Proposed mechanisms of action include: (1) increased butyrate or propionate production, which may result in reduced methane production due to the utilisation of metabolic H_2 by acetogenic bacteria to produce acetate (Lila et al., 2004); (2) decrease in the number of ciliate protozoa in the rumen (Broucek, 2018); high populations of protozoa generally are associated with higher ruminal ammonia concentrations and increased methane production; this suggests that protozoa themselves or associated bacteria actively degrade dietary proteins and are methanogenic; (3) increase in lactic acid-utilizing bacteria, resulting in a reduction of lactic acid, leading to a more stable ruminal environment (Boadi et al., 2004).

Although the mechanism of action is not fully understood, studies have been performed on a broad range of DFMs for methane mitigation, with varied results. It is proposed that because some strains of yeast increase rumen bacterial growth (Chaucheyras-Durand et al., 2008), less methane may be produced due to a shift in partitioning of hydrogen between microbial cells and fermentation products (Newbold and Rode, 2006).

The scientific literature points to the idea that although the concept of using DFMs as mitigators of enteric methane emission is not novel, scientists have not yet elucidated the exact mechanism by which this occurs. Doyle et al. (2019) summarises studies which have used LAB as DFM to reduce methane, and although methane inhibition *in vitro* is evident, these seem to yield mixed results where efficacy tends to be strain-specific and dependent on delivery mode. Furthermore, a limited number of available animal trials make it difficult to draw an outright conclusion, therefore more research is needed to identify whether the use of DFM supplements can the use of DFM supplements can be used effectively to mitigate methane generation in ruminant livestock.

The use of DFMs as feed additives and their effect on enteric methane production has been tested with a range of diets, organisms and ruminants, of which is summarised in Table 1. Many trials incorporate the use of a combination of DFMs, such as yeast and LAB (Thota et al., 2017).

Yeast such as *A. oryzae* has been seen to reduce methane by 50% which was correlated directly to a 45% decrease in the population of protozoa by

Frumhloz et al. (1989). More recently, Mwenya (2004) showed promising results when yeast was added as part of feed for sheep, where a reduction ($P<0.05$) in methane production (L per day) was observed in the supplemented diets compared to control. Conversely, Martin and Nisbet (1990) found that adding *S.cerevisae* and *A.oryzae* resulted in increased methane production.

Methane reduction by yeast may be strain-dependent and variable in the impact on the rumen, as indicated in a study by Chung et al. (2011), where 15 non-lactating Holstein cows were fed a diet containing two strains on *S.cerevisae* at $1x10^{10}$ CFU per cow daily. Results indicated that yeast strain 1 did not affect methane emission intensity compared with the control treatment, while strain 2 lowered methane emissions but increased the risk of acidosis. More research is needed to screen yeast strains which can confer a probiotic benefit when used in feed and reduce methane simultaneously.

In general, studies investigating the effect of *S.cerevisae* on enteric methane production have shown differing conclusions. A meta-analysis compiled by Darabighane et al. (2019) comparing 46 scientific publications on dairy and beef cattle, concluded that supplementation of yeast does not significantly reduce methane production or methane/DMI. A comparison of 11 studies of yeast- recipient versus control group indicated that the addition of yeast, when it reduced methane emissions was not statistically significant (standard mean deviation (SMD) = −0.051; P = 0.792). The authors of this meta-analysis suggested that the results should be interpreted with caution because they were based on a small number of studies. A compilation of studies investigating the effect using *S. cerevisiae* as a DFM for reducing rumen methanogenesis showed inconsistent results between *in vitro* and *in vivo* studies (Jeyanathan et al., 2014). This could be attributed to the discrepancies in experimental conditions.

In terms of LAB/LUB, a meta-analysis completed by Krehbiel et al. (2003), indicated a generally positive trend for the improved health of young cattle treated with DFM inoculants. The use of bacteriocin like particles from LAB and LUB is of particular interest. Bacteriocins have antimicrobial proteinaceous properties which are ubiquitous in nature and are produced by a range of gram-positive and gram-negative organisms. Bovicin, a bacteriocin produced by *Streptococcus bovis*, has been found to reduce methane in vitro by up to 50% (Lee et al., 2002). Bacteriocins can be useful in directly inhibiting methanogens and/or reducing H_2 to other reductive microorganisms (Garsa et al., 2019).

Nisin is composed of 34 amino acids with two structural domains and is classed as a lantibiotic. This bacteriocin produced by *Lactococcus lactis* species, with GRAS (generally regarded as safe) status, has also shown methane reduction potential. However, Nisin supports the propionate production and depicts selective activity against gram-positive bacteria of rumen origin; therefore, complete exploration must be carried out before its use as an animal additive (Garsa et al., 2019). *Megasphaera elsdenii* (one of the most important lactate-utilizing species in the rumen) has been reported to establish a successful DFM product, but ruminal pH and fermentation have been inconsistent (Klieve et al., 2003; Henning et al., 2010)

Bacterial DFMs do not always result in positive results. Jeyanathan et al. (2019) reported that DFM treatment results in no mitigation effect, as well as no effect on milk composition (Table 1). Similarly, it was seen that in a study using eight Holstein Friesian dairy cows, treated with both long- and short-term LAB inoculations of *Lactobacillus plantarum, Lactococcus lactis* and *Lactobacillus buchneri*, no methane reduction was observed (Ellis et al., 2016). Variances in strain and dose, as well as difference in basal silage conditions may be responsible for the lack of effects observed. There have been other attempts to inoculate the rumen with LAB and fungi (*Candida kefyr*) along with nitrate supplementation to both control methanogenesis and possibly prevent nitrite formation, but no consistent animal data, have been reported (Takahashi, 2011). Although fermentation of lactate to VFA would help prevent a decreased ruminal pH, introduction of lactate-producing DFM would require careful scrutiny in situations in which sub-acute rumen acidosis might occur (Hristov et al., 2013).

5.2 Nitrous oxide and carbon dioxide

Diet can play a fundamental role in manure emissions, as it influences the volume and composition of manure. In particular, diet affects the amount, form and partition of N excretion between urine and faeces, and the amount of fermentable organic matter excreted (Hristov et al., 2013). Reducing ruminally degradable protein concentration can reduce NH_3 (Ammonia) emissions from manure, through a marked reduction of urinary urea excretion, NH_3 concentration and potentially N_2O emissions from dairy manure (Forabosco et al., 2017). Feed additives and dietary manipulation options targeting nitrous oxide emissions are mostly studied in isolation, but can have unexpected synergistic or antagonistic effects. Further research in this field needs to be carried out to test this.

6 Strengths and challenges of direct-fed microbials (DFMs)

6.1 Consumer acceptance

Realising the GHG mitigation potential of agriculture is ultimately dependent on farm-level decisions based on how adoption will benefit the individual farmer (Chandra et al., 2016). Mitigation options that both reduce GHG emissions and increase farm productivity, that is, cost-effective practices, are more likely to be adopted (Smith et al., 2007, 2008) than practices which would negatively affect farmers' income.

6.2 Expenditure

Studies have shown that DFMs as probiotics offer economic advantages, with a cost savings of 1–5%. Initiatives such as Pasture Base Ireland aims to help farmers make better decisions around grassland management, thus ensuring that the grass offered to the animals is of the highest quality resulting in reduced methane emissions (Wims et al., 2010). This will reduce methane emissions by minimising the amount of silage and supplemental feed in the diet and improving feed quality (Analysis Ireland, 2020–2030). Table 2 summarises the possible benefits of using commercially available DFMs, which in the long run will provide financial benefits.

