compared diets with CP increasing from 15.1% to 16.7% and 18.4% by adding soya meal to the diet. Milk and milk protein yields increased with the first increment of CP but not the second. The only result from increasing dietary CP to 18.4% was the increased excretion of urinary N, which accounted for nearly all of the increment of dietary N. Recently, a trend for lower dietary CP has been observed in high-producing herds. Diets with as little as 14.9% CP can support milk production in excess of 45 kg/day when properly balanced for N and carbohydrate fractions and supplemented with key ruminally protected amino acids (Fessenden et al., 2020). In 2010, the five highest producing herds in the state of Wisconsin were being fed diets containing an average of 16.9% dietary CP, with the lowest at 16.3% (Broderick, 2018). Over the period from 2004 to 2010, CP content of dairy diets in Wisconsin decreased 1.1 percentage units, but milk and protein production increased by 1700 and 51 kg per lactation. Clearly, minimising dietary CP needed to support high milk production pays dividends in the way of decreasing ration cost and environmental excretion of N, without sacrificing productivity.

7 Genetics and feed conversion efficiency

Using RFI as a measure of FCE has the advantage that it is independent of maintenance requirements and is not an efficiency determined by the level of production per se. A disadvantage of the measurement is that animals that are more efficient have negative RFI, which is non-intuitive and difficult for producers to accept. Reported heritability estimates of RFI in dairy cattle generally are low to moderate, with estimates ranging from 0.01 to 0.40 among lactating cows (Connor, 2015). Tempelman et al. (2015) determined that RFI had a heritability of 0.15–0.18. This means that the trait could be improved through genetic selection but that much of the variation in phenotype must be attributable to other environmental factors. Genetic correlations suggest no undesirable relationships detected between RFI and fat-corrected milk yield, productive life or feeding behaviours, and desirable relationships between RFI and predicted methane production in lactating cows (Connor, 2015).

There is currently interest in the potential selection of dairy cattle for improved feed efficiency (e.g. Lin et al., 2013; VandeHaar et al., 2020) and lower methane emission or methane yield (e.g. Breider et al., 2019; Lassen and Løvendahl, 2016). However, these traits must not be considered in isolation; for example, reductions in methane yield in sheep were shown to be driven by higher rates of feed passage through the rumen attributable to smaller rumen volume and thus reduced total feed intake capacity (Goopy et al., 2013).

The benefits of selection for RFI make the prospect of its application promising. For example, Holstein–Friesian heifers in New Zealand and Australia fed a forage-based diet that were in the bottom 10% of the sample population for RFI (i.e. most efficient) consumed 15%–20% less feed relative to heifers in the top 10% for RFI (least efficient; Williams et al., 2011; Waghorn et al., 2012). Differences are similar to differences in DMI of 12–13% reported in low versus high RFI groups of growing Angus–Hereford steers (Cruz et al., 2010). The dairy heifers cited showed no differences in feed intake, yields of milk or milk components, change in BW or body condition score when evaluated during days 75–195 of their first lactation (Macdonald et al., 2014). These results indicate that considerable savings in feed costs can be achieved by maintaining only the most feed-efficient growing heifers in the herd, with no negative consequences on future lactation performance.

In addition to selection for RFI, it might be possible to use genetic selection to improve N efficiency. Marshall et al. (2020) used breeding values for milk urea N (MUN) to create high and low lines of Holstein–Friesian dairy cows. There was a positive relationship between MUN breeding value and MUN, with MUN decreasing 1.61 mg/dL per unit decrease in MUN breeding value. Urinary N concentration decreased 0.67 g/L per unit decrease of MUN breeding value, with no difference in urine volume or urinary frequency, which resulted in a 165 g/day decrease in urinary urea N excretion between animals with the highest and lowest MUN breeding value. At the same milk yield, milk protein percentage increased by 0.09 per unit of MUN breeding value. Such preliminary results are positive both for decreasing environmental excretion of N and for improving N partitioning into milk for greater producer profitability.

Relative to greenhouse gas emissions, cattle with lower RFI have a lower DMI than less efficient animals at similar production levels (Connor, 2015), thus decreasing one major contributor to CH_4 production. By definition, animals with lower RFI have less manure output for a given level of production, which should decrease the release of CH_4 and N_2O from stored manure (Montes et al., 2013). Recent research demonstrated that cows with greater FCE (lower RFI) also used protein more efficiently, which would help reduce N excretion in urine (Liu and VandeHaar, 2020).

8 Postabsorptive metabolism and feed conversion efficiency

Heat energy lost in the conversion of ME to net energy (NE) typically accounts for 20–30% of gross energy intake in dairy cattle. But, in contrast to digestibility, the variation and opportunities to decrease these losses are more limited. The effects of forage type, processing, and forage to concentrate ratio on the efficiency of ME utilisation for milk and meat production (and FCE) have been extensively researched (Reynolds, 2011). Such effects are a greater concern in extensive systems relying heavily on poorer quality forages. Because the digestive system and liver account for as much as 50% of body heat production in ruminants, their metabolism has an impact on the partial efficiency of ME use for production that is disproportionate to their mass. Forage amount and digestibility impact ME utilisation for NE, which is largely attributable to the tissues of the gut and may reflect differences in the work of digestion and gut mass (McLeod and Baldwin, 2000). In contrast, nutrient re-partitioning agents such as growth hormone impact energy utilisation by altering metabolism in the muscle, adipose tissue, and mammary gland to increase milk production, which improves FCE by dilution of maintenance.

Reducing losses of dietary energy as heat may be one of the main factors affected by selection for improved RFI. Only 19% of the variation in RFI among animals may be attributable to differences in diet digestion and heat of fermentation, with the remainder likely due to differences in physical activity, body composition, protein turnover, and other metabolic processes associated with maintenance requirements and partitioning of nutrients between protein and lipid deposition (Herd and Arthur, 2009).

The effects of excess protein on energy utilisation in cattle have generated much discussion. Tyrrell et al. (1970) reviewed results of calorimetry studies and reported a reduction in ME or NE of diets when digestible protein was fed in excess of requirements. This effect was included in the calculation of NE for lactation (Moe et al., 1972). Some have attributed this effect of excess protein to the energy costs of urea synthesis in the liver, but studies in sheep and cattle catheterised for measurements of liver metabolism have consistently failed to show an effect of increased ammonia absorption and subsequent urea production by the liver on hepatic oxygen consumption (Reynolds, 2006). In contrast, supplemental protein fed in excess of requirement does increase liver oxygen use (i.e. heat production), as well as oxygen use by the gut, suggesting that the effect of excess protein on the efficiency of energy utilisation is associated with amino acid catabolism, rather than urea synthesis per se (Reynolds, 2006). Over 100 years ago, Rubner showed that the postprandial rise in heat production in dogs, termed 'specific dynamic action', associated with consumption of protein was greater than for carbohydrates and fats (Brody, 1939), which also reflects the catabolism of amino acids in excess of requirements. These effects might be attributable to stimulation of protein turnover and greater activation of the sympathetic nervous system. Regardless of the mechanism, the potential benefits of feeding protein and ruminally protected amino acids more precisely to cattle extend beyond just the environment and economics to improving FCE.

9 Conclusion

Methane intensity of dairy production is related inversely to FCE. By diluting methane associated with cow maintenance, increasing milk production and increased FCE serve to decrease methane production per unit of milk energy produced. Nutritional practices that boost productivity usually boost FCE and will help to decrease methane intensity. Some of these include improving forage quality, increasing concentrate supplementation, and using supplemental fats and oils. Genetic selection for improved FCE (measured by RFI) will decrease methane intensity. Minimising dietary CP will help decrease urinary N losses, which contribute to increased N_2O and decreased efficiency of N capture into milk protein.

10 Future trends in research

Increasing FCE is directly related to profitability and will be a continued goal of research for improvement in the dairy industry. Decreased methane intensity should be a collateral benefit of such improvement. Determining the genetic basis for FCE, as measured by RFI, may eventually lead to improvements in the overall efficiency of milk production. Improving genetic aspects of forage digestibility and methods to improve use by cows will help decrease methane intensity. The research will continue to find compounds or strategies that will decrease methane yield without compromising DMI or productive efficiency. Novel mitigation strategies might include inhibitors or early life microbial modulation to change the balance between hydrogen producers and methanogens. In addition, the possibility that synergistic effects between strategies might occur, such as combining 3-nitrooxypropanol with lipids, should be investigated. Research will continue to identify genetic opportunities to minimise the environmental burden of livestock production as well as urinary N excretion.

11 Where to look for further information

A comprehensive discussion of strategies to mitigate methane emissions in dairy cattle can be found in Knapp, J. R., Laur, G. L., Vadas, P. A., Weiss, W. P., and Tricarico, J. M. (2014), 'Invited review: Enteric methane in dairy cattle production: Quantifying the opportunities and impact of reducing emissions', *J. Dairy Sci.,* 97, 3231–3261.

Chapter 8

Improving grassland/forage quality and management to reduce livestock greenhouse gas emissions

Michael O'Donovan, Teagasc, Ireland

1 Introduction

Pasture-based systems of production face multiple challenges, including global food demand, continuing to balance environmental sustainability, and ensuring product quality meets the highest consumer standards of nutrition and health. The challenge ahead for grassland farmers is imposing, but system sustainability and reducing methane emissions by improving management and forage quality is an aspect of pasture farming that needs to be addressed intensely by all elements of the industry. European grasslands sustain a large number of domestic herbivores, 150 million cows and 150 million sheep, which is roughly 15% of the global animal production. Grazers impact the cycling of C and N within pastures via defoliation, excretal returns and mechanical disturbance. They emit CO_2 via their metabolic activity and methane (CH_4) through enteric fermentation. Improving grassland management practise on farms is a key avenue of addressing further reductions of CH_4 emissions at farm level. There are many ways of

http://dx.doi.org/10.19103/AS.2020.0077.11

completing this successfully, and the challenge is to ensure these methods are employed at farm level through:

i optimising the use of home-grown grass;
ii increasing the proportion of grazed grass in the overall diet of the grazing ruminant;
iii extending the grazing season, especially in spring and autumn, thereby reducing the indoor feeding period;
iv adopting a strategy of grazing lower pre-grazing herbage masses during the grazing season (adapting sward morphology);
v grazing swards with higher levels of clover content, targeting levels of >20% in the sward, on average, across the grazing season;
vi improving grass dry matter intake (DMI), milk solids and average daily gain at grass; and
vii measurement of pasture quality at farm level across the growing season and appropriate supplementation patterns based on these figures.

These themes are discussed in the rest of the chapter.

2 Grassland areas and productivity in Europe

Europe maintains one of the highest livestock densities in the world. In 2018, the 27 member states of the European Union (EU-27) produced: 26%, 13%, 22%, 12% and 11% of the world's milk, beef, pork, poultry and eggs, respectively (FAO, 2009). Following considerable growth in the 1960s and 1979s, cattle numbers in Europe have been decreasing since 1980. More recently, reductions in animal production in Europe are related to market developments as well as to changes in agricultural and environmental policies. Between 1970 and 2013, 5.9 million ha of grassland in the EU9 were lost to other purposes (Table 1), equating to a 15.3% reduction in the proportion of permanent grassland. The proportions of permanent grassland reduced significantly in Germany (31.8%), the Netherlands (30.1%), France (28.1%), Denmark (25.9%) and Belgium (21.7%), while the reduction in Italy was much lower (13.3%). There was a small reduction in Ireland (2.2%) and Luxembourg (0.8%), while there was an increase in the United Kingdom (6.4%). Similar reductions in grazing land areas accrued in Austria, Greece, Spain and Hungary.

Grassland productivity will be affected by botanical composition, soil characteristics, climate conditions, altitude, latitude and management (De Vliegher and Carlier, 2007). Lee (1983) reviewed grassland potential productivity data from most European countries, and it was divided into five major geographical/climatic regions:

Table 1 Changes in the proportion of utilised agricultural area in permanent grassland area in EU9 between 1970 and 2013

		1970		2013	
	Total UAA	Permanent grassland (ha)	Proportion (%)	Permanent grassland (ha)	Proportion (%)
Belgium	1 307 900	621 253	47.5	486 539	37.2
Denmark	2 619 340	264 553	10.1	196 451	7.5

3 South-east Europe;
4 Mediterranean Europe; and
5 Northern Europe.

Factors that are considered to influence the grassland productivity are altitude, water stress, temperature and aspects such as slope and soil depth.

A coordinated experiment organised under the auspices of the FAO Lowland Grassland Sub-network measured the production and productivity of cutting grassland according to a standardised protocol in 32 European sites. The average annual production ranged from 10 t DM ha^{-1} to 14 t DM ha^{-1} (Peeters and Kopec, 1996). The extremes in grass production were very different ranging from 2 t DM ha^{-1} in Portugal to 20 t DM/ha in Germany (Kiel) (Peeters and Kopec, 1996; Fig. 1). The most productive sites (>15 t DM ha^{-1}) were located on the Atlantic side of Europe between 52°N and 57°N latitude.

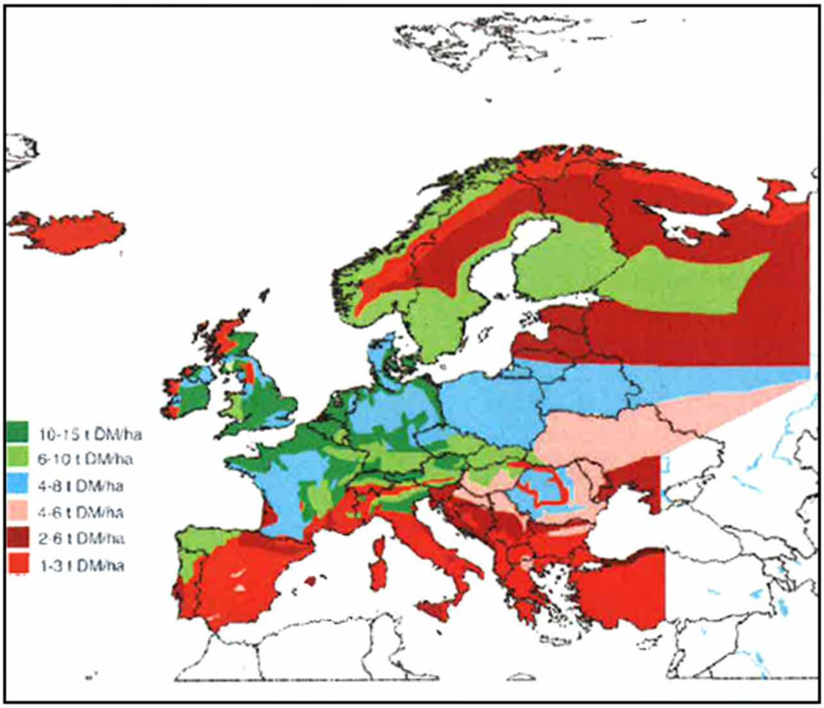

Figure 1 Production potential (annual yields in t DM/ha) of mown and heavily fertilised grasslands (source: Peeters and Kopec, 1996).