Table 2 Composition and benefits of commercially available DFM products

DFM name	Bacterial #'s	CFUs	Benefits
Generator D	Nine species of live bacteria	24 billion CFU per 2 g	Replaces digestive organisms, higher milk and meat production
Generator Elite	Fourteen species of live bacteria	264 billion CFU	Replaces beneficial organisms, supports appetite, helps maintain pH, aids DM intake
Generator ProSacc	Nine species of live bacteria	2.27 trillion CFUs	Lactic acid-producing bacteria, enzymes to break down feed, B vitamins
Generator ULTRA	Eight species of live bacteria	68.25 billion per feeding	Enzyme-producing bacteria, purified digestive enzymes
Generator PYK	Eight species of live bacteria	480 billion CFUs	Digestive supplement, ideal as a calf starter
ProP169	Propionibacterium freudenreicheii strain P169	60 billion CFUs per feeding	Increase rumen propionate yield
Bovine DFM Powder	Unknown	300 billion CFUs per pound	Improves palatability of feed and rumen function, increased fibre digestion, feed intake and milk/meat production
Blended Fermentation Product Series – COMBO	Five species of live bacteria	100 million – 4 billion CFUs per gram	Source of amino acids, cellular proteins, vitamins (B), minerals

6.3 Inconsistent results

There is inadequate evidence of the direct enteric methane mitigating effect of yeast and other DFMs. DFMs function as probiotics which stabilize pH and stimulate rumen function. These have been reported to result in significant improvement in animal productivity and enhanced feed efficiency. This ultimately reduces methane emission intensity. However the issue of maintaining antimethanogenesis in the rumen has not been fully studied and it seems that DFMs would have to be continuously administered to maintain their efficacy (Jeyanathan et al., 2011).

6.4 Alternative hydrogen sinks

It has been suggested that rumen function will be disrupted if methane production is significantly decreased by directly inhibiting methanogenic archaea without the provision of alternative hydrogen sinks (McAllister and Newbold, 2008). Of all the hydrogen sinks present in the rumen, methane production is the most important in that the activity of rumen methanogens lowers H_2 concentration to about 1 μM, which permits a more rapid fermentation of the feed, giving the animal access to more VFA in a given time (Wolin, 1979). Conversely, high concentrations of H_2 in the rumen slows the microbial activity of feed fermenters, potentially slowing down the conversion to VFAs (Buddle et al., 2011). It is therefore important to introduce a system that will ensure that the accumulation of hydrogen in the rumen is minimised.

It has been proposed that inhibiting methanogenesis could favour microbial biomass production as an alternative hydrogen sink (Henderson et al., 2015). Inhibiting methanogenesis could have consequences on microbial ATP generation. In anaerobic systems like the rumen, part of the negative Gibbs energy change associated with fermentation is used to generate ATP through substrate level- and electron transport-linked phosphorylation. Changes in the H_2 sink levels could also affect such energy generation pathways. Inhibiting methanogens without providing alternative electron acceptors commonly results in an overall reduction in feed digestibility and often, reduced animal productivity (Beauchemin, 2009).

7 Other methane mitigation methods

7.1 Rumen manipulation

Biochemical pathways and microorganisms that play a role in methanogenesis directly or indirectly can be targeted and modulated. The amount, type and rate of fermentation of dietary carbohydrates affect both the total amount and proportions of individual VFAs formed and, ultimately, the amount of methane produced. Methylotrophs are microorganisms that can use single carbon organic compounds such as methane and methanol (Jeyanathan et al., 2015). These are key players in the carbon cycle and can be used to compete against methanogens for substrates (Iguchi et al., 2015). Acetogens are microorganisms that generate acetate as an end product of anaerobic respiration, directly producing the H_2 required for methanogenic growth. Targeting acetogens to reduce their population levels in the rumen has been shown to divert hydrogen away from methane production during ruminal fermentation (McGinn et al., 2004). Nitrate can act as an alternative H_2 sink, which has the potential to reduce rumen methanogenesis. Nitrate-reducing bacteria such as *W.succinogenes* and *S.ruminantium* are present in concentrations of 10^6 cells/mL of rumen fluid (Jeyanathan et al., 2011); however, to compete with methanogenesis, they must be present in higher concentrations. Sulphate-reducing bacteria (SRB) can act both in a competitive or co-operative association with methanogens, depending on levels of sulphate available. When sulphate levels are unlimited, SRB compete with methanogens for H_2, formate and acetate. In depleted sulphate environments, SRB co-operate with methanogens by acting as net producers of H_2.

7.2 Methane inhibitors

Bromochloromethane (BCM) has been found to decrease methane production in ruminants and is considered one of the most effective mitigative strategies for methane inhibition (Martinez-Fernandez et al., 2016). The BCM dramatically increases H_2 expelled without affecting DM intake and feed digestibility. However, the use of BCM has been restricted due to its ozone-depleting capacity. Recently, another chemical, 3-nitrooxypropanol (3NOP), which has been developed synthetically has been shown to reduce methane emission levels by up to 30% without negatively affecting animal performance (Hristov et al., 2015). This non-toxic compound has shown promise as a feed additive as some studies have reported increase in animal weight gain in dairy cows (Haisan et al., 2014 and Hristov et al., 2015) while consistently decreasing methane production. 3NOP is a structural analogue which inhibits methanogens by binding to the active site of the enzyme methyl-coenzyme M reductase which is responsible for the final step in methanogenesis pathway (Martinez-Fernandez et al., 2018). This chemical methane inhibitor is still under development and requires registration as a zoo-technical feed additive under European Union legislation (Rooke et al., 2016).

In terms of its practicality as methane inhibitor on-farm, administering 3 NOP at doses of 111 mg/kg diet DM or less resulted in 21% reduction in methane. However, there was a large degree of uncertainty (95% confidence interval, 13–29%) due to the variation in dose and method of administering 3NOP. Current view of the manufacturers is that the method for administration would appear to be critical and currently recommendations include dosing of a total mixed ration to ensure coupling of feed intake to intake of methane inhibitor (Rooke et al., 2016).

The product could be supplied as a premix to be incorporated into diets on farm. The daily recommended dose of 106 mg/kg diet DM is small enough that it may be practicable to administer the compound as a bolus into the rumen to release 3NOP over an extended time period and therefore compatible with the grazing situation.

7.3 Archael phage

Bacteriophages, or phage, are viruses which attack bacteria. Although not yet isolated from the rumen, *Siphroviridae* phages have been reported to infect *Methanobrevibacter*, *Methanococcus* and *Methanobacterium* species (McAllister and Newbold, 2008). Phages are highly specific and their use as methane biocontrol agents would likely not disrupt the normal microbial composition of the rumen ecosystem.

7.4 Natural feed supplements

Recently there have been several studies investigating the effects of seaweed (or macroalgae) as a livestock feed supplement and its potential to reduce methane production in ruminants. Antimethanogenic compounds are known to exist naturally in seaweed. The tropical red algae species of *Asparagopsis taxiformis* produces the halogenated antimethanogenic compounds, bromoform and dibromochloromethane which have been shown to reduce methane production by up to 80% when fed to sheep (Li et al., 2016). Another red algae species, *Asparagopsis armata*, has been demonstrated to reduce methane emissions by around 20% in dairy cattle, which was increased to around 60% reduction with an increased inclusion level of 1% (Roque et al., 2019).

8 Conclusion

DFMs are a viable method for the reduction of GHG emissions in livestock. DFMs may be used in conjunction with existing technologies, that is, vaccines, and small molecule inhibitors. For this to work in on-farm operations, there needs to be a balance between the reduction of GHGs, cost-effectiveness, animal welfare and animal productivity. Essentially, improving feed quality and the overall efficiency of dietary nutrient can be an effective way of decreasing the intensity of GHG emissions from livestock.

9 Acknowledgements

METHLAB, refining DFMs and silage inoculants for reduction of methane emissions from ruminants has been funded by FACCE ERA–GAS, an EU ERA–NET Cofund programme, whereby national money is pooled to fund transnational projects, and the European Commission also provides co-funding for the action. FACCE ERA–GAS is the ERA–NET Cofund for Monitoring and Mitigation of Greenhouse Gases from Agri- and Silvi-culture, and comprises funding agencies and project partners from 19 organisations across 13 European countries. Teagasc, the Agriculture and Food Development Authority in Ireland, is the overall coordinator of the ERA–NET. METHLAB was one of 10 successful projects to be funded from 79 proposals from across Europe, the United States and New Zealand. The New Zealand contribution to the METHLAB project is funded by the New Zealand Government in support of the objectives of the Livestock Research Group of the Global Research Alliance on Agricultural Greenhouse Gases.

Chapter 11

Modifying the rumen environment to reduce greenhouse gas emissions

Yajing Ban, University of Alberta, Canada; André L. A. Neves, Embrapa Dairy Cattle, Brazilian Agricultural Research Corporation (Embrapa), Brazil; Le Luo Guan, University of Alberta, Canada; and Tim McAllister, Lethbridge Research and Development Centre, Agriculture and Agri-Food Canada, Canada

1 Introduction

The dramatic increase in the human population – estimated to reach 9.7 billion people by the year 2050 – will require an approximately 25% increase in gross agricultural output between 2020 and 2050 to meet the global food demand of humanity (FAO 2018; Nations 2019). However, increased animal production has placed an added strain on the environment as a result of the production of greenhouse gases (GHGs) (Huws et al. 2018) and nutrient accumulation in intensive livestock systems (Tullo et al. 2019). Ruminant production produces a number of GHGs including carbon dioxide (CO_2) mainly due to the use of fossil fuels, methane (CH_4) from enteric fermentation and manure, and nitrous oxide (N_2O) from manure and nitrogen fertilizer (Lynch and Pierrehumbert 2019). CH_4 is a particularly prominent GHG, as it has a global warming potential that is 28 times greater than that of CO_2 (Jackson et al. 2019). Globally, it has been shown that ruminants contribute about 11% of total anthropogenic GHG production, with approximately 6% arising from enteric CH_4 from ruminants (Rojas-Downing et al. 2017; Grossi et al. 2019; Beauchemin et al. 2020). In addition to the negative impacts on the environment, enteric CH_4 emissions can also represent a 2–12% loss in gross energy intake (Johnson and Johnson

http://dx.doi.org/10.19103/AS.2020.0077.16
Published by Burleigh Dodds Science Publishing Limited, 2021.

1995). Theoretically, if this energy loss could be reduced through mitigation technologies, the energy saved could be redirected toward meat and milk, improving production efficiency. Although the carbon footprint on an intensity basis from livestock husbandry has declined in the past 50 years owing to improvements in animal production efficiency, a trend that is expected to continue, the increasing demand for animal protein may limit the achievement of the Paris accord target of limiting temperature increases to 1.5°C above pre-industrial levels (Ripple et al. 2014; Beauchemin et al. 2020; Leahy et al. 2020). Therefore, the mitigation of enteric CH_4 emissions is essential to a reduction of agricultural GHG emissions.

This chapter contains three sections: the first section highlights the rumen microbiome and its contribution to CH_4 emissions; the second section summarizes the main factors (rumen- and feed-associated) that influence CH_4 production in ruminants; the final section discusses the most promising current strategies used to reduce CH_4 emissions in ruminants.

2 Greenhouse gas production and the role of the rumen microbiome

2.1 Greenhouse gas production in ruminants

The major GHGs associated with ruminant production are CO_2, CH_4, and nitrous oxide (N_2O), which are emitted either directly from enteric fermentation (CH_4) and manure (CH_4, N_2O) or indirectly from land-use change, fertilizer use and burning of fossil fuels (CH_4, N_2O, CO_2) during feed production (Schils et al. 2005; Grossi et al. 2019). CO_2 emitted by respiration is not considered as a net contributor to GHGs as its release to the atmosphere (via respiration) is offset by plants that capture CO_2 to form biomass through photosynthesis (Steinfeld 2006). However, CO_2 generated as a result of the use of fossil fuels for transport of ruminant feed or products (e.g. milk, beef), generation of electricity and other on-farm practices may exceed 41 million tonnes per year (Steinfeld 2006). Thus, the two major GHGs emitted directly by ruminants are enteric CH_4 and N_2O generated from manure (Gerber et al. 2013). Combined, these two GHGs account for approximately 80% of the total emissions arising from the livestock sector and thus are significant contributors to the global GHG budget (Opio et al. 2013). It is estimated that 44% of the total GHG emissions produced by ruminants are in the form of CH_4 (Fig. 1a), which arises as a result of the reduction of CO_2 to CH_4 by archaea in the rumen and in manure (Gerber et al. 2013). The main sources of N_2O are derived from chemical fertilizer and N deposition from manure, which are influenced by manure management and indirect emissions that arise from the volatilization of NH_3 from intensive livestock systems and its downwind deposition. Nitrous oxide comprises 31% of the 7.1 Gt of CO_2 equivalents that are produced annually by the livestock sector (Gerber et al.

Published by Burleigh Dodds Science Publishing Limited, 2021.

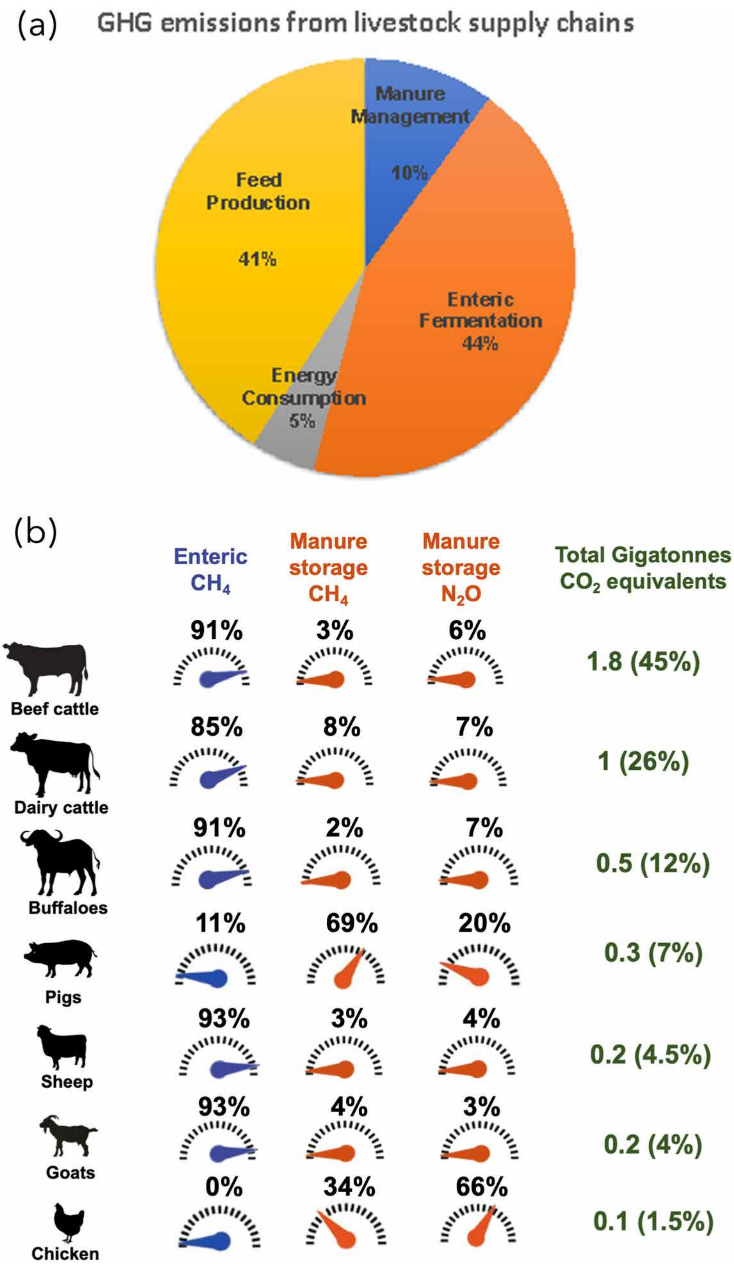

Figure 1 (a) Emissions in livestock supply chains from enteric fermentation, feed production, manure management and energy consumption (adapted from FAO 2017). (b) The farm-gate non-CO_2 emissions (%) from enteric fermentation and manure storage by livestock species in carbon dioxide equivalents (Grossi et al. 2019).