These included the Netherlands, Great Britain, Ireland, Belgium, north-western France and northern Germany. The less-productive sites were situated at high or low latitudes in Europe.

The EU (28 countries) currently has a permanent grassland area of about 60 million ha (Eurostat, 2017). Permanent and temporary grasslands represent 40% of the total utilised agricultural area in Europe (Huyghe et al., 2014) and a large acreage of these grasslands is exclusively used as ruminant feed, as either grazed grass or grass silage/hay. This asset of grasslands is extremely important for the human population since ruminants deliver food for humans by converting human-inedible plant biomass into high-quality human edible proteins. By providing feed to ruminants, grasslands contribute to the feeding of member state populations. Grass-based ruminant production delivers a number of other services to society, like carbon (C) sequestration (e.g. Soussana et al., 2010; Conant et al., 2017) and biodiversity (e.g. Isselstein et al., 2005; Van den Pol-van Dasselaar et al., 2019)).

Under climatically and topographically favourable conditions, the European grasslands area has been significantly reduced during the last 30 years (Huyghe et al., 2014). According to the 3rd report of the EU MAES initiative (Mapping of Ecosystems and Ecosystem Services), between 2006 and 2012 the main causes for this process were the conversion of grasslands into arable crops like maize (including for the production of biofuels) and other crops (32% of the lost area), the sprawl of urban areas, economic sites and infrastructures (30%), and the withdrawal from farming (17%) (Erhard et al., 2016). In many countries, the number of dairy cows decreased in the last 30 years but the milk yield of individual cows increased during the same period, with the number of cow reductions mainly driven by the implementation of the milk quota regime. Between 2010 and 2016, however, the bovine population slowly grew again by 1.4% (Eurostat, 2017).

The improvement in individual animal milk production is achieved based on an increasing amount of concentrates and maize in cow rations and declining herbage use from grassland (e.g. Isselstein et al., 2005). More and more farmers have changed to all-year housing and do not provide access to grazing for their cows, for example, and only

- 42% of German dairy cows have access to pasture (Gurrath, 2011); and
- 25% of Danish dairy cows have access to pasture (Van den Pol-van Dasselaar, 2016).

Such a decline in the access to grass has led to increases in milk production costs at farm level, and a worrying dependence on imported feed inside the farm gate; if continued it will lead to more GHG from the ruminant population.

3 The challenge of greenhouse gas emissions from livestock

Greenhouse gas emissions (GHG) from livestock are closely related to ruminant numbers. Factors other than ruminant numbers also have an impact. The size and productivity of animals affects their feed intake and enteric CH_4 emissions. Rarely, if ever, have the levels of grassland management, and the type of grassland offered to the grazing animal, been considered as a mitigation factor for CH_4 production. We know clearly that ruminants produce CH_4 during enteric fermentation of feed and CH_4 and N_2O are released from stored manure. Farm-based studies indicate that there are large differences among farms in terms of animal productivity and environmental impacts. These differences are often related to the management skill of the farmer, technologies applied and environmental conditions. We will discuss the possibilities to reduce CH_4 levels through better grazing management practises and the choice of more appropriate pasture species, given the changes in European grassland area and practise over recent years.

Ruminants lose between 2 and 12% of ingested energy as CH_4. Improvement in forage quality and more specifically forage digestibility has been investigated as a means of enteric CH_4 mitigation (Hristov et al., 2013). Structural carbohydrates have been reported to be more methanogenic than soluble carbohydrates. In ruminants with high feed intakes, reductions in enteric CH_4 emissions per unit intake with increased digestibility of feeds have been reported (Hristov et al., 2013). Greater digestibility is associated with a fermentation profile in the rumen that is unfavourable to CH_4 production. Hristov et al. (2013) stated a more digestible feed is associated with greater intake and production, diluting maintenance energy requirements and resulting in less CH_4 per unit of animal product. The literature is full of studies having evaluated feeds in indoor feeding systems based on concentrates and forage diets. Grazing studies with CH_4 emissions measured are currently scarce but increasing.

4 Grazing management to combat climate change: grazing season

4.1 Grazing season length and impact of climate change

Implementing good grazing management practises to improve the quality of pastures will increase animal productivity and lower CH_4 per unit of product (Boadi et al., 2004). A long grazing season can increase the annual proportion of grazed grass in ruminant diets, which can reduce feed costs and increase profitability (Dillon et al., 2005; Finneran et al., 2012). Grazing is generally positively perceived by consumers when compared to indoor feeding systems

(Van den Pol-van Dasselaar et al., 2019). Phelan et al. (2015) investigated the spatial variation in grazing season lengths from 32 European countries obtained from the results of the EUROSTAT Survey on Agricultural Production Methods (SAPM) and bioclimatic variables for dairy farms. The reference year was 2012 for all countries with the exception of Spain and Portugal which had 2009 as the reference year. Grazing season length was positively correlated with mean temperature during the coldest quarter and negatively correlated with precipitation in the wettest month. Figure 2 illustrates the observed and predicated grazing season lengths for dairy farms in all 32 European countries. The predicted grazing season lengths were longer than observed in Belgium, Estonia, Germany, Hungary and the Netherlands but shorter in Bulgaria, France, Latvia and Lithuania.

4.2 Early season grazing

Grazed grass can be increased in the overall diet of the dairy cow by allowing cow's access to grass early in spring; this is an opportunity for all member states. Many studies have shown an improvement in milk production and composition with this practise (O'Donovan et al., 2004; Kennedy et al., 2006). As well as improving animal performance, early spring grazing can have beneficial effects

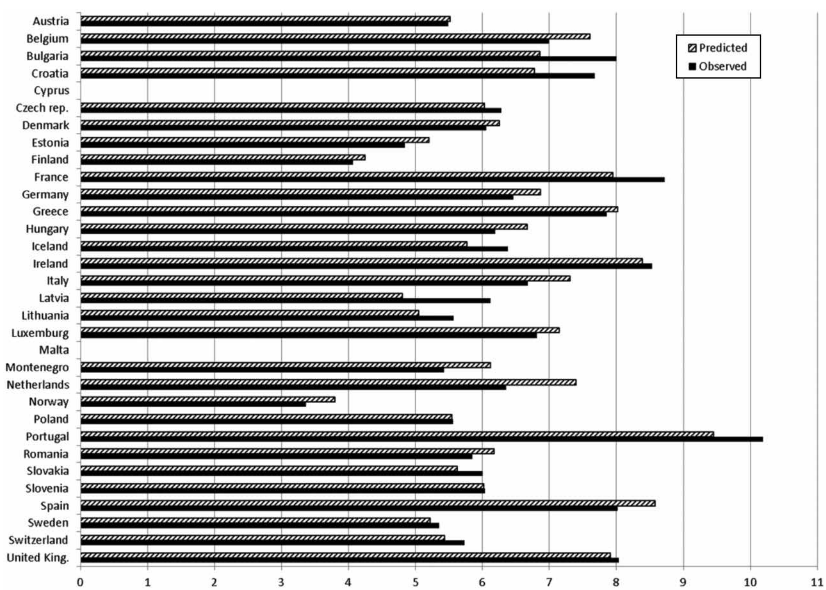

Figure 2 Observed and predicted grazing season length (months) for 32 European countries (source: Phelan et al., 2015).

including increasing grass utilisation, sward quality and simplifying grazing management. Late turnout to grass can lead to under-grazing of pastures for a variety of reasons, for example, excessively high pre-grazing herbage mass, low-grazing stocking rates or poor grass utilisation conditions. O'Donovan et al. (2004) found that early spring grazing can act as a sward conditioner, that is, avoids build-up of excessively high pre-grazing yield. They found high milk production from early grazed swards even with a low grass allowance compared to late-grazed swards, clearly showing the beneficial effects of early grazing on sward structure and quality. The early use of grass reduces the need for supplementary feed, making better use of home-grown feed. Early spring grazing reduces the large requirement for machinery, fuel and fertilisers, and facilitating less GHG production on farms.

O'Neill et al. (2011) and Robertson and Waghorn (2002) found that in early lactation pasture-fed cows produced less CH_4 emissions per day than cows offered a total mixed ration (TMR) diet. The higher DMI exhibited by TMR cows is likely to have caused the increased CH_4 emissions by these cows.

Increasing DMI increases CH_4 production as greater DMI provides a greater intake of fermentable substrate, including both structural and non-structural carbohydrates (Moe and Tyrrell, 1980). In addition, saliva is an important rumen buffer (Owens et al., 1998) and higher saliva production may give rise to increased rumen pH which would maintain favourable rumen fermentation conditions for fibre digestion and methanogenesis (Krause et al., 2002). Pinares-Patiño et al. (2007) found that in their study saliva production was positively correlated with higher daily CH_4 emissions and feed intake.

5 Grazing management to combat climate change: sward structure and quality

5.1 Sward structure characteristics

The presented herbage mass very much dictates the grazing intensity and level of DMI achieved by the grazing animal. Pre-grazing herbage mass also dictates the source from which the animal selects its diet (Wade, 1991). The presented herbage mass influences the sward characteristics presented to the grazing animal. Grazing animals prefer living to dead material, younger to older material, leaf to stem and legume leaves to grass leaves (Leaver, 1985). Michell and Fulkerson (1985) showed that pre-grazing herbage mass increased at the sward base in the latter part of the season, due to stem and dead material accumulation (Mayne et al., 1987). High levels of death and decay accompany poor herbage utilisation. Curran et al. (2010) agreed with those findings, and his work showed that high pre-grazing herbage mass swards had greater accumulations of dead material in the second half of the season due to a lax post-grazing height and low levels of grass utilisation. Korte et al. (1984) suggested that a high grazing intensity reduced the production and development of reproductive tillers. Fulkerson and Donaghy (2001) stated that severe defoliation removes too much water soluble carbohydrate (WSC) storage capacity and reduces regrowth, while under lax defoliation, the loss of DM through leaf senescence and reduced rates of tillering are not compensated for by the increased growth rate that results.

Criteria for determining when to defoliate pastures have been based on rotation length, sward height and pre-grazing herbage mass (HM) (Mayne et al., 2000). Pre-grazing herbage mass takes account of sward height and density, and is an animal sward interface indicator of when the sward is ready to graze. Previous studies by O'Donovan et al. (2004) and Kennedy et al. (2006) showed that high HM swards supported greater stocking rates; however, grazing low HM swards had a positive effect on herbage quality, milk production and grass DMI. Curran et al. (2010) found that low herbage mass swards supported high stocking rates due to a greater number of grazing rotations and improved sward quality due to intense grazing. O'Donovan et al. (2004) found that herbage from early grazed swards (February/March) was of higher quality (increased organic matter digestibility (OMD) and UFL value) relative to late grazed swards (April). This in part reflects seasonal trends in the accumulation of dead herbage. Wade (1991) found sward stem (true and pseudostem) as a barrier to increasing grass DMI, and this is true when cows are forced to graze to low post-grazing residuals. Sheath resistance increases in importance as a barrier to intake as pre-grazing herbage mass and pre-grazing height increase.

Wims et al. (2010) found that dairy cows grazing high pre-grazing herbage mass swards increased their CH_4 production per cow per day (+42 g), per kg of milk yield (+3.5 g/kg), per kg milk solids (+47 g/kg) and per kg grass DMI (+3.1 g/kg). The main difference in these swards was a 10-day difference in rotation length. In both early and late season measurements, Wims et al. (2010) found that cows grazing high HM swards lost a greater proportion of their gross energy intake as CH_4 during both measurement periods (+0.9% and +1% for summer and autumn, respectively). Wims et al. (2010) offered low HM swards to cows which maintained higher grass DMI and milk output; however, while no significant differences were found in CH_4 production, the conclusion was that grazing lower pre-grazing herbage mass swards tended to reduce CH_4 per unit of DMI (−8.2%) and energy corrected milk yield (−10%) compared to grazing high HM swards. Both these studies agreed that offering lower HM swards to grazing cows constituted a viable CH_4 mitigation strategy.

5.2 Maintaining sward quality

Ruminant CH_4 originates from the digestible fraction of the diet rather than the whole diet and fermentation of cell wall carbohydrates (NDF) produces more CH_4 than fermentation of soluble sugars (Moe and Tyrrell, 1980). Blaxter and Clapperton (1965) reported relationships between dietary factors and CH_4 emissions for indoor-fed animals. These authors stated that absolute emissions (g d^{-1}) and CH_4 yield (% of gross energy intake) increase and decrease, respectively, as feed intake increases above maintenance requirements, but both absolute CH_4 emissions and CH_4 yield decreases with increasing digestibility. Plant maturity is the most important factor affecting the morphology and forage quality. As maturity stage increases, the proportion of cell wall (neutral detergent fibre (NDF)) contents increases, whereas the proportion of cell contents decreases. The NDF contents are negatively correlated to rates of digestion and passage and herbage intake (fill effect).

Hammond et al. (2011) found 0.87 of the variation in total enteric CH_4 emissions of grazing sheep was predicted by OM intake, and the relationship between forage chemical composition and total CH_4 emissions and CH_4 yield (g/kg of DM intake) were weak. O'Neill et al. (2011) found that cows grazing a high-quality perennial ryegrass diet had lower CH_4 per unit of feed intake than cows that offered a TMR of lower digestibility. The effect of forage quality on CH_4 emissions most likely depends on the extent of contrast in forage quality between treatments in the completed studies.