2013; Adler et al. 2015). On average, the enteric CH_4 in CO_2 equivalents accounts for over 90% of the farm-gate non-CO_2 emissions from ruminant production (Fig. 1b), with beef cattle producing the largest proportion of these emissions (Grossi et al. 2019). In all, these outcomes indicate that there is an urgent need for the development of strategies to mitigate GHG production by ruminants, while concurrently improving animal husbandry systems to meet the increasing demand for sustainable food production.

As enteric CH_4 is the largest contributor to GHG emissions from ruminants, research efforts have been primarily directed toward the development of strategies to reduce ruminal CH_4 production. CH_4 emissions are commonly expressed as CH_4 production (g/day), yield (g/kg dry matter intake) and intensity (g/kg average daily gain or energy corrected milk) (Niu et al. 2018; Ornelas et al. 2019). Rumen microbiota play a fundamental role in feed digestion and provision of energy for the host (Russell and Rychlik 2001), with CH_4 being a by-product of the rumen fermentation process. A variety of molecular, genomic, microbiological, nutritional and chemical approaches have been explored for their ability to reduce enteric CH_4 emissions, most of which have had limited success. The production and flow of reducing equivalents among the rumen microbiota is complex, and it is likely that any successful CH_4 mitigation strategy will be based on a fundamental understanding of the various roles of rumen microbiota in CH_4 production.

2.2 Rumen archaea and methanogenesis

In the rumen, archaea are one of the four main microbial groups. The domain archaea are divided into two different kingdoms: Euryarchaeota, consisting of methanogens and extreme halophytes, and Crenarchaeota, consisting of hyperthermophiles and nonthermophiles (Bayley et al. 1999). The assessment of the rumen archaeal community present in the ribosomal database project revealed 3516 archaeal sequences, representing an estimated 1500 species (Kim et al. 2011). Despite this diversity, studies have shown that 90% of rumen archaea are methanogens. Rumen methanogens are exclusively members of the Euryarchaeota, ranging from 10^6 to 10^8 cells per mL of rumen fluid, accounting for less than 4% of the rumen microbial population (Lin et al. 1997; Janssen and Kirs 2008). *Methanobrevibacter* (63.2% of the methanogenic population), *Methanomicrobium* (7.7%), *Methanosphaera* (9.8%), Rumen Cluster C (now referred as *Methanomassiliicoccaceae*, 7.4%), and *Methanobacterium* (1.2%) represent the majority of the methanogens in the rumen (Janssen and Kirs 2008; Patra et al. 2017).

Rumen methanogens produce CH_4 by transferring reducing equivalents formed by other microbiota (i.e. bacteria, fungi, and protozoa) to CO_2 (Deppenmeier 2002). Interspecies hydrogen transfer plays a key role in this process as it ensures a low partial pressure of H_2 (~162 Pa) in the rumen and avoids the inhibition of fermentation as a result of an accumulation of reduced co-factors (Janssen and Kirs 2008; Ungerfeld 2013; Rojas-Downing et al. 2017). During methanogenesis, reduced co-factors (e.g. NADH, NADPH, FADH and Fd) are oxidized and the reducing equivalents are transferred to methanogenic archaea through a series of biochemical steps to reduce CO_2 to CH_4 (Ungerfeld 2015). The hydrogenotrophic pathway is the predominant pathway for CH_4 production in the rumen, with *Methanobrevibacter* species accounting for the majority of this activity and typically accounting for over 90% of rumen archaeal 16S rRNA reads (Hristov et al. 2012). Most methanogens can also use formate as the electron donor for CO_2 reduction as a result of the activity of formate dehydrogenase. Formate is produced during fermentation by microorganisms that possess pyruvate-formate lyase or from the fermentation of plant metabolites like oxalic acid. Ruminal methanogens (e.g. *Methanosarcina, Methanosphaera, Methanimicrococcus*) can also utilize methanol, methylamines, and methylated sulphides as substrates for the synthesis of CH_4 (Ellis et al. 2008; Janssen and Kirs 2008; Poulsen et al. 2013; Tapio et al. 2017).

Recent studies have shown that the total number of methanogens in the rumen is not necessarily directly related to CH_4 yield, but rather it can be related to the abundance of particular archaeal species (e.g. *Methanobrevibacter gottschalkii*) (Zhou et al. 2011). However, it seems that the expression of genes involved in methanogenesis may be a more accurate predictor of rumen methanogenesis (Roehe et al. 2016) than the abundance of certain archaeal species (Zhou et al. 2011). The expression of genes within the methanogenesis pathway (e.g. *methyl-coenzyme M reductase alpha subunit – mcrA*) has been shown to be greater in high-CH_4-emitting cattle as compared to their low-emitting counterparts (Shi et al. 2014). It is worth noting that many factors influence rumen methanogenesis (e.g. diet, intake, rate of passage, rumen volume), and consequently the amount of CH_4 produced.

2.3 Other rumen microbiota and methane production

In the rumen, bacteria are the most abundant cellular microbiota (density of 10^{10}–10^{11} cells per mL rumen fluid), making up at least 50% of the microbial cell mass (Creevey et al. 2014). The rumen bacteria ferment feed to produce volatile fatty acids (VFA) and microbial protein, providing the main nutrients utilized by the host and other rumen microbiota (Ellis et al. 2008). Other bacterial fermentation end-products can also be used as substrates for methanogens (Zinder 1993).

Methanogens share a commensal relationship with rumen ciliates, and these protozoa-methanogen consortia account for approximately 30–40% of the enteric CH_4 produced in ruminants (Finlay et al. 1994). Protozoa are present at 10^4–10^6 cells per mL in rumen fluid and account for 20–50% of the rumen microbial biomass (McSweeney and Mackie 2012). They are involved in lipid hydrolysis and can produce large amounts of hydrogen via organelles known as hydrogenosomes (Tymensen et al. 2012), which provide substrates to methanogens via interspecies hydrogen transfer (Gijzen et al. 1988; Hobson and Stewart 1997; Kittelmann et al. 2015). Removal of protozoa from the rumen, a process known as defaunation, can suppress fiber digestion (Mosoni et al. 2011), but it is also consistently associated with a reduction in CH_4 production (Morgavi et al. 2012; Newbold et al. 2015). However, this reduction in CH_4 production is often transitory with emissions often returning to original levels within a month after defaunation as a result of an increase in hydrogen transfer between bacterial populations and methanogens (Guan et al. 2006).

Anaerobic rumen fungi are active players in the degradation of lignocellulosic feedstuffs and therefore produce reducing equivalents that are used by methanogens to reduce CO_2 to CH_4 (Gruninger et al. 2014). Anaerobic rumen fungi, such as *Neocallimastix frontalis*, have a synergistic relationship with methanogens through interspecies hydrogen transfer and also possess hydrogenosomes. This synergistic relationship increases the enzymatic activity of rumen fungi and their ability to degrade plant cell-wall carbohydrates and produce fermentation products (Hook et al. 2010). As a result of this relationship, greater fungal abundance has been associated with increased CH_4 emissions (Tapio et al. 2017). These findings suggest that rumen fungi are positively linked to methanogenesis through their provision of reducing equivalents for methanogens.

3 Factors influencing methane production in ruminants

As the largest forestomach in ruminants, the rumen is the primary site of CH_4 production within the digestive tract, with less than 5% of the emissions being emitted as flatulence (Lassey 2007; Hammond et al. 2016). Microbiological, physiological, nutritional and genetic factors all influence enteric CH_4 production in ruminants (Fig. 2).

3.1 Rumen-associated factors

3.1.1 Shifts in the rumen microbiome

It is clear that the rumen microbiome is associated with enteric CH_4 production and manipulating its structure and function through the diet is one of the simplest approaches in reducing CH_4 production in ruminants. For example, increasing the proportion of concentrate in the diet shifts the microbiota from

Published by Burleigh Dodds Science Publishing Limited, 2021.

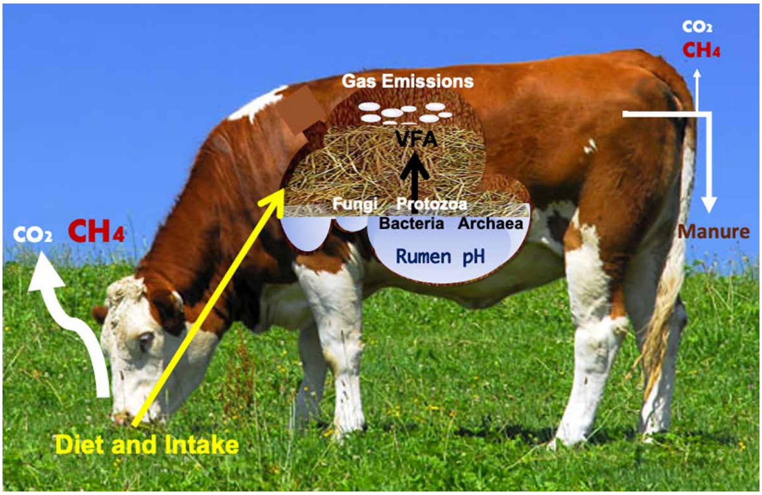

Figure 2 Rumen fermentation and factors associated with enteric CH_4 emissions. CH_4 is produced during rumen fermentation and influenced by rumen-associated factors (e.g. host genetics, rumen microbiota or physiological processes) as well as feed-associated factors (e.g. diet composition or feed intake). The weight of the white arrows represents the proportion of GHG emissions out of the mouth versus from manure and flatulence.

species that degrade plant cell-wall carbohydrates to those that degrade non-fiber carbohydrates (Zhang et al. 2017). This shift increases the production of propionate in the rumen and decreases the production of acetate. As propionate is a net sink of reducing equivalents, their availability to reduce CO_2 to CH_4 is decreased. A high-concentrate diet also has the capacity to change the rumen environment through shifts in ruminal pH, which in turn affects the diversity and composition of rumen microbiota. Unlike other members of the rumen microbiota, the diversity of archaeal communities appears to stay relatively stable during shifts from a high-forage to a high-concentrate diet (Kumar et al. 2015). This may reflect their role in the reduction of CO_2 to CH_4, a biochemical function that is common to both forage- and concentrate-based diets. It does appear that the composition of methanogenic archaea community does change with age of the host, with methylotrophic methanogens being predominant in the neonate, whereas hydrogenotrophic methanogens are responsible for the majority of CH_4 production in the mature rumen (Friedman et al. 2017).

3.1.2 Rumen pH

Rumen pH is one of the major factors influencing enteric CH_4 production. A rapid shift from a roughage-based to a grain-based diet can cause acute ruminal acidosis, shifting volatile fatty acid production toward lactate and dramatically reducing the diversity of rumen microbiota (Dijkstra et al. 2012; Petri et al. 2013). In this context, Slyter et al. (1966) studied the effect of ruminal pH on rumen fermentation and microbial population in vitro, finding a significant reduction in VFAs and CH_4 production at a pH below 6.0. Similarly, Van Kessel and Russell (1996) observed that CH_4 production was reduced in the rumen fluid from a cow fed a concentrate-based diet when the pH declined to 5.45, but if the pH was restored to 7.0 with NaOH, CH_4 production resumed to a level similar to that of the rumen fluid which was collected when the cow was fed forage. The increase in propionate production with concentrate-based diets could account for a portion of the decline in CH_4 production, as propionate-producing bacteria which are abundant in these diets also utilize reducing equivalents, while the growth of methanogens is inhibited (Janssen and Kirs 2008). The optimal pH for the growth of methanogens in vitro ranges from 6.0 to 7.2 (Paynter and Hungate 1968; Jarvis et al. 2000; Kumar et al. 2009; Hook et al. 2011). However, responses of methanogens to pH in vitro may differ from those observed in vivo. Studies with heifers fed a high concentrate diet found that CH_4 production was the highest during the period after feeding, when the ruminal pH was the lowest (Fig. 3; Hünerberg et al. 2015). Methanogens exist within biofilms on feed, protozoa and the rumen wall and metabolic conditions within these microenvironments may differ from that in free rumen fluid or in in vitro cultures.

Consequently, although high-concentrate diets can reduce the intensity of CH_4 production (i.e. CH_4 per kg of meat or milk) they may not result in a reduction in absolute emissions. Furthermore, care must be taken to ensure that ruminal pH does not decline to levels that promote subclinical or clinical acidosis.

3.1.3 VFA production and absorption capacity of the rumen wall

Carbohydrates are broken down into VFA during ruminal fermentation to supply the host animal with the energy required for growth and maintenance. In this process, feed particles are fermented by rumen microbes to simple sugars that are then converted to VFAs, CH_4 and CO_2. The formation of acetic acid and butyric acid releases reducing equivalents, while the formation of propionic acid consumes reducing equivalents. Therefore, the types of VFAs produced in the rumen are closely linked to methanogenesis, such that CH_4 production can theoretically be predicted by the following equation (Moss et al. 2000):

$$\begin{aligned} CH_4(\text{mol}) = {} & 0.45\ \text{acetic acid}(\text{mol}) + 0.40\ \text{butyric acid}(\text{mol}) \\ & - 0.275\ \text{propionic acid}(\text{mol}). \end{aligned}$$

This equation shows that the production of acetate and butyrate enhances CH_4 production while propionate formation inhibits methanogenesis by

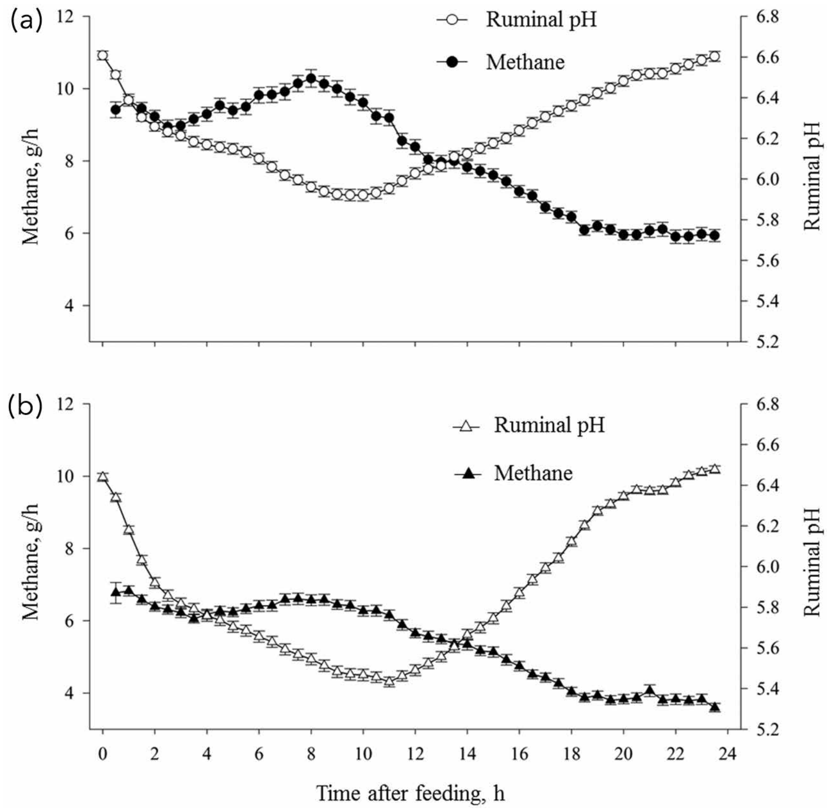

Figure 3 Diurnal CH_4 emission rate (g/h) and ruminal pH of beef heifers fed high-forage (a) or high-concentrate (b) diets. CH_4 was measured using 4 open-circuit respiratory chambers, with each chamber housing 2 heifers. Continuous rumen pH of individual heifers was measured using indwelling pH loggers. The ruminal pH and CH_4 emission rates were averaged between heifers housed in the same chamber (n = 8; means ± SEM) (Hünerberg et al. 2015).