Figure 3 shows the impact of grass quality on the actual post-grazing sward height achieved over two grazing seasons by dairy cows grazing sward plots. It is clear that grass varieties with greater grass quality values have subsequently lower post-grazing sward height, meaning improved grass utilisation. Since 2013, Ireland has introduced the Pasture Profit Index (McEvoy et al., 2011), and key traits of this index are seasonal DM yield, pasture quality, silage DM yield and persistency. New traits such as grazing utilisation will be introduced into this index in the next year.

5.3 Grass dry matter intake at pasture

Achieving high grass utilisation consistently takes a considerable amount of grazing management discipline, and its application can be poor on farms. Within the typical range of herbage allowance (HA) in grazing systems, herbage intake increases on average by 0.10–0.15 kg/kg HA at ground level and 0.20–0.25 kg/kg HA above 4–5 cm (Delagarde et al., 2011). This means that the marginal response of pasture utilisation rate when increasing HA is very small (15–25%). There is a consensus that increasing feed intake reduces CH_4 yield as g CH_4/kg DMI although its effect is larger with high- versus low-quality diets

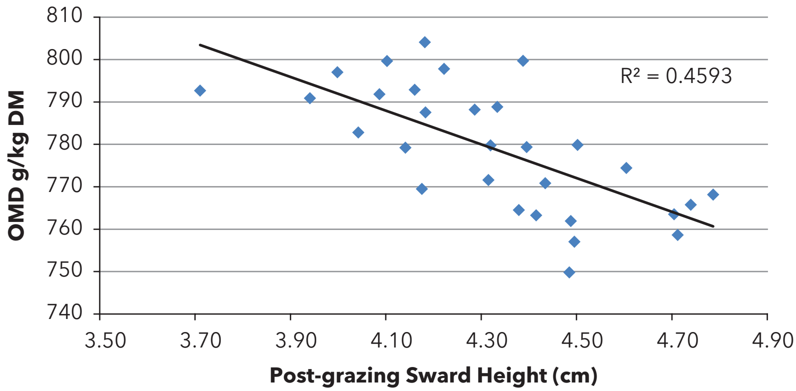

Figure 3 The effect of pasture quality (OMD) on post-grazing sward height over the grazing season (Tubritt, personal comm).

(Blaxter and Clapperton, 1965). Combined with good grassland management, allocating the correct daily HA and pre-grazing HM, CH_4 from grazing dairy cows can be reduced. It is important to maintain a high-quality diet, as possible, when grazing.

5.4 Grass clover swards with dairy cows

Higher animal performance from swards containing white clover can be expected because of its superior nutritional value compared to perennial ryegrass due to higher crude protein content (Butler, 2000), lower structural fibre values (Thomson, 1984) and higher OMD (Wilman and Riley, 1993). White clover is a potential option to reduce CH_4 emissions because of higher grass DMI and higher milk production (McClearn et al., 2019). Grass-white clover has lower aNDF and high voluntary DMI compared to grass-only (Ulyatt, 1970; Enriquez-Hilalgo et al., 2014). Lower aNDF concentration in white clover may lead to rapid ruminal degradation and passage rate, which should lower CH_4 yield as g CH_4/kg DMI.

A balance between the optimum sward white clover content for milk production and pasture production must be achieved to optimize both animal and pasture performance. Within the sward, white clover proportion changes seasonally; to achieve consistent clover content is a real challenge in grazing management. It is difficult to maintain optimum levels of white clover in the sward because of climatic factors (drought, waterlogging, colder soils), poor grazing managements, suboptimal soil fertility and pests. Dineen et al. (2018) completed a meta-analysis from a number of studies which had white clover included in the diet of grazing dairy cows. The mean sward white clover content was 31.6%, mean daily milk yield and milk solids yield per cow were increased by 1.4 kg and 0.12 kg, respectively, milk and milk solids yield were unaffected when cows grazed grass clover compared to grass-only swards.

McClearn et al. (2019) created swards with an average annual sward white clover content of 23.6% and 22.6% in tetraploid perennial ryegrass and white clover swards and diploid perennial ryegrass and white clover, respectively. Milk production did not differ between grass ploidies during a 4-year study, but cows grazing the perennial ryegrass-white clover treatments had significantly greater milk yield (+597 kg/cow per year) and milk solids yields (+48 kg/cow per year) compared with cows grazing the perennial ryegrass-only swards. Increased milk output has been associated with higher herbage nutritive value for perennial ryegrass-white clover swards, especially mid-season, compared to perennial ryegrass-only swards (Soegaard, 1993) and an increase in voluntary herbage DMI (Ribeiro Filho et al., 2005) with numerous studies having shown selective grazing of white clover over perennial ryegrass (Rutter et al., 2004). McClearn et al. (2019) found the difference in milk production from the perennial ryegrass-white clover swards was observed from May onwards in each year. This pattern was consistent with white clover content in the sward increasing as the season progressed and is similar to what Woodward et al. (2001) and Egan et al. (2018) reported. Andrews et al. (2007) suggested that sward-white clover content greater than 20% is required to establish an animal production response. Establishing such white clover proportions on farms will be and is a real challenge. Egan (personal comm) has shown high clover germination rates on farms but low establishment. He found that successful rates of establishment were only 60% across all farms, 12 months after over seeding. Direct reseeding perennial ryegrass-white clover swards is the only reliable way of establishing these swards on farms.

Methane emissions related to gross energy intake of animals-fed legumes are lower than animals-fed grasses (Beauchemin et al., 2008). Some previous research has shown that clover inclusion in pasture can reduce dairy cow CH_4 emissions and others have found no effects (van Dorland et al., 2007). Enriquez-Hilalgo et al. (2014) found that an average annual white clover content of 20% was not sufficient to improve overall sward production, quality or dairy cow productivity. The cows grazing the grass-white clover swards had a tendency to consume more and emitted less CH_4 than cows grazing the grass-only swards.

Structural carbohydrates are fermented at slower rates than non-structural carbohydrates such as starch and sugars to yield more CH_4/unit substrate fermented. Slower rumen fractional outflow rates and higher rumen volumes increase rate of CH_4 emission, most probably by allowing increased digestion of structural carbohydrates and providing a better environment for the growth of methanogens. The higher readily fermentable carbohydrate:structural carbohydrate ratio in white clover compared with perennial ryegrass may decrease the rumen acetate:propionate ratio, which is expected to lower CH_4 yield.

6 Grazing management to combat climate change: legume forages

Legume forages have a substantially higher nutritive value than grasses, biologically fix N and the condensed tannin (CT) containing legumes birdsfoot trefoil and sainfoin (*Onabrychis vicifolia* Scop.) and may have further advantages over non-tannin containing forages such as alfalfa. Sainfoin contains higher concentrations of condensed tannins (50–80 g/kg DM) compared to 5–47 g/kg DM for birdsfoot trefoil. Condensed tannins bind strongly to proteins and it has been proposed that some plants evolved CT production as a chemical defence, first against invasion by pathogenic microorganism, then against being eaten by insects and finally against being eaten by grazing herbivores. Originally it was thought that CT-containing forages were the Lotus species, sulla (*Heddysarium coronarium*) and sainfoin. Newer technologies have shown the presence of CT in grasses, legumes and herbs (Table 2).

Bloat is caused by very high solubility of forage proteins leading to the development of stable foam in the rumen, and it is prevalent in cattle and sheep-fed legumes. Because of their protein-precipitating properties, grazing CT-containing legumes has long been known to eliminate bloat. Recently it has been proposed that the plant CT concentration needed to make forage bloat safe was 5 g CT/kg DM or greater. Most common legumes and grasses used in temperate agriculture have CT concentrations well below this value (Table 2). It will be a challenge to raise CT levels through plant breeding, but it is on the agenda as a breeding goal of the major grass and legume breeding companies worldwide. In temperate systems the challenge will be to integrate such legumes consistently into a sward growth pattern.

Both chicory (*Cichorium intybus L.*) and plantain (Plantago lanceolata L.) are suitable herbs for inclusion into swards managed under intensive grazing because of their high yield potential and ability to maintain sward quality mid-season (Cranston et al., 2015). The use of multispecies swards containing chicory and plantain is of particular interest on sites which are prone to soil moisture deficits, because of their deeper root systems and greater drought tolerance (Lee et al., 2015). Swards containing chicory and plantain can support higher levels of animal performance particularly in summer and autumn because of its ability to maintain sward quality in comparison to grass-white clover swards (Cranston et al., 2015). Grazing management, such as rotation length and post-grazing sward height, affects the growth, persistence and nutritive value of swards containing chicory and plantain (Lee et al., 2015). Multispecies swards containing clover and herbs can persist under grazing for 3–5 years, but are

Table 2 The extractable and bound condensed tannin content of legumes, grasses and herbs fed to ruminants in temperate grazing systems, measured by the butanol-HCl method

Forage	Extractable	Condensed Protein-bound	Tannin (g/kg DM) Fibre-bound	Total
Legumes				
Big trefoil *(Lotus pedunculatus)*	61	14	1	77
Birdsfoot trefoil *(Lotus corniculatus)*	36	9	2	47
Sulla *(Hedysarum coronarium)*	33	9	3	45
Sainfoin *(Onabrychis vicfolia)*	29			
Red clover *(Trifolium pratense)*	0.4	0.6	0.7	1.7
Lucerne *(Medicago sativa)*	0.0	0.5	0.0	0.5
Grasses				
Perennial ryegrass (*Lolium perenne*)	0.8	0.5	0.5	1.8
Herbs				
Chicory (*Chicorium intybus*)	1.4	2.6	0.2	4.2
Sheep's burnet (*Sanguisorba minor*)	1.0	1.4	1.0	3.4

suited to a 3–4-week rotation length with lax grazing to 8 cm (Cranston et al., 2015). These grazing guidelines are very much in contrast with those necessary for modern perennial ryegrass varieties. Their role in more modern grazing systems is currently under evaluation in a number of countries.

7 Grazing management to combat climate change: measurement issues

7.1 CH_4 measurement at grazing

Respiration chambers (RC) have been considered the gold standard for measuring enteric CH_4 emissions from farm animals, but this is only the case if RC are operated properly and recoveries are fixed and preferably close to 100%. Animals in RC must have stable daily feed intake. Approximately 30% of today's CH_4 emissions are as a result of the previous day's DMI. Daily variation in DMI can cause variation in CH_4 emissions.

Compared to housed animals, grazing animals have higher energy requirements due to the added cost of walking and grazing. There is continual debate about measurement methods – the standard method for CH_4 measurement is open-circuit respiration calorimeter chambers – yet this bears no relation to the activity of the grazing animal, when grazing the animal selects their chosen herbage, is exposed to the variances in climate, and has to forage, this is the opposite to the behaviour in an enclosed chamber, where the diet selection is somewhat compromised and supply is regular. Data from chambers cannot be applied to all farm situations; this is why the SF_6 and Green Feed (GF) system need to be more widely used in grazing systems.

Variability with the SF_6 method has been notoriously high but modifications by Deighton et al. (2014) addressed the most important sources of error, and the modified technique produced CH_4 measurements with accuracy similar to measurements using RC. Some of the variation with SF_6 seems intrinsic to the technique because the estimated CH_4 emission rate appears sensitive to factors that affect the proportions of exhaled and eructated air in the air samples and distance of the sampling point from mouth to the mouth/nostrils (Berends et al., 2014). A recently introduced technique for direct measurement of enteric CH_4 emissions is the automated head chamber system, GF, which was developed for spot sampling for exhaled and eructated gases (Zimmerman and Zimmerman, 2012). When used properly with repeated animal measurements, GF can be a reliable technique for measuring enteric CH_4 emissions from ruminants. An important prerequisite for decreasing uncertainty of the measurement when using GF is that all animals visit the unit at times that enable estimation of the diurnal pattern of CH_4 emission over successive 24 h period. For accurate daily emissions estimates, animal visits need to be distributed appropriately over the 24-h feeding cycle and a number of repeated days of measurements are required for each animal. Both GF and SF_6 methods are established techniques, and they can provide accurate estimates of enteric CH_4 emissions when properly used and calibrated. Direct comparisons of both techniques have shown acceptable agreement (Grainger et al., 2007; Huhtanem et al., 2018), and both provide valuable data required for grazing systems.

7.2 Life cycle assessment (LCA) with pasture-based diets

Comparisons of results between life-cycle assessment (LCA) studies is difficult due to differences in computation of life cycle inventories and choice of functional unit (de Boer, 2003; Van der Werf et al., 2009). In many previous LCA studies of grass and confinement systems, CH_4 from enteric fermentation was identified as the main cause of on-farm GHG emission (Casey and Holden, 2005). O'Brien et al. (2012) found that GHG emissions from cultivation of purchased concentrate and forage, emissions associated with the manufacture of inputs, that is, fertiliser used in the production of on-farm forages, were the main contributors to off-farm GHG emissions. Off-farm GHG emissions from confinement systems were more than double the off-farm GHG emission from grass-based system in the O'Brien et al. (2012) study, because of the greater quantity of concentrate feed. Consequently, total GHG emission per unit of milk produced was greater for the confinement system relative to the grass-based system.

Grassland systems can be further improved with strategic use of concentrate feed. Cederberg and Mattison (2000) suggested that the environmental impact of concentrate feed could be reduced by using domestic or regionally produced rapeseed meal rather than imported soya bean meal. Concentrate impacts can be reduced further by lowering the crude protein levels in concentrate by more appropriate diet formulation, in line with the chemical value of the diet, for example, avoiding the use of higher concentrate feeds. This would in turn have positive impacts on reducing N losses and further enhance N-use efficiency. There is much more to be learned about grassland and its seasonal quality fluctuations if there is more emphasis on pasture quality assessment across the growing season.

8 Conclusion

The continual decline in the area of permanent grassland in Europe is not assisting farmers in developing better grassland management practise and many countries are growing their dependence on imported feed (both forage and concentrate). The focus on farm needs to be to optimise the level of home-grown feed in the ruminant's diet.

None of the aspects of grassland management solely will deliver key movements in reducing CH_4 emissions; however, some of the gains that can be made are interacting with one another. High-grazed grass utilisation systems can be effective in this role, not all countries can adapt totally to this system type, but at different stages in the growing season, grass can be capitalised upon. Table 3 shows the effects of new and improved innovation and applications to reduce CH_4 emissions. Some of the improvements are gradual, improvement in animal productivity (based on proper national breeding goals), adapting grassland management, using appropriate grass varieties and clovers. The key aspect of such changes is that they have to be established inside the farm gate, herein is a crucial challenge for the grassland/ruminant sectors. Using home-produced feed, much of the efficiency in CH_4 can be harnessed as set out at the start of this chapter. Diet manipulation through adopting different grazing strategies that improve the forage quality available to the herds is

Table 3 Summary of methane mitigation strategies for grazing animals

Strategy	Potential CH_4 reduction	Technology availability/ feasibility	Production cost benefits
Improving animal productivity	20–30%	Feasible and practical	Increased feed cost Increased milk production Use of fewer animals Less feed per kg of milk
Forage species and maturity	20–25%	Feasible	Increased feed efficiency Increased milk production
Rotational grazing of animals/early grazing	9% or more	Feasible	Increased feed intake Increased milk production
Managed grazing of animals versus confined feeding	25% or more	Feasible needs more investigation	Cheaper feed costs Supplement use Reduced milk fat/ protein content Higher net return
Use of high-quality forages/pastures	25% or more	Feasible	Increased feed intake Increased milk production
Genetic selection (use of high net feed efficiency animals)	21%	Long-term feasibility	Decreased feed intake Increased feed efficiency

Source: Boadi et al. (2004).

readily available to farmers; however, many times it is not clearly advocated by the wider industry. Including grass and legumes in the diet of the grazing ruminant does not require major investment, but an overall change in mind-set. It is clearly a CH_4 mitigation factor and is positively viewed by the wider consumer population.

9 Where to look for further information

While the number of organisations across the world and indeed in Europe completing grazing research combined with measurement of GHG emssions is relatively small, there is a recently assembled research infrastructure consortium in Europe called the Smartcow network (www. Smartcow.eu). Ireland (Teagasc), United Kingdom (SRUC and University of Reading), France (INRAE), Belgium (CRAW), Denmark (Aarhus University), Germany (FBN), the Netherlands (Wageningen University) and Spain (IRTA) are collaborating partners of the consortium, their objective to ensure a commonality in research approach, measurements and protocols in methane research and other research intiatives. This type of infrastructure model will become more important into the future as it will allow a more smooth comparison of research techniques across countries, and this is really important with the techniques involved in GHG measurement at grazing.

Chapter 9

The use of plant bioactive compounds to reduce greenhouse gas emissions from farmed ruminants

Cécile Martin, Vincent Niderkorn, Gaëlle Maxin, INRAE, France; Jessie Guyader, INRAE-ADM NEOVIA, France; and Maguy Eugène and Diego P. Morgavi, INRAE, France

1 Introduction

Livestock farming activities account for 14.5% of global greenhouse gas (GHG) emissions of anthropogenic origin (Gerber et al., 2013). Concerning the ruminant livestock sector, the largest contribution is from cattle and sheep mainly in the form of methane (CH_4) and nitrous oxide (N_2O) emissions, which represent, in carbon equivalent, 44% and 30% of GHG emissions, respectively. Methane has a digestive (enteric) origin in ruminants and is mostly eliminated into the atmosphere by eructation. During the microbial fermentation process of feeds in the rumen (bacteria, protozoa and fungi), hydrogen (H_2) is produced and is immediately used by archaea methanogens to reduce carbon dioxide into CH_4. Nitrous oxide is produced in the soil during microbial processes (nitrification and denitrification) of urinary nitrogen (N) (urea and ammonia) excreted by ruminants (De Klein and Eckard, 2008; Selbie et al., 2015). Both enteric CH_4 emissions and urinary N waste represent loss of dietary energy (2–15%) and N (75–95%) ingested, which could be otherwise available for animal production (Hristov et al., 2013b). Therefore, decreasing enteric CH_4 emissions and N excretion from ruminants is important for reducing the environmental impact of ruminant production and for improving feed efficiency and the sustainability of this sector.

Compounds produced by the secondary metabolic processes of plants have been used for medicinal purposes by humans since antiquity (Wink, 2015).

http://dx.doi.org/10.19103/AS.2020.0077.13

Research on the use of compounds in animal production increased when the use of antibiotics as growth promoters was banned in Europe and other parts of the world in the mid-2000s. The potential use of plant bioactive compounds in animal nutrition to reduce CH_4 emissions and N waste is the subject of renewed interest as they are seen as a natural alternative to chemical additives and are well perceived by consumers. Some plant compounds have marked biological activity and, depending on their concentration in ruminant diets, can have positive or negative effects on animal responses. Plant bioactive compounds are promoted as improving health (are antiparasitic, reduce bloating and are antioxidant) and performance (N use efficiency). Conversely, they can decrease intake and diet digestibility (Mueller-Harvey, 2006) and can be toxic to animals (Reed, 1995).

We reviewed the current information on the use of plant bioactive compounds in ruminant nutrition to promote livestock farming that is not only more environment-friendly and efficient in the use of feed but also compliant with consumer demands for quality and safety in animal products. We focussed on the potential of plant bioactive compounds to mitigate enteric CH_4 production in ruminants and, when information is available, N waste. The main families of compounds considered as plant lipids are secondary compounds that are tannins, saponins, halogenated compounds and essential oils. Priority was given to information from *in vivo* studies by exploring the ability of plant compounds to positively modulate not only ruminant responses but also their mechanisms of action and utilization on farms. We selected two case studies showing the value of growing and using sainfoin forage in ruminant diets to decrease GHG emissions at the farm scale and combining dietary strategies with different modes of action to increase enteric CH_4 abatement. Future research on the use of plant bioactive compounds to reduce GHG emissions from farmed ruminants is also considered.

2 Families of plant bioactive compounds

2.1 Lipids

Lipids have a high nutritional value. The primary reason to use lipids in the diet of ruminants was to increase the potential production of animals and to improve the quality of meat and dairy products in terms of fat content and composition. However, an excessive dietary fat supplementation (> 7% dry matter [DM]) can affect microbial fermentation and fibre digestion in the rumen (Palmquist and Jenkins, 2017). The variable effects of lipids on ruminal fermentation are usually attributed to differences in their lipid structure (Bayat et al., 2018; Vargas et al., 2020). One factor is their degree of unsaturation because unsaturated fatty acids (from oleaginous oils or seeds and by-products such as residues from food processing plants) inhibit fermentation more than saturated fatty acids.

Commercial inert lipids (e.g. calcium salts of saturated fatty acids) are rumen bypass fats, which do not affect fibre digestion in the rumen at normal levels of supplementation in the diet.

Lipids are a proven dietary strategy for reducing CH_4 emissions from ruminants whose effectiveness depends on many factors, such as the dose, the source and the mode of distribution (Martin et al., 2010; Beauchemin et al., 2020).

Meta-analyses agree that the CH_4-mitigating effect of lipids are dose-dependent (Giger-Reverdin et al., 2003; Eugène et al., 2008; Grainger and Beauchemin, 2011; Doreau et al., 2011); the decrease in CH_4 emissions (g/kg DM intake [DMI]) varies between 1% and 7% per 10 g/kg of fat added DM in the diet. For low doses of added dietary lipids (< 2% DM), the mitigating effect was not systematic in cattle (Chung et al., 2011; Veneman et al., 2015). For high doses of added dietary lipids, the decrease is linear in cattle with rapeseed oil (0%, 5.4% and 9.5% added lipids; Jentsch et al., 1972) and coconut oil (0%, 1.3%, 2.7% and 3.3% added lipids; Hollmann et al., 2012) or quadratic in sheep with coconut oil (0%, 3.5% and 7% added lipids; Machmüller and Kreuzer, 1999). In dairy cows, many trials have shown the decreasing effect of lipids on methanogenesis (Martin et al., 2016; Bayat et al., 2018; van Gastelen et al., 2017) with different forage-based diets. The dose-response effect of extruded linseed (0%, 1.8%, 3.6% and 5.4% added lipids) on CH_4 emissions was more substantial with a corn silage-based diet compared to a hay-based diet (Martin et al., 2016). This more marked effect on methanogenesis was related to the adverse effects of lipids on animal performance (intake, digestibility and milk yield) with high doses of lipid supplementation.

The form of presentation of lipids also greatly influenced CH_4 output from dairy cows: inhibition of methanogenesis increased with the theoretical availability of linseed lipids in the rumen (oil > extruded seed > whole seed) (Martin et al., 2008). In practical conditions, extruded linseed is the most used form, because it is more readily available, easy to use, and less costly than oil and more efficient than crude linseed.

Concerning the source of lipids, conclusions of meta-analyses are not consensual: Grainger and Beauchemin (2011) did not find an effect of the source of lipids on CH_4 emissions, whereas medium chain and polyunsaturated fatty acids were reported to be more potent than others, according to the study of Doreau et al. (2011). In addition, the CH_4-mitigating effect of extruded linseed (2–3% added lipids) persisted for up to 1 year in dairy cows fed diets based on grazed pasture (80%) or grass silage (60%) (Martin et al., 2011). The persistency of this effect is very important for practical use.

The modes of action of lipids in the mitigation of ruminal methanogenesis are multiple (Martin et al., 2010). A common effect for all lipids is that when carbohydrates are substituted by lipids, as lipids are not fermented in the rumen, they do not contribute to H_2 production, unlike the carbohydrates they replace. Moreover, lipids have a toxic effect on some microbial populations (Popova et al., 2011; Vargas et al., 2020), more particularly on H_2-producing microbes (cellulolytic bacteria and protozoa), and reduce the metabolic activity of archaea methanogens by limiting H_2 availability and consequently CH_4 production. Ruminal biohydrogenation of unsaturated lipids may also help decrease methanogenesis, but the H_2 sink function of this biohydrogenation process was estimated to be negligible (i.e. 1–2%) based on stoichiometric (Czerkawski, 1986) and modelling (Mills et al., 2001; Giger-Reverdin et al., 2003) approaches.

Adding fat supplements in a proper dose to ruminant diets is a real opportunity to persistently reduce enteric CH_4 emissions without altering animal performance. This dietary strategy can be immediately implemented on commercial farms, especially if the quality of the meat and milk produced is improved, as is the case with unsaturated lipid sources. Most of the time, lipids are added in mixed diets as oil, oilseeds or food by-products, which limits their utilization for grazing ruminants. Notwithstanding, the use of lipids as feed ingredients in ruminant diets is relatively costly; if they are not locally produced, they may have a higher carbon footprint, which should be considered before adopting this approach. The combination of lipids with other dietary strategies has the potential to further reduce enteric CH_4 emissions (see Section 3).

2.2 Secondary compounds

2.2.1 Tannins

Among the polyphenolic compounds, special emphasis has been placed on the effects of tannins as they may act at several levels to reduce GHG emissions from ruminants.

First, the well-known ability of tannins to bind dietary proteins and reduce rumen proteolysis results in an increase of N duodenal flow and a shift from urinary to faecal N excretion (Aufrère et al., 2008; Theodoridou et al., 2010). As urinary N deposition results in N_2O emissions that are much higher than those arising from faecal N deposition (Luo and Kelliher, 2010), incorporating tannins in ruminant diets has great potential to decrease these emissions. In addition, a direct application of tannin extract (rather than feeding it) to barns reduces urease activity, thereby decreasing ammonia loss from dairy barn floors (Powell et al., 2011). Finally, if tannins are from forage legume species, such as sainfoin (*Onobrychis viciifolia*), birdsfoot trefoil (*Lotus corniculatus*) or sulla (*Hedysarum coronarium*), their ability to fix and transfer atmospheric N into the soil reduces the use of N fertilizers, which are a source of N_2O emissions through microbial nitrification and denitrification processes (Bouwman, 1996).

Second, abundant literature reports show that tannins in ruminant diets decrease enteric CH_4 emissions (review of Piluzza et al., 2014). The effect of these molecules on methanogenesis is highly variable between studies according to their nature (condensed or hydrolyzable), their chemical structure (molecular weight), especially the dose ingested by the animal, and the form of presentation. Given the extremely diverse structure of tannins in the plant kingdom, efforts have recently been made to understand their structure/activity relationships to facilitate their applicability (Mueller-Harvey et al., 2019). This aim was achieved, thanks to remarkable progress in the chemical analysis of both condensed (Zeller, 2019) and hydrolyzable tannins (Engström et al., 2019).

Using purified hydrolyzable (from chestnut and sumach) and condensed tannins (from mimosa and quebracho), Jayanegara et al. (2015) showed *in vitro* that hydrolyzable tannins have a greater effect in reducing CH_4 emissions with a less detrimental effect on digestibility than condensed tannins. Rira et al. (2019) reported the same conclusion with tropical forages tested *in vitro*: hydrolysable tannin-rich sources (*Acacia nilotica*) were more effective in supressing methanogenesis than condensed tannins-rich sources (*Calliandra calothryrsus* and *Leucaena leucocephala*). In addition, a combination of these plants did not highlight synergies between these two types of tannins. The type of molecular interaction that drives the protein-binding capacity of tannins is highly related to the structure of both tannins and proteins. Protein precipitation increases consistently with the mean degree of polymerization and tends to be higher with prodelphinidin-rich condensed tannins due to a greater number of potential hydrogen-bond participants available to interact with proteins (Zeller, 2019). The ability of hydrolyzable tannins to form insoluble complexes with the protein seems to be related not only to their molecular weight (oligomers are superior to monomers) but also to the type and number of functional groups (e.g. galloyl groups) in monomers (Engström et al., 2019).