competing for reducing equivalents in the rumen. The production of VFAs, however, is not necessarily directly related to their concentrations in rumen fluid due to variations in their absorption rate across the rumen wall and their rate of passage from the rumen. Indeed, Dijkstra et al. (1993) showed that concentrations of VFA in rumen fluid may not reflect VFA production, particularly at low rumen pH where rates of VFA absorption are increased. In this context, Penner (2014) reported that VFA absorption through the ruminal wall is linked to ruminal pH and is influenced by the passive diffusion of protons or by the secretion of bicarbonate through anion exchange mechanisms. In general, ruminal VFA concentrations have been shown to be positively correlated with VFA production (Leng 1970) and as a result some studies have attempted to predict ruminal CH_4 production based on VFA concentrations. Williams et al. (2019) developed a model that considered the production and removal of VFAs via absorption through the ruminal wall, and concluded that CH_4 yield (MY, g/kg DMI) in dairy and beef cattle could be predicted using the following equations:

$$MY = 4.08 \times (\text{acetate/propionate}) + 7.05;$$

$$MY = 3.28 \times (\text{acetate} + \text{butyrate})/\text{propionate} + 7.6;$$

$$MY = 316\,/\,\text{propionate} + 4.4;$$

where the unit of VFAs is mol/100 mol total VFA. However, VFA concentrations may not be suitable predictors of daily CH_4 production in all feeding situations, as it has been shown to be the case for grazing sheep (Robinson et al. 2010). The lack of information on molar proportions of VFAs, rumen pH and fractional rates of VFA absorption in pastured ruminants may account for this shortcoming (Bannink et al. 2006).

3.2 Feed-associated factors

3.2.1 Feed intake

It is well known that total daily CH_4 production is primarily affected by feed intake and differs widely among ruminant species (Kirchgessner et al. 1991; Shibata et al. 1993; Benchaar et al. 2001). Past studies showed that CH_4 production can be estimated from dry matter intake (DMI), particularly when feed intake is less than 1.5 times maintenance energy requirements (Moe and Tyrrell 1979). The positive correlation between CH_4 production and DMI at lower intake levels (< 1.5 times the maintenance) was used by Shibata et al. (1992) to develop an equation to estimate CH_4 production in ruminants:

$$CH_4\,(\text{L/day}) = 0.0305 \times \text{DMI}(\text{g/day}) - 4.441\,(r = 0.992).$$

However, CH_4 production per unit of feed intake is negatively correlated with an increase in feed consumption for cattle and sheep, although the total output of CH_4 may increase at higher intakes (Hammond et al. 2013; Warner et al. 2017; Goopy et al. 2020). Higher levels of intake are usually achieved by increasing the level of concentrate in the diet, which can increase the production of propionate production and decrease the production of CH_4 (Coppock et al. 1964). A reduction in retention time of feed in the rumen as a result of increased

DMI may also account for the decline in CH_4 production per unit of feed intake (Lechner-Doll et al. 1991). Therefore, maximizing feed intake can be an effective strategy to reduce CH_4 yield per kg DM consumed.

CH_4 production differs among ruminant species, and Shibata et al. (1993) were one of the first authors to use a simple quadratic equation to accurately describe the relationship of CH_4 production and DMI at different feeding levels in dairy cattle, beef cattle, sheep and goats:

$$CH_4 \text{ production} \left(\text{L/day}\right) = -17.766 + 42.793X - 0.8749X^2 \left(r = 0.966\right);$$

where X is DMI (kg/day).

Charmley et al. (2016) reported the equation to predict CH_4 production of forage-fed Australian cattle:

$$CH_4 \text{ production} \left(\text{g/day}\right) = 20.7 \left(\pm 0.28\right) \times \text{DMI} \left(\text{kg/day}\right).$$

Several equations to estimate CH_4 production have been developed based on diet composition across a number of ruminant species (Mills et al. 2003; Beauchemin and McGinn 2006; Ellis et al. 2007; Patra et al. 2016; Bell et al. 2016; Niu et al. 2018). These equations consider not only DMI, but also other nutritional traits such as digestible energy, non-fiber carbohydrate, and neutral detergent fiber. Consequently, the chemical composition of the feed (i.e. forage to concentrate ratio, feed type and quality) can also have a direct influence on CH_4 emissions in ruminants.

3.2.2 Diet composition

Moe and Tyrrell (1979) found that the production of CH_4 per unit of structural carbohydrates (i.e. cellulose and hemicellulose) was higher than that for soluble carbohydrates (i.e. starch and sugars). Later, Johnson and Johnson (1995) suggested to further separate non-cell wall carbohydrates into soluble sugar and starch to improve the estimation of CH_4 production per unit of feed. This differentiation is necessary as, according to Johnson and Johnson (1995), soluble sugars tend to produce more CH_4 than starch. For example, high grain, starch-rich diets can exhibit increased passage rates, propionate production and decreased ruminal pH. As a result, CH_4 production is usually lower with high concentrate than high forage diets. Chemical composition of the feed can also influence enteric CH_4 production. For example, corn grain results in lower CH_4 production than barley grain (Beauchemin and McGinn 2005), and likewise cattle fed corn silage produce less CH_4 than those fed barley silage (Benchaar et al. 2014). These differences likely reflect the high fiber and lower starch content of barley grain and barley silage as compared to corn grain and corn silage. Ruminal CH_4 yields have also been reported to be lower from legume forages (alfalfa, clover, etc.) than grass forages (McCaughey et al. 1999; Benchaar et al. 2001). This may also reflect the lower structural carbohydrate levels of legume forages versus grass forages and possibly their higher rate of passage through the rumen. Finally, plant maturity is also a critical factor in determining the amount of CH_4 produced by ruminants, as the fiber content of forages increases with maturity (Russell et al. 2007). Consequently, DMI decreases and CH_4 production per unit of forage typically increases with advancing maturity (Pinares-Patiño et al. 2007; Molano and Clark 2008). Additional diet components which may impact CH_4 yield (g/kg DMI) in ruminants include the level of digestible organic matter, lipid, neutral detergent fiber, acid detergent fiber and lignin content (Ellis et al. 2007; Bell et al. 2016). As a result, feed quality can be a major determinant of CH_4 emissions in ruminant production systems.

It is well known that CH_4 production is usually lower with high concentrate than high forage diets as has been shown in lactating cows (Kurihara et al. 1997; Lovett et al. 2005; Aguerre et al. 2011), beef cattle (Lovett et al. 2003; Doreau et al. 2011) and goats (Kurihara et al. 1997). Beauchemin and McGinn (2005) reported that CH_4 emissions as a percentage of gross energy intake dropped from 7.42% with a high-forage diet to about 3% with a high-grain diet fed to Angus cattle. However, this practice may result in subacute or acute rumen acidosis (Owens et al. 1998; Plaizier et al. 2008), as well as higher CH_4 emissions from manure (Hindrichsen et al. 2006). Moreover, grain supplementation did not influence daily CH_4 production from grazing beef steers (Boadi et al. 2002), and similar observations were also reported as there was no difference in enteric CH_4 emissions when goats were fed diets at maintenance that differed in forage to concentrate (Lima et al. 2013). This may reflect differences in the quality and quantity of the forage selected during grazing.