Using purified condensed tannins of different structures from eight plants, Huyen et al. (2016b) showed *in vitro* that the proportion of prodelphinidins in condensed tannins had the largest effect on CH_4 production and fermentation characteristics, followed by the average polymer size. Other *in vitro* studies have shown that condensed tannins with a high degree of polymerization are more potent in lowering CH_4 production and the diversity and abundance of rumen methanogens (Hatew et al., 2016; Saminathan et al., 2016). Similarly, Baert et al. (2016) investigated *in vitro* how the degree of oligomerization of purified ellagitannins, an important family of hydrolyzable tannins, can influence their ability to alter ruminal fermentation including CH_4 production. They showed that large oligomers have more detrimental effects on gas production and volatile fatty acids (VFA) than small oligomers, while being similarly effective in their ability to decrease CH_4 production.

The meta-analysis conducted by Jayanegara et al. (2012), including data from a total of 30 experiments (both *in vitro* and *in vivo*), helped to partly clarify the underlying mode of action of tannins on methanogenesis. These authors reported that related CH_4 reduction is associated with reduced OM digestibility, especially fibre, because of a decreased number/activity or impaired substrate adhesion of fibrolytic microbes. This inhibitor effect of tannins on fibrolysis was more marked for condensed tannins than for hydrolysable tannins in dairy ewes (Buccioni et al., 2015). Recently, Costa et al. (2018) reported in sheep that gram-positive specialized fibrolytic bacteria (*R. albus, R. flavefaciens* and *B. proteoclasticus*) were more affected by condensed tannins than gram-negative bacteria (*F. succinogenes*, *S. ruminantium* and *P. bryantii*), with a decrease in rumen volatile fatty acids concentration, mostly acetate.

Methane emissions also declined when expressed per kg of digested organic matter (DOM), suggesting that other mechanisms account for the anti-methanogenic activity of tannins (Jayanegara et al., 2012). Tannins have been shown to directly inhibit H_2 using methanogens in the rumen of sheep (Liu et al., 2011) and beef cattle (Yang et al., 2017). This direct effect of tannins on methanogens microbiota, without affecting fibre digestion, would be more specific to hydrolysable tannins as reviewed by Vasta et al. (2019).

The potential of tannins to reduce methanogenesis has been widely reviewed in both *in vitro* and *in vivo* studies, thus highlighting the large variability of data (reviews of Piluzza et al., 2014 and Vasta et al., 2019). Archimède et al. (2016) observed a linear relationship between the condensed tannins content of three tropical-rich plants (*Glyricidia sepium, Leucaena leucocephala and Manihot esculenta*) and CH_4 reduction *in vivo*. The potential of mitigation ranged between 13% and 36% in sheep fed a forage diet containing between 1.5% and 4.0% DM of condensed tannins. The authors also reported better palatability (and intake) of tannin-rich tropical plants and a strong decrease in CH_4 emissions in animals fed the plants as pellets. Concerning hydrolysable tannins, their potential of mitigation ranged between 10% and 25% with sheep (Liu et al., 2011) and 11–30% with beef cattle (Yang et al., 2017) fed diets containing 1–3% DM of tannins from chestnut and pure hydrolysable tannins, respectively.

Few general equations of CH_4 prediction concerning tannins, mostly derived from *in vitro* trials, are available because of the diversity of the chemical analysis methods and the types of tannins (Jayanegara et al., 2012). We conducted a quantitative review of the literature by meta-analysis to assess the specific effect of tannins (condensed or hydrolyzable) on *in vivo* CH_4 emissions in ruminants (Eugène et al., 2019). Using an existing database (Methafour, INRA, 2018) on the effect of forages fed to ruminants on CH_4 emissions, we were able to significantly improve the accuracy of Eq. [1] based on the animal-feeding level and forage diet composition to predict CH_4 emissions, by taking into account the tannin content of the forage diets as mentioned in Eq. [2]:

- Eq. [1] for forage diets

$$CH_4 / DOM = 34.95 - 4.05FL + 0.027NDF - 0.010DOM$$
$$(n = 412, nexp = 153, RMSE = 3.1)$$

- Eq. [2] for forage diets containing tannins

$$CH_4 / DOM = 34.26 - 3.96FL + 0.027NDF - 0.008DOM - 1.72Log_{10}(1 + TAN)$$
$$(n = 398, nexp = 147, RMSE = 3.1)$$

where CH_4/DOM is the CH_4 production (g/kg DOM), FL is the feeding level (kg DM intake, % liveweight), NDF is the NDF content (g/kg DM), DOM is the DOM content (g/kg DM) and TAN is the tannin content (g/kg DM) of the diet, which is transformed on a logarithmic basis to account for its largely abnormal distribution (Sauvant et al., 2018).

The coefficients of regression of all variables remain stable between Eq. [1] and Eq. [2], highlighting the specific effect of tannins on methanogenesis. Based on current scientific knowledge, we propose to use the coefficient of TAN in Eq. [2] to evaluate the average quantitative effect of tannins *in vivo* on CH_4 emissions in all types of diets (Fig. 1). Our results confirm that CH_4 mitigation increases with the dose of tannins in the diets (Jayanegara et al.,

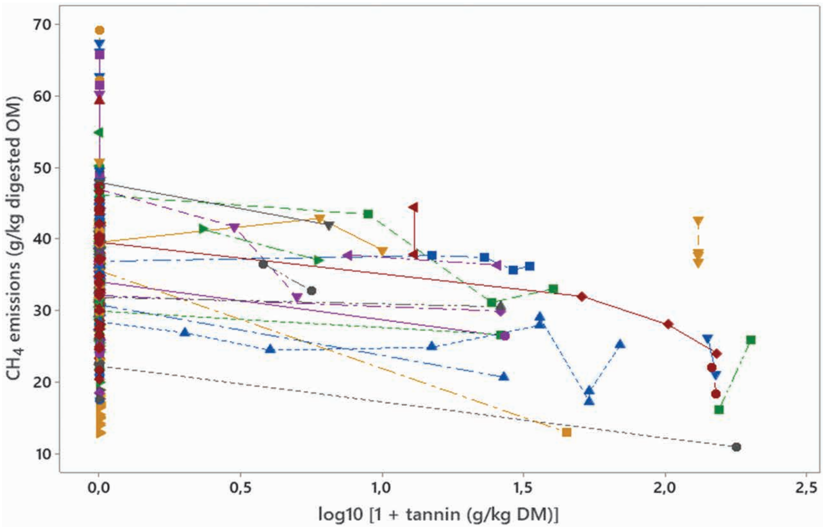

Figure 1 Relationship between methane emissions (g/kg DOM) and tannin content (g/kg DM) in the diet.

2012). Unfortunately it is not possible to give a minimum threshold of tannins content to observe an effect on methanogenesis because it is modulated by the FL, NDF and DOM contents of the diet.

Tannins are consumed by animals as plants or added as an extract to rations. The use of fodder-containing tannins is particularly relevant for grazing ruminants since many forage legumes are rich in tannins. New insights into the chemical structure of tannins help to explain the inconsistencies of the effects on protein-binding ability and on CH_4 emissions reported in the literature. Despite this progress, there are still questions to address concerning the use of tannin-rich resources on farms. Considering the variability in tannin activity, one solution could be the production of batches of feeds or plant extracts analysed before their marketing. Also, in the context of agro-ecological ruminant production systems, the use of integrated solutions such as tannin-containing legumes offers opportunities to act at multiple levels of GHG production (see Section 3).

2.2.2 Saponins

Saponins are secondary metabolites present in seeds, leaves and roots of a broad variety of plants. They are usually classified into two major classes, triterpenoids (soy, pea, garlic, sunflower and panama bark) and steroid glycosides (e.g. oat, eggplant, tomato, yucca and fenugreek), but Vincken et al. (2007) refined their classification in 11 main categories based on their carbon skeleton. Despite some negative effects upon feeding in animal nutrition (increased membrane permeability of erythrocytes and enterocytes, or impaired animal production and reproduction; reviews of Addisu and Assefa, 2016; Francis et al., 2007), saponins can have beneficial effects on rumen fermentation and animal health when used in a proper dosage. Among others, saponins can decrease *in vivo* degradability of feed protein, avoid N accumulation and increase efficiency of microbial protein synthesis in the rumen (Francis et al., 2007; Patra and Saxena, 2009). In addition, saponins from *Quillaja saponaria* (known as quillaja saponins), *Yucca schidigera* (known as yucca saponins) and *Camellia sinensis* or *assamica* (known as tea saponins) have been extensively studied for their mitigating effect on rumen methanogenesis. Other saponin sources have shown interesting CH_4-mitigating impacts: mangosteen peel powder (Wanapat et al., 2014) and alfalfa saponins (Klita et al., 1996), but these effects need to be confirmed.

The underlying mechanism mainly involves an inhibitory effect towards rumen microbes and more particularly protozoa, which produce large amounts of H_2 and are known to live in symbiosis with methanogenic archaea (Guyader et al., 2014; Morgavi et al., 2010). The membrane-disrupting activity of saponins would explain their toxic effect on protozoa through the formation of complexes with sterols present in the protozoal cell wall, thereby inducing cell lysis (Morgavi et al., 2010).

The CH_4 mitigation potential of saponins depends on the dose and source of saponins (Patra and Saxena, 2010). Most studies on this subject have been conducted *in vitro*. In a meta-analysis combining 23 studies, Jayanegara et al. (2014) reported a linear inhibiting dose-response effect of saponins towards methanogenesis (tested dosage between 0% and 0.6% DM). Compared with quillaja and tea saponins, yucca saponins induced the greatest reduction in CH_4 expressed as mL per unit of incubated substrate. However, when expressed as a percentage of total gas produced, all tested saponin sources were statistically similar and produced less CH_4 than the control. However, *in vivo* results are not as clear. Using up to 1.4% DM of quillaja saponins in the diet, Pen et al. (2007) and Holtshausen et al. (2009) did not observe a difference in CH_4 emissions of sheep and dairy cows, respectively. Patra and Saxena (2009) summarized published papers studying the *in vivo* effect of saponins, including yucca saponins, on fermentation parameters. Only two articles out of five showed a significant reduction (−14% in Santoso et al., 2004; −7% in Wang et al., 2009) in methanogenesis with sheep fed a diet containing 1.3% DM of yucca saponins. Similarly, the effect of tea saponins seems to be highly variable. With similar dosages comprising between 0.4% and 0.8% DM, three articles reported a decrease in CH_4 yield (g/kg DMI) on adult sheep (−17% in Yuan et al., 2007; −26% in Zhou et al., 2011) and on lambs (−69% in Mao et al., 2010). More recent papers showed an absence of effect on steers (Li and Powers, 2012) and non-lactating cows (Guyader et al., 2015), or even an increase in CH_4 emissions on lactating dairy cows (+18% in Guyader et al., 2017) with the same dosages. Concerning the effect of tea saponins on other digestion parameters, data are scarce but mostly indicate an absence of effect on nutrient digestibility or N balance. However, milk yield in dairy cows (Guyader et al., 2017) and average daily weight gain in growing steers (Li and Powers, 2012) decreased (−18% and −80%, respectively) as a consequence of lower intake in both studies (−12% and −27%, respectively). However, 0.4% tea saponin in a Chinese wild rye-based diet did not affect feed intake or growth of lambs (Mao et al., 2010).

Four main reasons might explain the variable effect of saponins on methanogenesis and limit their utilization in animal nutrition. The quality of saponins is an important criterion for their CH_4-mitigating efficiency (Jayanegara et al., 2014). Plant maturity, geographical area of production and extraction methods are three parameters affecting the final concentration and quality of saponins (Li and Powers, 2012). Denaturation of saponins might also be possible during pelleting processes. Indeed, a modification of the miscellaneous structure of quillaja saponins was observed after heating from 20°C to 60°C (Mitra and Dungan, 1997). Guyader et al. (2015) assumed that denaturation was one possible explanation for the lack of effect on CH_4 production of tea saponins fed to non-lactating dairy cows.

The transient effect of saponins on rumen microbes is another limitation for their utilization. After adaptation, rumen bacteria are able to separate the active compound of saponins (sapogenin) from the sugar moiety, leading to their inactivation (Ramos-Morales et al., 2017). Newbold et al. (1997) supplemented sheep with saponins from foliage of an African multipurpose tree, *Sesbania sesban*. Protozoa concentrations dropped by 60% after 4 days, but the population recovered after 10 days. However, the time for adaptation of rumen microbes seems to be dependent upon the source of saponins: the anti-protozoal effect of saponins from *Sapindus rarak* was persistent over 105 days in sheep (Wina et al., 2006). The chemical modification of their structure to avoid microbiota adaptation may maximize the CH_4-mitigating potential of saponins (Ramos-Morales et al., 2017).

The CH_4-mitigating response seems to be dependent on the composition of the basal diet. For instance, in a study with young Holstein males, Wang et al. (2019) concluded that changes in the ruminal microbial community with tea saponin supplementation were different between alfalfa-, hay- or soybean hull-based diets. Given that the protozoal community is strongly affected by the basal diet, Patra and Saxena (2009) assumed that the diet-dependent effect of saponins is related to their selectivity for specific protozoal species.

Finally, the last challenge in saponin utilization is their impact on feed intake. Reduced intake has been reported following dietary supplementation with tea saponins in lactating dairy cows (Guyader et al., 2017) and steers (Li and Powers, 2012). Nevertheless, this drawback is not systematic: among the 43 papers compiled by Patra and Saxena (2009), who did not include recent articles on tea saponins, only two reported a decrease in feed intake with yucca saponin supplementation.

The effects of saponin supplementation in the diets of ruminants are highly contrasted. The conditions in which yucca, quillaja and tea saponins reduce CH_4 emissions from ruminants must be refined (optimal dose, long-term persistency). In addition, given the wide variety of saponin structures, screening of other plants might highlight the beneficial effect of new sources available for localized markets. Before adoption by farmers, the potential effects of saponins on digestion efficiency and zootechnical performance should also be investigated in depth.

2.2.3 Halogenated compounds

Halogenated products (e.g. bromoform, dibromomethane, dichloromethane, bromochloroacetic acid, etc.) exist naturally in seaweed at different concentrations, and much more in red and brown algae than in green ones.

These compounds may be produced as defense against disease and marine herbivores, anti-oxidants or by-products of metabolic processes (Keng et al., 2020).

Different macroalgae have been shown to decrease *in vitro* CH_4 production effectively (Dubois et al., 2013; Machado et al., 2014; Kinley and Fredeen, 2015). Among 20 tropical species screened, the red macroalgae, *Asparagopsis taxiformis*, was identified as the most efficient (Machado et al., 2014). Low doses (2% OM incubated) of *A. taxiformis* almost eliminated *in vitro* CH_4 production (Machado et al., 2016a), without any effect on forage digestibility (Kinley et al., 2016) and without compromising other fermentation parameters at a 5% OM supplementation rate (Roque et al., 2019a).

The CH_4-mitigating effect of red seaweed *Asparagopsis* spp. *(A. taxiformis and A. armata)* was recently confirmed in three *in vivo* trials. Li et al. (2016) reported a consistent (over a 72-day period) and dose-dependent reduction in CH_4 emissions (−50% to −80%) when adding *A. taxiformis* at 1–3% of diet OM, respectively. In dairy cows, adding *A. armata* at 0.5% and 1% of diet OM reduced CH_4 emissions (−26% and −67%, respectively) over 21 days while compromising animal performances (milk yield and intake) only at the high dose (Roque et al., 2019a). A recent experiment in feedlot beef cattle, *A. taxiformis* was tested in a high grain diet at three inclusion levels (0.05%, 0.10% and 0.20% of diet OM) over a 90-day period (Kinley et al., 2020). Steers receiving 0.10% and 0.20% *A. taxiformis* demonstrated decreased CH_4 emissions up to −40% and −98% and demonstrated weight gain improvements of +53% and +42%, respectively. There was no negative effect on daily feed intake, feed conversion efficiencies or rumen function, and no residues or changes in meat-eating quality were detected.

Bromoform is the most abundant natural product in *Asparagopsis taxiformis* and thus has been identified as the compound involved in CH_4 reduction, even if a combination of the different compounds may play a role in this reduction (Machado et al., 2016b). Halogenated compounds in *Asparagopsis taxiformis* appear to act as structural analogues of coenzyme M and thus inhibit the final step of the methanogenesis pathway (Liu et al., 2011). It has been shown that the decrease in abundance of methanogens in the rumen was positively correlated with the decrease of methanogenesis and increase in H_2 emissions (Machado et al., 2018; Roque et al., 2019a). Emissions of bromoform into the atmosphere may occur during the growth of seaweed or during desiccation processes (Keng et al., 2020), which would prevent – or at least greatly hamper – the farming of red seaweed on a commercial basis.

Macroalgae have a tremendous potential to inhibit methanogenesis in ruminants at low doses of supplementation. *Asparagopsis* spp. are the most effective species. Further investigations are required to confirm a long-term persistency effect on methanogenesis and long-term safety in animal responses before adoption by farmers. In addition, widespread use of red seaweed for animal nutrition raises concerns about their contribution to biogenic halocarbon emissions and their impact on the environment (i.e. ozone depletion related to bromoform). The carbon footprint of each step of algae production (harvesting, drying process, delivery, etc.) also needs to be considered for upstream emissions.

2.2.4 Essential oils

In addition to the compounds considered in previous sections, there are other plant bioactive compounds, collectively known as 'essential oils', that have the potential to mitigate CH_4 and ammonia production in ruminants (Cobellis et al., 2016). The name essential oil is not specific; it mainly comprises a diverse group of terpene and phenylpropene compounds as well as organo-sulphur compounds (Benchaar and Greathead, 2011). There are thousands of compounds that are qualified as essential oils, and many of them have been tested *in vitro* (reviewed by Calsamiglia et al., 2007; Hart et al., 2008; Benchaar and Greathead, 2011; Cobellis et al., 2016). However, for multiple reasons only a handful of these compounds have been pursued in animal studies. Many of the compounds tested decreased methanogenesis through a general reduction in feed degradation and fermentation in the rumen and, therefore, are not further considered in this chapter. The effect of some compounds was observed at high doses not compatible with their incorporation (as an extract or as the plant containing the active component) in the diet. In addition, for some compounds or plants, there are issues of toxicity, palatability, cost and availability that preclude their utilization even for experimental purposes. Further, the majority of *in vivo* studies have tested the effects of essential oils on general production parameters and only a handful of them included measurements of enteric CH_4 emissions (Cobellis et al., 2016). In this section, we will focus on those plant secondary compounds that were tested *in vivo* for their anti-methanogenic activity.

Most metabolites tested to reduce CH_4 production in ruminants are naturally produced by plants to fend off microbial invasion. Compounds that are effective *in vitro*, such as eugenol, which is abundant in the essential oil of clove, and cinnamaldehyde, which is abundant in cinnamon (Macheboeuf et al., 2008; Patra and Yu, 2012), did not reduce CH_4 emissions when tested on dairy cows (Benchaar, 2015; Benchaar et al., 2015). Carvacrol is a monoterpene with a phenol ring structure that is abundant in oregano and thyme. Oregano (*Origanum vulgare*) leaves fed to lactating dairy cows at doses of 250, 500 or 750 g/d decreased CH_4 production by up to −40% for the medium dose (Tekippe et al., 2011; Hristov et al., 2013a). But the CH_4 measurements were done up to 8 h after feeding, and the authors noted that 24-h continuous measurement is needed to validate the results. In another study on dairy cows, the use of oregano extract mixed into the diet at 0.056% DM tended to reduce CH_4 yield (g/kg DMI) by −22% (Kolling et al., 2018).

Flavonoids are a class of plant secondary compounds that have antimicrobial, anti-inflammatory and anti-oxidative functions. These compounds have been extensively studied in animal nutrition (Olagaray and Bradford, 2019). In studies with ruminants, supplementation of diets with flavonoids from mulberry decreased CH_4 yield (g/kg DMI) by −11% in sheep (Ma et al., 2017). The main flavonoids of mulberry are quercetin glycosides and rutin, a glucorhamnoside of quercetin (Ju et al., 2018). In contrast, the use of pure rutin or rutin contained in buckwheat seeds did not have any effect on CH_4 emissions in dairy cows (Stoldt et al., 2016). Catechins, flavonoids contained in green tea leaves, decreased CH_4 emissions (g/kg digestible DMI) in dairy cows by −18% (Kolling et al., 2018). Green tea also contains saponins that may have a synergistic effect in reducing CH_4. Notwithstanding, a commercial purified catechin extract linearly decreased CH_4 emissions in sheep by 7–13% (Aemiro et al., 2016). Catechins have known antimicrobial activities including a toxic effect on protozoa (Aemiro et al., 2016), but they are also known H_2 sinks that can compete with CH_4 production in the rumen environment (Becker et al., 2014). For flavonoids, in general, it is noted that those that have anti-inflammatory functions in the host animal are not effective in reducing CH_4 emissions or modulating microbial fermentation in the rumen (Olagaray and Bradford, 2019).

Sinigrin is a glucosinolate found in some plants of the Brassicaceae family, such as black mustard and horseradish, which is naturally converted to allyl isothiocyanate when the plants are processed (Mohammed et al., 2004). The latter compound is responsible for the strong flavour of horseradish and low palatability if used as a feed additive (Mohammed et al., 2004). A coated additive would avoid the problem of palatability and provide a gradual release of the sinigrin. A cyclodextrin-coated horseradish oil added to the diet of steers decreased CH_4 emissions by −19%. Although the mechanism of action is not well understood, the number of methanogens also decreased significantly. A parallel *in vitro* study showed a large increase in H_2 associated with CH_4 reduction (Mohammed et al., 2004), similar to that observed with specific inhibitors of methanogens or methanogenesis, such as garlic or halogenated compounds.

A particular mention is made for organo-sulphur compounds from garlic (*Allium sativum*). Sulphur compounds in garlic have both general antimicrobial properties and are specific inhibitors of the enzyme hydroxymethylglutaryl-CoA (HMG-S-CoA) reductase, which is essential for the production of the cell wall of archaea methanogens. These compounds remarkably reduce CH_4 production *in vitro* (reviewed by Hart et al., 2008; Benchaar and Greathead, 2011). However, there are few reports describing the *in vivo* use of garlic oil or diallyl disulphide, the main component of garlic oil. A decrease of about

−8% (g CH_4/kg digestible OM intake) was reported in sheep supplemented with garlic extract (Ma et al., 2016), whereas garlic leaves, which are normally discarded after harvesting the bulbs, reduced emissions by −10% (g CH_4/kg DMI) in sheep (Panthee et al., 2017).

Garlic oil combined with linseed oil reduced emissions in lambs, but the effect cannot be ascribed solely to garlic oil (Saro et al., 2018). Similarly, dried garlic combined with mangosteen peel rich in tannins and saponins reduced CH_4 emissions in cattle (Manasri et al., 2012), but the effect is confounded. In contrast, no effect was observed in a study with diallyl disulphide, garlic oil or raw garlic (Klevenhusen et al., 2011; Patra et al., 2011). More recently, a commercial mixture of garlic and citrus extracts (Mootral) was tested in dairy cows with positive results (Roque et al., 2019b; Vrancken et al., 2019). These results are encouraging but should be confirmed with further studies. For instance, in the work of Roque et al (2019b) the reduction in CH_4 was observed in the last week of the 12-week study, but not before. In addition to the product mentioned previously, there are several commercial products based on mixtures of essential oils that have been tested for their CH_4-reducing activity. The most tested are CRINA Ruminants (DSM; mixture of essential oil components) and Agolin Ruminant (Agolin; mixture of coriander oil, eugenol, geranyl acetate and geraniol, among others) and XTRACT Ruminant (Pancosma; mixture of cinnamon, cloves and capsicum oleoresin from chili peppers). The first product showed no effect on CH_4 emissions in beef cattle (Beauchemin and McGinn, 2006; Tomkins et al., 2015). The effect of Agolin Ruminant on dairy cows was recently evaluated in a meta-analysis (Belanche et al., 2020). A total of 23 *in vivo* experiments and on-farm studies were identified in which the additive was supplemented at 1 g/d/cow. Of these, nine had records of enteric CH_4 that showed an average decrease of −8.8% in CH_4 production (g/d), of −12.9% in CH_4 yield (g/kg DMI) and −9.9% in CH_4 intensity (g/kg milk) without a negative effect on feed digestibility or milk yield. The effects were observed only after an initial period of adaptation of at least 4 weeks.

Anacardic acid is an akylphenolic compound that is found in the shell of the cashew nut. It has antimic activity, particularly against gram-positive bacteria. In the rumen, it decreased the numbers of H_2- and formate-producing bacteria such as *Ruminococcus flavefaciens*, *Butyrivibrio fibrisolvens* and *Treponema bryantii*, whereas succinate-producing bacteria such as *Prevotella* spp., *Selenomonas ruminantium*, *Anaerovibrio lipolytica* and *Succinivibrio dextrinosolvens* increased (Shinkai et al., 2012; Konda et al., 2019). Methanogen numbers also decrease with changes in the community composition (Shinkai et al., 2012; Kang et al., 2018). The use of cashew nut shell liquid (CNSL) as a feed additive reduced CH_4 emissions in Holstein cows by −19% and −38% in a dose-dependent manner (Shinkai et al., 2012). The anti-methanogenic effect of CNSL was also observed in Thai native cattle and buffaloes (Konda et al., 2019). These changes in CH_4 were observed along with increases in propionate and decreases in acetate in the rumen. The technical grade CNSL (t-CNSL) is the main by-product of the cashew industry that does not contain anacardic acid, as during the production process it is converted into cardanol. The utilization of t-CNSL was not as effective at reducing enteric CH_4 emissions in dairy cows (Branco et al., 2015), suggesting that anacardic acid is the main active component in CNSL.

Essential oils used to mitigate CH_4 emissions and N waste have been extensively studied mainly *in vitro*, but validation of the results *in vivo* is still scarce. The use of cocktails of molecules in most *in vivo* studies makes it difficult to identify active molecules and to understand the mechanisms of action. Work still needs to be done to demonstrate the effectiveness of certain essential oils and to consider their synergistic or antagonistic interaction with other compounds. For most compounds, there is also a need to assess their efficacy in the long term, not only in reducing CH_4 emissions but also in the production and welfare of animals, to facilitate adoption by farmers.

3 Case studies

3.1 Sainfoin, a traditional forage legume containing condensed tannins

Several methods can be used to deliver tannins to the animals, using crude extracts from plants, by-products, wood or whole plants. Agro-ecological and local solutions that integrate several dimensions of ruminant nutrition can decrease GHG emissions at multiple levels, while improving protein self-sufficiency and reducing inputs such as fertilizers and drug treatments (Soussana et al., 2015). In this context, one option is to include legume species containing tannins in animal diets. Recently, a European multidisciplinary research consortium of agronomists, plant breeders, ruminant nutritionists, veterinarians and experts in tannin chemistry focussed on sainfoin, a traditional forage legume (Mueller-Harvey et al., 2019). Here, we present the specific results of this project regarding the potential of sainfoin to decrease GHG emissions (Fig. 2).

A first interesting result was obtained at the field level, where symbiotic N fixation by sainfoin was shown to be comparable with major N-fixing species such as white and red clover without treatment with a commercial rhizobia product (Malisch et al., 2017). The authors concluded that sainfoin has great potential for cropping grass-legume mixtures with increased forage yields, especially when cutting frequency and N fertilizer input are low. These results indicate that sainfoin is relevant to local production of high-protein forage without applying excessive N fertilization leading ultimately to N_2O emissions.