Since feed quality affects enteric CH_4 production, corn grain-based diets can be used to replace barley grain diets to lower CH_4 emissions (Beauchemin and McGinn 2005; Fellner et al. 2008; Yurtseven and Ozturk 2009). Similarly, the consumption of legume forages needs to be encouraged in regions where legume forages are suitable for cultivation as ruminant feed, as CH_4 emissions are generally lower for legume forages (McCaughey et al. 1999; Benchaar et al. 2001). Secondary compounds of plants such as condensed tannins may also contribute to the lowering of CH_4 emissions associated with legume forages (Woodward et al. 2002; Beauchemin et al. 2009). Other plants or plant extracts with high levels of bioactive compounds (e.g. saponins, flavonoids, and essential oils) can reduce ruminal CH_4 emissions by affecting metabolic processes and/or the activity of rumen microorganisms, but the effectiveness varies depending on the source, type and concentration of the bioactive (Patra and Saxena 2010; Bodas et al. 2012; Kim et al. 2015). In addition, feed intake and the maturity of the plants need to be considered in this strategy. Feeding

Published by Burleigh Dodds Science Publishing Limited, 2021.

alfalfa hay harvested at the mid-bloom stage is recommended compared to using vegetative-stage hay due to the 15% decrease in CH_4 production relative to gross energy intake (Benchaar et al. 2001).

In addition, forage processing methods may reduce enteric CH_4 production from ruminants if feed intake is not restricted. Grinding or pelleting forages leads to a faster rate of passage and lower fiber digestibility, reducing CH_4 production by 20–40% (Blaxter 1989; Johnson and Johnson 1995; Boadi et al. 2004). However, the extent of physically effective fiber needs to be considered while using forage processing methods to ensure the minimal quantity of fiber required to maintain rumen health and function. Increased ruminal passage rates with pelleted forages can also result in reduced ruminal fiber digestion.

4 Modifying the rumen environment to reduce methane emissions

A number of strategies have been investigated for their ability to reduce enteric CH_4 emissions, either by directly targeting methanogens or limiting the availability of reducing equivalents to convert CO_2 to CH_4. A number of approaches have been undertaken including diet manipulation, a variety of feed additives, immunization, defaunation, genomics technologies, and genetic selection of the host (Table 1).

4.1 Rumen manipulation

4.1.1 Specialty feed and additives

4.1.1.1 Fat supplementation

Addition of fat increases the energy density of the diet and has been shown to effectively mitigate CH_4 emissions in ruminants. Supplementing fat for fermentable carbohydrates can reduce rumen fermentation and decrease the growth of ruminal methanogens and protozoa (Prins et al. 1972; Czerkawski et al. 1975; Zhou et al. 2013). For example, CH_4 emissions (g/day) were reduced by 22% when sunflower oil (400 g/d, 5% of DMI) was added to the diets of Holstein steers (McGinn et al. 2004). In addition to sunflower oil, coconut oil, crushed whole oilseeds (rapeseed, sunflower and linseed) and rumen-protected crystalline fat have been assessed for their ability to lower CH_4 emissions. Machmüller et al. (2000) found that coconut oil and oilseeds decreased CH_4 production (ml/kg live weight) by 10–27% in lambs, a response that was associated with lower numbers of protozoa and a decline in the acetate to propionate ratio. Beauchemin and McGinn (2006) reported that adding canola oil at up to 4.6% of DMI reduced CH_4 emissions (g/d) by 32%, but care needs to be taken as an inclusion of total dietary fat at levels above 6% of diet DM can suppress feed intake and fiber digestibility.

The extent to which fat suppresses CH_4 production depends on the source (i.e. oilseed, tallow, nuts), the form (i.e. whole seed, extruded, extracted oil, protected fat), fatty acid profile, supplementation level, and the composition of the diet (Machmüller et al. 2000, 2003; Machmüller 2006; Jordan et al. 2006a; Petrie et al. 2009). Unsaturated fatty acids can serve as a minor hydrogen sink via biohydrogenation of the double bonds, decreasing the availability of reducing equivalents for methanogens (Johnson and Johnson 1995). Fat supplements that contain high levels of medium-chain fatty acids (e.g. coconut oil, palm kernel oil) are particularly effective at reducing CH_4 emissions as they appear to be toxic to ruminal methanogens (Machmüller and Kreuzer 1999; Machmüller et al. 2003). Long-chain fatty acids may also reduce CH_4 production in an undesirable fashion by lowering DMI and fiber digestion (McGinn et al. 2004; Jordan et al. 2006b). Beauchemin et al. (2007) reported that adding 3% of either saturated or unsaturated long-chain fatty acids in the form of tallow, sunflower oil or whole sunflower seeds to a forage diet reduced CH_4 emissions by 14%, 14% and 33%, respectively. Of these sources, sunflower oil inhibited fiber digestion the least. Fat supplementation has also been shown to reduce CH_4 emissions in grazing cattle (Pinares-Patiño et al. 2016; Beck et al. 2019). However, ensuring uniform intake of fat supplements among individuals in a herd is difficult and care must be taken to ensure that fiber digestion is not inhibited. Furthermore, oilseeds can be expensive and often do not fit into diets that are formulated on a least-cost basis.

4.1.1.2 Ionophores

Ionophores (i.e. monensin, lasalocid, salinomycin, narasin, maduramicin, laidlomycin and semduramicin) are antibiotics that are frequently added to ruminant diets to cause favorable changes in rumen fermentation (Novilla et al. 2017). Monensin, produced by *Streptomyces cinnamonensis,* is the most widely used ionophore and has been extensively used to improve ruminal fermentation and feed efficiency in beef and dairy cattle (Russell and Strobel 1989; Sauer et al. 1998). Monensin reduces CH_4 production by decreasing the ratio of acetate to propionate and inhibiting the growth of ruminal hydrogen-producing bacteria and disrupting the association between methanogens and protozoa (Russell and Houlihan 2003; Guan et al. 2006; Beauchemin et al. 2008). Some studies have shown that monensin can lower CH_4 production by up to 25% (Van Nevel and Demeyer 1995; Tedeschi et al. 2003), but reductions are usually less than this and often do not persist. Guan et al. (2006) tested the effect of monensin on steers fed either a low- or a high-concentrate diet and observed that its inhibitory effects on CH_4 emissions declined over time. Moreover, the effect

Published by Burleigh Dodds Science Publishing Limited, 2021.

of monensin on CH_4 production is dose-dependent. Beauchemin et al. (2008) conducted a meta-analysis (Sauer et al. 1998; McGinn et al. 2004; Van Vugt 2005; Guan et al. 2006; Odongo et al. 2007; Waghorn 2007) and concluded that a dose less than 15 ppm of monensin had no effect on CH_4 production (g/kg DMI).

4.1.1.3 Nitrate

Nitrate (NO_3^-) acts as an electron acceptor which utilizes H_2 as it is reduced to ammonia (NH_3) via nitrite (NO_2^-), a reaction that is thermodynamically more favorable than the reduction of CO_2 to CH_4 by methanogens (Ungerfeld and Kohn 2006). Nitrate can also be directly toxic to methanogens and thus stands out as a potential feed additive to suppress ruminal CH_4 production. However, the reduction of NO_3^- to NO_2^- occurs more rapidly than the reduction of NO_2^- to NH_3 and as a result NO_2^- in the rumen can enter the bloodstream and reach toxic levels (Latham et al. 2016). Nitrite can convert Fe^{2+} to Fe^{3+} within hemoglobin, forming methaemoglobin, which is no longer capable of transporting oxygen (Lee and Beauchemin 2014). The clinical symptoms of acute NO_3^- toxicity include reduced feed intake and gain, reproductive failure or even death (Bruning-Fann and Kaneene 1993).