When ensiled with grass, sainfoin preserves silage quality via increased fermentation intensity and reduction in protein degradation in the silos (Copani

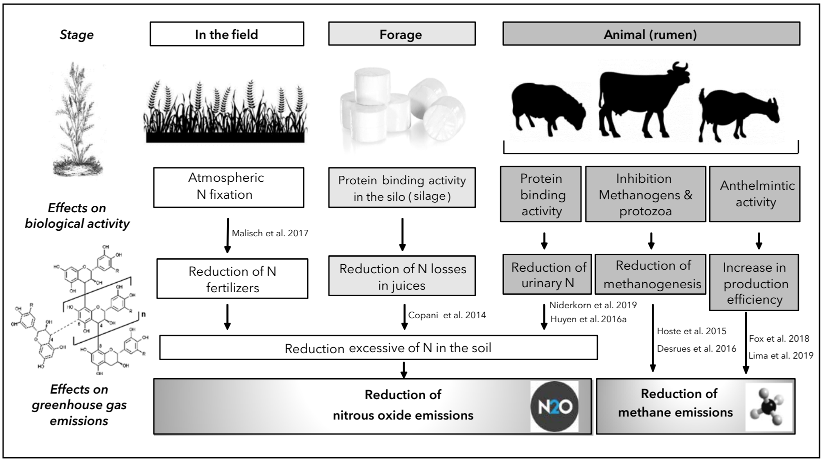

Figure 2 Multiple effects of growing and using sainfoin in ruminant diets to decrease greenhouse gas emissions.

et al., 2014). This was shown by a lower proportion of soluble N and ammonia (relative to total N) in silage compared to grass silage, which reduces N losses in fermentation juices and decreases the adverse impacts on the environment.

At the animal level, the decrease in CH_4 yield (g/kg DMI) and changes in N partition when sainfoin is incorporated in the diet were consistently observed in sheep (Niderkorn et al., 2019) and dairy cows (Huyen et al., 2016a). A particularly interesting result was obtained in dairy cows when a sainfoin-containing diet reduced CH_4 yield and diet digestibility of fibre but improved milk yield compared to the same diet in which sainfoin was replaced by grass. The authors hypothesized that sainfoin may redirect metabolism towards body protein accretion at the expense of body fat (Huyen et al., 2016a). Sainfoin-condensed tannins were shown to have anthelmintic activities in both small (Hoste et al., 2015) and large ruminants (Desrues et al., 2016), showing that a large spectrum of these compounds counteracts infection by gastrointestinal nematodes. This effect may help to decrease GHG emissions by animals, as shown by recent results indicating that parasitism increases CH_4 emissions in sheep (Fox et al., 2018; Lima et al., 2019).

3.2 Additive effect of different anti-methanogenic dietary strategies, a proof of concept

Lipids have emerged as a persistent option for mitigating enteric CH_4 emissions from ruminants (Doreau et al., 2014). However, their potential mitigation is moderate (~20%) if used at a suitable dose avoiding negative effects on animal performance (see Section 3.1).

As proof of concept, we tested whether it was possible to increase the CH_4-mitigation potential of lipids (linseed oil) by combining them with another dietary strategy (nitrate) with a different mode of action on the metabolism of H_2 in the rumen. In a meta-analysis, we reported that lipids may be relevant in reducing H_2 production (via reduction of protozoa), whereas nitrate may stimulate H_2 consumption (H_2 sink) by a competitive pathway to methanogenesis (Guyader et al., 2014). We assumed that simultaneous manipulation of H_2 production and H_2 utilization allows a greater reduction in CH_4 emissions than when acting on a single pathway. To test this hypothesis, we tested the effect of linseed oil and nitrate fed alone or in combination on CH_4 emissions and digestive processes in non-lactating cows.

The daily kinetics of CH_4 emission measurements clearly showed an additive effect of the dietary strategies (−32% reduction for linseed + nitrate vs. −17% and −22% reduction for linseed and nitrate fed alone, respectively). Linseed oil supplementation reduced CH_4 emissions throughout the day compared to the control diet, while nitrate had a transient but marked action for 3 h post-feeding. Combination of the strategies cumulated the two modes of actions (Fig. 3).

In addition, we showed that linseed oil plus nitrate fed to lactating cows for 2 months induced a constant reduction of CH_4 emissions (−29% g/kg DMI), without any effect on digestibility of nutrients, N balance and milk performance. This persistent effect showed the absence of adaptation of rumen microbiota. However, the energetic benefits from the decreased CH_4 emissions did not appear beneficial for dairy cows (Guyader et al., 2016).

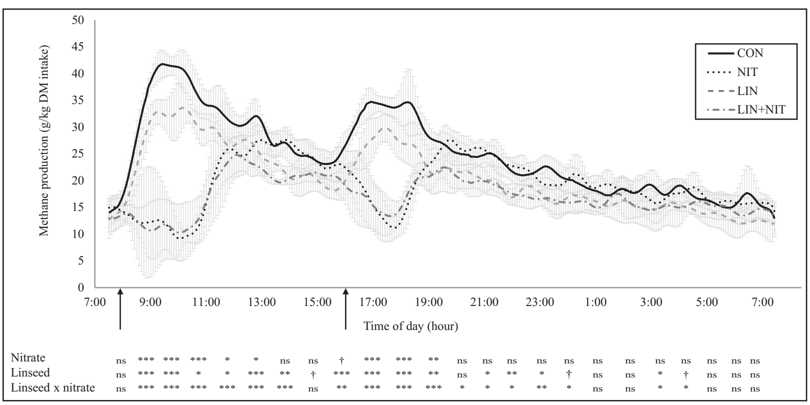

Figure 3 Daily methane production pattern of non-lactating cows fed four different diets containing linseed oil and calcium nitrate alone or in association (n = 4). Treatments consisted of control diet (CON), CON plus 3% calcium nitrate (NIT), CON plus 4% linseed oil (LIN) and CON plus 4% linseed oil and 3% calcium nitrate (LIN+NIT). The arrows indicate time of feeding. Error bars indicate SD. Adapted from Guyader et al. (2015).

Our work confirmed the initial working hypothesis that combining dietary strategies with different mechanisms of action to reduce H_2 availability in the rumen reduces methanogenesis more markedly than when lipids are fed individually. This opens up a range of possibilities for designing new strategies to increase CH_4 abatement (Beauchemin et al., 2020).

4 Outstanding questions and future trends in research

Considering the current health crisis, integrating animal production into a 'one health' approach is more relevant than ever: it s important to consider health care for humans, animals and the Earth in a systemic and integrated way at local, national and global levels. In this context, the use of plant bioactive substances from local resources in animal nutrition is a strong 'card to play' for promoting efficient and safe livestock farming to feed populations, while minimizing its environmental impact.

Many feed resources contain lipids and secondary compounds that are likely, if used properly, to improve animal performances and health, decrease enteric CH_4 emissions and N waste, and improve the quality of animal products. However, many questions have to be addressed before widespread application at the farm level. One demand of stakeholders concerns the possibility of standardized resources with a guaranteed content in active principle. This implies further research to characterize active molecules and their mode of action in order to design and evaluate new feeding strategies that are more efficient in minimizing GHG emissions from ruminants.

Evaluation of new resources based only on the traditional feed value is not sufficient. A multicriteria approach of these resources, as well as practices (crop growing, conservation, processing, feed delivery), is required to consider all animal responses, without neglecting the evaluation of the cost-benefit ratio for farmers. Another challenge is to develop resources with valuable properties for pasture-based systems in order to better integrate the context of agro-ecological ruminant production.

Chapter 10

The use of feed supplements to reduce livestock greenhouse gas emissions: direct-fed microbials

Paul Ross, Teagasc Moorepark Food Research Centre and University College Cork, Ireland; and Catherine Stanton, Teagasc Moorepark Food Research Centre, University College Cork and VISTAMILK SFI Centre – Teagasc, Ireland

1 Introduction

The agricultural sector contributes approximately 24% of all global greenhouse gas (GHG) emissions (IPCC, 2014). The main routes of production for GHG emissions are enteric fermentation and manure management (Haque, 2018). The main gases produced are methane and nitrous oxide, and to a lesser extent, carbon dioxide (McMichael et al., 2007). In 2010, total anthropogenic methane and nitrous oxide emissions accounted for approximately 20% and 5% of all emissions to date, respectively, based on the fifth assessment report (IPCC, 2014).

At a global level, livestock annually produce around 80 million tonnes (Tg) of enteric methane (Patra, 2012). Of these 80 million tonnes of enteric methane,

http://dx.doi.org/10.19103/AS.2020.0077.14

an estimated 18.9 Tg are attributed to dairy cattle, 55.9 Tg to beef cattle, and 9.5 Tg to sheep and goats (Hook et al., 2010). Of all livestock, ruminants are the main producers of enteric methane (Lassey et al., 2007). These animals contain a four-chambered stomach, which generates methane primarily via eructation and belching as a result of the complex microbiological fermentation that occurs in the rumen. This enteric fermentation involves degradation of cellulose and other macromolecules (Boadi et al., 2004) to allow for adsorption into the bloodstream. The large and diverse microbial population ferments the polymers to volatile fatty acids (VFAs), carbon dioxide (CO_2) and methane (Kataria, 2015).

Due to methanogenesis, the ruminant suffers a loss of ingested feed-derived energy of approximately 6–14% depending upon the diet (Johnson and Johnson, 1995). Rather than losing resources to an ineffective microbial process, this energy could instead be used by the animal to produce better-quality milk for its own development (Tapio et al., 2017). It has been predicted that reducing methane generation in the rumen would mean that more energy would be retained by the animal, thereby enhancing its nutritional efficiency (Yang et al., 2016).

Methane production by ruminants is influenced by various factors such as the physical and chemical characteristics of the feed, the feeding schedule and the feed additives. Methane is derived from ingested feed and therefore diet composition, while intake can be used to manipulate fermentation by altering the microbial interactions through feed additives, that is, direct fed microbials (DFMs). This would also have the potential to positively impact animal production. Manipulating host diet may reduce methane emissions by decreasing fermentation of organic matter, therefore shifting the site of fermentation of organic matter from the rumen to the intestine, consequently diverting hydrogen away from methane production (McGinn et al., 2004). For the cattle industry, reducing methane losses can represent an improvement in feed efficiency. Therefore, mitigating methane losses from cattle has both long-term environmental and short-term economic benefits (McGinn et al., 2004). There is a challenge, however, to maintain a balance between productivity, household food security and environmental preservation (Wright et al., 2011).

2 Methane and agriculture

Methane is a prominent GHG which is found in natural wetlands, rice fields, livestock and biomass burning. It is emitted through human activities such as the production and transport of coal, natural gases and oil, as well as naturally, through animal fermentations and gas deposits, such as peatlands. As the second most abundant GHG, it has been projected that one tonne of methane will absorb 34 times more thermal energy than one tonne of carbon dioxide, over a 100-year period (IPCC, 2013). Due to its thermal conductivity, methane levels have the potential to influence climate change on short-time scales (Rice et al., 2016).

Since the beginning of the industrial revolution, the levels of methane observed in the atmosphere have increased more than two-fold, with a continued 1–2% rise per annum since the 1980s, as measured by the National Oceanic and Atmospheric Administration (Singh et al., 2018). Realising the catastrophic threat posed by climate change, the 2015 Paris Agreement, under the United Nations Framework Convention on Climate Change (UNFCCC) and backed by 195 countries, aims to limit the increase in global average temperatures to below 2°C and, where/if possible, limit it to 1.5°C. It is expected that methane emissions from domesticated ruminants will decline in developed countries, due to an ever-growing trend towards an animal-free diet. However, factors such as population growth, rising incomes and commercialisation of previously small-scale farms will result in increased methane production in developing countries (EPA, 2014). In this way, global methane emissions from enteric fermentations are estimated to increase 32% by 2020 (EPA, 2013).

The microbial composition of the rumen, the fore-stomach of the ruminant animal, has a major influence on the feed digestion and the release of end products, such as methane, into the environment. The rumen is home to a vast array of protozoa, anaerobic fungi, anaerobic bacteria and archaea. This diverse array of microorganisms are responsible for the degradation of lignocellulose, which is used as an energy source for the animal. Short-chain fatty acids (SCFAs) are produced from these soluble sugars, and absorbed into the rumen epithelium, resulting in by-products of hydrogen (H_2), carbon dioxide (CO_2), formate and methyl-containing compounds. These by-products are important substrates for methane-forming archaea.

Due to the high microbial diversity within the rumen, methane is formed by many types of methanogens, each using distinct metabolic pathways and precursors. Although methane production can also occur in the lower gastrointestinal tract, a surprising 89% of methane emitted from ruminants is produced in the rumen itself and exhaled through the mouth and nose (Hook et al., 2010). In general, methanogenic archaea use $H_2 + CO_2$, formate, methylated C1 compounds, or acetate as energy and carbon sources for growth (Deppenmeier, 2002). The majority of rumen methanogens have been shown to belong to the *Methanobrevibacter* genus, accounting for 74% of all archaea (Henderson et al., 2015). When combined with *Methanosphaera* spp. and two *Methanomassiliicoccaceae*-affiliated groups, there are five dominant methanogen groups that comprise 89.2% of the community (Henderson et al., 2015).

Methanogenesis is a complex process dependent upon a range of microbes, which contribute either indirectly by creating the appropriate environment required for the growth of methanogens or directly by producing the substrates used by methanogens. The production of methane in cattle is also influenced by diet composition (ingredient and chemical), feed intake, and digestibility (Hristov et al., 2018). It has long been established that an increase in concentrate levels in the diet results in a decrease in methane emission as a proportion of energy intake or expressed by unit of animal product such as milk or meat (Wanapat et al., 2015).

High-starch diets have been shown to decrease methane emissions in ruminants better than fibrous diets, such as those containing beet pulps. Non-structural carbohydrates such as starch and sugars are associated with higher ruminal fermentation rates and accelerated feed turnover which cause a change in the rumen physico-chemicals and a shift in the microbial population. A shift in VFA (volatile fatty acid) production from acetate towards propionate occurs with the development of starch-fermenting microbes. This results in lower methane production because the relative proportion of ruminal hydrogen sources declines whereas that of hydrogen sinks increases. As propionate production and methanogenesis are competing pathways, starch-fermenting bacteria can compete with methanogens for hydrogen, therefore less methane would be produced in the rumen (Moss et al., 2000). For this reason, maize silage or whole-crop silage can reduce methane production in the rumen (Haque, 2018).

Manipulating feed in a manner which will improve feed utilisation and ameliorate product yields while reducing methane emissions will be beneficial for farm production and preferable for the environment.

3 Nitrous oxide and carbon dioxide in agriculture

Nitrous oxide (N_2O) is a potent GHG with a 100-year global warming potential 298 times greater than carbon dioxide (EPA, 2017). Currently, the main sources of anthropogenic N_2 emissions are agriculture, industry, biomass burning and indirect emissions from reactive nitrogen, leaching and atmospheric degradation (Reay et al., 2012). When considering direct agricultural emissions, 38% is attributed to N_2O, 32% to methane from ruminants, 12% from biomass burning, 11% from rice production and 7% from manure management (Bellarby et al., 2008). Livestock-related nitrous oxide emissions are estimated to total between 1 and 2 million tonnes of nitrous oxide-N each year, mainly due to animal waste. Nitrous oxide from synthetic fertilisers, manure applications and crop residues left on farms account for over 40% of total agricultural emissions (WRI, 2014). Nitrous oxide is an intermediate gas for both nitrification (transformation from ammonium to nitrate) and denitrification (the biological reduction of nitrate to N_2 gas), and these processes are both facilitated by microbial action (Mosier et al., 1998). The amount of N_2O released depends on the system and duration of waste management.

Nitrogenous fertilisers and manure pits combine to drive the growth of these emissions. Fertilisers are in general applied in excess and not fully absorbed by the plants themselves, which leads to only 50% recovery of fertilizer N in global crop production (Eickhout et al., 2006). Consequently, a great proportion accumulates in soil and is either lost directly as nitrous oxide, or leaches into water courses, enhancing downstream, indirect N_2O emissions. The amount lost will greatly depend on many other factors such as climate, soil and management practices (Brentrup et al., 2004; Eickhout et al., 2006).

Fertilisers containing N compounds consume up to 10 times more energy and consequently result in more GHG emissions, than fresh manure which is a low C-emitting alternative. Fertilisers are commonly used in agriculture, with the production of fertilisers emitting ~1.2% of the world's total GHGs (Wood and Cowie, 2004). Efficacy in the manufacturing of fertilisers can contribute to a significant reduction in nitrous oxide levels. Improvements would be related to greater energy efficiency in ammonia production plants, introduction of new nitrous oxide reduction technologies and other general energy-saving measures in manufacturing. With an increasing population and a demand for greater food production, N_2O emissions are likely to continue to rise in the coming decades (Reay et al., 2012).

Carbon dioxide is a colourless, odourless gas, released through natural processes such as respiration and volcanic eruptions, as well as human activities of deforestation, land-use changes and the burning of fossils fuels. Increasing concentrations of atmospheric CO_2 and other radioactive greenhouse gases, will ultimately lead to profound effects in the ecosystem. CO_2 does not break down easily in the atmosphere and can persist for several centuries.

Carbon sequestration refers to the process by which atmospheric CO_2 is transferred to soil or vegetation (Teagasc, 2017). The earth's soils contain approximately 1500 Pg (Picogram) of carbon, making it the largest surface of terrestrial carbon (C) (Post et al., 1990). Agricultural soil can act as both a source and sink of atmospheric CO_2 because it not only produces C but can also store C in soil and vegetation (Baah-Acheamfour et al., 2016; Paustian et al., 2000). Soil organic carbon (SOB) is influenced by the physical and chemical environments of the soil (e.g. moisture, temperature, aeration, pH and nutrient availability), the characteristics of the organic matter (i.e. susceptibility to microbial decay) and the physical accessibility of the organic matter to microbes (Paustian et al., 2000). Reconstructions of global land-use change suggest that terrestrial ecosystems have contributed as much as half of the increases in CO_2 emissions from human activity in the past two centuries (Post et al., 1990; Houghton and Skole, 1990).

Current knowledge suggests that agricultural soils have the capabilities to act as CO_2 sinks, however, this is dependant on changes in management practices. Management adaptation strategies which may be incorporated to reduce CO_2 emissions from agricultural soils include: (1) reduced tillage (2) cropping intensification and increased production efficiency (Paustian et al., 2000).

Arguments in favour of using agricultural soil C sequestration as a mitigation option are that additional benefits such as improving soil and water quality, reducing erosion, enhancing better soil fertility and crop production will rise from increasing soil organic matter (Paustian et al., 2000). However, carbon sequestration may lead to important water and nutrient depletion and increased soil salinity and acidity (Jackson, 2005). Although sequestration reduces the levels of CO_2 in our atmosphere, these negative effects on crop yield are not favoured, with an ever-increasing world population and demand for food.

4 Direct-fed microbials (DFMs)

Direct-fed microbials (DFMs) refer to microorganisms which are used to supplement feed to exert a beneficial effect on the animal. They contain live, viable cells, rather than additives which may only contain bacterial constituents. The term probiotic and DFM can be used interchangeably. The US Food and Drug Administration (FDA) authority define DFMs as 'products that are purported to contain live (viable) microorganisms (bacteria and/or yeast)'. DFMs are regulated as feed ingredients by the American Association of Feed Control Officials (AAFCO) and the FDA. DFMs are provided to the ruminant in the form of a bolus or mixed in with feed (Khan and Oh, 2015). According to USDA's National Animal Health Monitoring System's (NAHMS) Dairy 2007 study, 20% of dairy and heifer operations used DFMs for preventative purposes, an increase from 14.4% in 2002. In the European Union, approximately 20 microbial feed additives are authorized for use (Meieregger et al., 2010).

DFMs have been shown to limit gastrointestinal infections and provide optimally regulated environments in the digestive tract (Seo et al., 2010). DFMs detoxify toxic compounds, modulate the innate immune system, and maintain optimal gut movement and mucosal integrity of the intestine (Kumar et al., 2015). These effects have been mainly shown in pre-ruminants, where their benefits include a reduction in the incidence of diarrhoea, a decrease in faecal shedding of coliforms, promotion of ruminal development, improved feed efficiency, increased body weight gain and reduction in morbidity (Krehbiel et al., 2003).

In adult ruminants, there is little research available in relation to the efficacy of DFMs containing lactic acid bacteria (LAB). The use of yeast as a DFM has shown varied results. *Saccharomyces cerevisiae* was shown to reduce methane by 6–10% with varying concentrations (Lila et al., 2004). Adversely, the use of three bacterial DFM treatments of *Propionibacterium freudenreichii* 53-W, *Lactococcus pentosus* D31 and *Lactococcus bulgaricus* D1 did not alter ruminal fermentation and failed to reduce methane emissions in lactating primiparous cows on a high-starch or high-fibre diet (Jeyanathan et al., 2019).

Due to the restriction of using antibiotics as animal supplements, DFM use has become more popular due to their potential to influence the rumen environment and enhance feed efficiency. There have been several recent studies (Table 1) which investigated the use of DFMs as methane mitigators, applied alone or in combination with other treatment methods.

4.1 Types of DFMs

Many types of DFMs exist, ranging from bacterial, to yeast and fungal sources. Natural methods for reducing GHGs also exist, such as seaweed and other organic feed supplements. The type of DFM used varies on its effectiveness and intended use. This review aims to outline both the most common DFMs used, as well as mentioning new feed supplement strategies that are also aiming to reduce our GHG levels.

4.1.1 Lactic acid bacteria

Lactic acid bacteria (LAB) are an order of gram-positive bacteria which have a G+C content below 55mol% (König et al., 2009) are acid-tolerant, generally non-sporulating, non-respiring, either rod or coccus shaped bacteria that share common metabolic and physiological characteristics. The LAB group is usually reserved for the genera such as *Lactobacillus, Leuconostoc, Pediococcus* and *Streptococcus*, as well as others.

LAB produce a variety of inhibitory compounds such as organic acids, hydrogen peroxide and ethanol, which may offer them a competitive advantage in the ruminal ecosystem by inhibiting pathogenic microbial species (McAllister and Newbold, 2008). In addition, LAB produce antimicrobial peptides such as bacteriocins, ribosomially synthesised proteins produced by a bacterium of one strain, which are active against those of a closely related strain (Yang et al., 2014). Bacteriocins are deemed safe, since they are non-hazardous to eukaryotic cells.

LAB are good candidates to use as DFM because they are environmentally robust and have a number of mechanisms whereby, they may alter or influence neighbouring microbial communities with a beneficial effect on the animal (McAllister et al., 2011). LAB used as DFMs may produce lactic acid, which results in a lower pH in the rumen environment.

4.1.2 Lactic acid-utilizing bacteria

Lactic acid-utilizing bacteria such as *Megasphaera elsedenii, Propionibacterium shermanii* and *P. jensenii* have also been proposed as DFMs and have been used

Table 1 Detailing the use of DFM as feed additives and their effect on enteric methane production

Study	Type of Diet	DFM used	Effect on methane	Effect on animal welfare/ productivity
Oh et al. (2019) Effects of *Saccharomyces cerevisiae*-based DFM and exogenous enzyme products on enteric methane emission and productivity in lactating dairy cows.	The basal diet consisted of (dry matter basis) 60% forage and 40% concentrates and contained 16.5% crude protein and 32.0% neutral detergent fibre.	*S. cerevisae* (SDM) and exogenous enzyme product (ENZ).	No effect.	SDM increased milk yield by 2 kg/d without affecting DMI or feed efficiency. Supplementation of the diet with ENZ did not affect DMI, milk yield or feed efficiency.
Meller et al. (2019) Potential roles of nitrate and live yeast culture in suppressing methane emission and influencing ruminal fermentation, digestibility and milk production in lactating Jersey cows.	Ground corn.	Live yeast culture and nitrate.	Nitrate decreased methane by 17% but decreased dry matter intake by 10% (from 19.8 to 17.8 kg/d) such that methane:dry matter intake ratio numerically decreased by 8%.	Milk and milk fat production were not affected, but NO_3- decreased milk protein from 758 to 689 g/d.
Deng et al. (2018) Ruminal fermentation, nutrient metabolism and methane emissions of sheep in response to dietary supplementation with *Bacillus licheniformis.*	Total mixed ration (TMR).	Spore-forming B*acillus licheniformis*.	Daily methane production in the treatment groups was lower than in the control.	Dietary *B. licheniformis* supplementation effectively increased energy and protein utilisation in the sheep.

Jeyanathan et al. (2019) Bacterial DFMs fail to reduce methane emissions in primiparous lactating dairy cows.	Cows were randomly divided into two groups that were fed a corn silage-based, high-starch diet (HSD) or a grass silage-based, high-fibre diet (HFD).	DFM treatments: *Propionibacterium freudenreichii* 53-*Lactobacillus pentosus* D31 *Lactobacillus bulgaricus D1*.	No mitigating effect of DFM was observed on methane emissions in dairy cows.	The effect of DFM on milk fatty acid composition was negligible. *Propionibacterium* and *L. pentosus* DFMs tended to increase body weight gain of cows.
Ellis et al. (2016) DFM inoculated silage with LAB.	Treatment with one of four grouping, with inoculant long term and short term. Diets consisted of grass silage and concentrate (75:25 on a dry matter basis).	*Lactobacillus plantarum, Lactococcus lactis* and *Lactobacillus buchneri*.	Methane levels were not affected.	Dry matter intake, energy, milk and fat composition were not affected.
Thota et al. (2017) Effect of probiotic supplementation on nutrient digestibilities, growth performance and enteric methane emissions in Deccani ram lambs.	12 Deccani ram lambs of uniform body weight (16.5±0.64 kg with 130.11±3.00 days of age) were randomly allotted to two treatments in a completely randomized design. Animals were fed basal diet (chopped sorghum stover), concentrate and chopped green fodder.	*S. cerevisiae47, S. boulardii, L. acidophilus* and *P. freudenreichii*	Mean enteric methane treatment was 21.9% less than control group.	Feed efficiency of the animals was improved.

successfully to decrease concentrations of lactate and maintain ruminal pH. Since propionate is the major precursor for gluconeogenesis in early lactation dairy cows (Reynolds et al., 2003), increments of propionate production in the rumen result in increases of hepatic glucose production (Stein et al., 2006), providing more substrates for lactose synthesis, improving energetic efficiency and reducing ketosis (Weiss et al., 2008). In addition, increased propionate may reduce hydrogen available for methane production in the rumen.

4.1.3 Yeast

The most commonly used DFM is the anaerobic yeast *Saccharomyces cerevisae* and the filamentous fungus *Aspergillus oryzae* (Phillipeau et al., 2017). Traditionally, yeast products were used as feed additives to improve animal health and welfare, thereby improving animal performance and its effect as a probiotic is well-established (Darabighane et al., 2019). As such, supplementation with yeast may indirectly reduce methane production per protein (milk and meat) produced through enhancing ruminal fibre degradation and overall feed conversion efficiency (Bayat et al., 2015).

Yeast can modify rumen fermentation in a manner that can potentially reduce methane formation by decreasing rumen pH or favouring the production of certain VFAs such as acetate, propionate and butyrate (Chung et al., 2011; Iqbal et al., 2008). This is dependent on the diet offered to the animal (Islam and Lee, 2019). It has been suggested that live yeast promote the use of hydrogen by ruminal acetogens and drive the fermentation process towards acetate production instead of methane formation (Kataria, 2015). Additional proposed mechanisms by which yeast reduce methane is by reducing protozoan numbers. High populations of protozoa generally are associated with higher ruminal ammonia concentrations and increased methane production.

5 Direct-fed microbials (DFMs) and greenhouse gas (GHG) reduction

Of all agriculture GHGs, methane is the most impactful. DFMs have been explored in terms of methane reduction; however, research is still lacking for the use of DFMs against CO_2 and N_2O.

5.1 Methane

There is an increasing interest in exploring the use of naturally occurring feed additives. DFMs are already used to improve productivity and health of ruminant livestock, therefore they can be used as a possible option to reduce methane (Jeyanathan et al., 2014). Although the exact mechanism for methane reduction by DFMs has not been elucidated, it is thought that DFMs are responsible for the redirection of H_2 away from the methanogenesis pathway, as well as decreased production of H_2 during feed fermentation (Jeyanathan et al., 2011). Rumen methanogens produce methane by reducing CO_2 using H_2; therefore H_2 is a limiting substrate for methanogenesis. The amount of hydrogen produced in the rumen is highly dependent on the diet and type of rumen microbes as the microbial fermentation of feeds produces different end products that are not equivalent in terms of hydrogen output (Mirzaei-Aghsaghali and Maheri-Sis, 2011).