Despite the risk of toxicity, several studies have evaluated the effect of NO_3^- on CH_4 emissions in ruminants. In general, NO_3^- has been shown to reduce CH_4 production in sheep (Sar et al. 2004; Van Zijderveld et al. 2010; Nolan et al. 2010), dairy cows (Van Zijderveld et al. 2011; Lund et al. 2014), and beef cattle (Hulshof et al. 2012; Velazco et al. 2014; Duthie et al. 2018). Van Zijderveld et al. (2011) reported that NO_3^- (21 g/kg DM) consistently decreased CH_4 emission by 16% in lactating dairy cows. Lund et al. (2014) also tested diets with NO_3^- (20 g/kg DM) and found a significant reduction in CH_4 production both in vivo (31%) with dairy cows and in vitro (10–16%). However, if NO_3^- was removed from the diet, CH_4 emissions returned to pretreatment levels. If the concentration of NO_3^- in the diet is gradually increased, rumen microbes can adapt and accelerate the conversion of NO_2^- to NH_3, reducing the risk of toxicity (Lee and Beauchemin 2014). However, even with this consideration, the risks of NO_2^- toxicity may be too high for NO_3 to be used to lower CH_4 emissions in ruminants under practical production conditions.

4.1.1.4 3-Nitrooxypropanol (3-NOP)

3-Nitrooxypropanol (3-NOP) is a small molecule that binds to methyl-coenzyme M reductase (MCR) and inhibits its active site nickel (I), thereby inhibiting the final step in methanogenesis (Duin et al. 2016). The main advantage of using 3-NOP is that it specifically targets *MCR* within methanogenic archaea without

Table 1 Summary of strategies for reducing enteric GHG emissions in ruminants

Strategy	Mechanism	Advantages/ Limitations	Feasibility of application
Diet Manipulation			
Increased concentrate	Alters VFA production toward propionate; decreases rumen pH and inhibits rumen microbes associated with methanogenesis	Can reduce CH_4 production; Improves production Decreases enteric CH_4 production but may not reduce total GHG emissions; Animals may have acidosis risk	Feasible for housing or grazing systems
Feed types and Forage quality/ maturity	Influences intake and digestibility; some feedstuffs contain secondary compounds that inhibit rumen microbes	Can reduce CH_4 production per unit of product; improves digestibility and animal production May increase feed costs; variable influence on CH_4 production	Feasible for multiple systems but highly dependent on feedstuff availability and environmental factors (e.g. rainfall, temperature)
Forage processing	Influences intake and digestibility	Can reduce CH_4 production immediately Animals may have acidosis risk; increases costs and energy to process forages	May not be feasible for grazing system
Feed Additives			
Fat supplementation	Inhibits microorganisms associated with methanogenesis	Can reduce CH_4 production; can increase diet energy density and animal performance Potential negative impacts on intake, fiber digestibility; needs more information on animal productivity	May not feasible for grazing system
Ionophores	Inhibits microorganisms associated with methanogenesis	Improves feed efficiency; mild to moderate reduction in CH_4 production Lack of long-term inhibitory effect; not approved in some countries	Feasible for housing or grazing system
Nitrate	Reduces H_2 availability, directly toxic to methanogens	Can reduce CH_4 production; can be used to replace urea as a protein source Risk of toxicity; may increase N excretion	Feasible for housing or grazing system

Published by Burleigh Dodds Science Publishing Limited, 2021.

3-NOP	Inhibits methanogens	Reduces CH_4 effectively Needs more information on animal performance, dose suggestions and food safety; not approved in the market	May not be feasible for grazing system
Algae	Inhibits methanogens	Reduces CH_4 effectively Lack of more in vivo studies to show animal performance and long-term effect; may require energy to process the algae	Experimental, but may not feasible for grazing system
Immunization	Inhibits methanogens	Applicable for grazing ruminants, easy to operate in farms Lack of effect information on CH_4 production, animal health and production	Feasible for different systems
Defaunation	Eliminates ruminal protozoa	Reduces CH_4 effectively Adequate level of defaunation depends on diet compositions; some chemical agents are toxic; Needs more research on animal health and performance	Difficult to implement for grazing system
Genomic technology	Inhibits microorganisms associated with methanogenesis	Important for developing vaccines or inhibitors to target microorganisms associated with methanogenesis; may improve feed efficiency and animal productivity by manipulating microbes and their pathways Research is in early stages	Experimental, may be feasible for different systems
Genetic selection	Animal breeding for low CH_4 production per unit of product by manipulating rumen microbiota	Increases the efficiency of production in multiple ruminant systems; may have long-term persistency on reducing CH_4 efficiently Needs to determine genotype and diet interactions; lack of ability to measure CH_4 production on a large population of animals; lack of information on long-term productivity and animal performance	Feasible for different systems

impacting the activity of other microbes involved in the fermentation of feed. To support licensing and application in ruminants, 3-NOP has been experimentally evaluated in dairy cows (Reynolds et al. 2014; Haisan et al. 2014; Hristov et al. 2015), beef cattle (Romero-Perez et al. 2014; Vyas et al. 2018; Martinez-Fernandez et al. 2018) and sheep (Martínez-Fernández et al. 2014) at various doses and with different diets. Early experiments studied the effect of 3-NOP (40 μL/L and 80 μL/L) in vitro using sheep rumen fluid and reported a reduction in CH_4 production of 86–96%, with no effect on total VFA concentration (Martínez-Fernández et al. 2014). Then, 3-NOP was tested in sheep at a dose of 100 mg/d per animal, resulting in a 26% decrease in CH_4 production (g/kg DMI). Haisan et al. (2014) also observed that CH_4 production was decreased by 60% in lactating dairy cows fed 3-NOP at 2.5 g/d, with no negative effect on DMI or milk production. A 30% reduction in CH_4 emissions was also reported in lactating dairy cows fed mixed rations with 40, 60 or 80 mg 3-NOP per kg of DM over 12 weeks (Hristov et al. 2015). In this study, body weight gain increased, indicating the potential repartitioning of energy that would have been lost as CH_4 toward tissue deposition (Hristov et al. 2015). 3-nitrooxypropanol was also shown to improve the feed efficiency of beef cattle fed high-forage diets and high-grain diets, with a 42% and a 37% reduction in CH_4 yield (g/kg DMI), respectively (Vyas et al. 2018). Based on these studies, the optimal dose of 3-NOP was proposed to range between 1 g/day and 2 g/day. Incorporation of 3-NOP into a pelleted supplement versus mixing it into a complete diet reduced CH_4 emissions in lactating dairy cows by 23% and 28%, respectively (Van Wesemael et al. 2019). As no significant difference was observed between the two supplementation methods, it is feasible to administer 3-NOP either in the complete diet or in a pelleted supplement.

When compared to other *MCR* inhibitors (e.g. bromoethane sulphonate – BES) (Grawert et al. 2014), 3-NOP did not reduce feed intake, digestibility or animal performance. Moreover, 3-NOP- (200 mg/kg DM for backgrounding or 125 mg/kg for finishing phase) mediated reductions in enteric CH_4 in beef cattle fed high-grain diets for at least 105 days (Vyas et al. 2018) and in dairy cattle for over 12 weeks (Hristov et al. 2015; Vyas et al. 2018). It has also been reported that 3-NOP decreases total VFA concentration, particular acetate, whereas it increases butyrate levels with no adverse effects on growth of the host (Melgar et al. 2020; Kim et al. 2020). While applications for registration of 3-NOP (Bovaer®) have been submitted to regulatory authorities in Europe and other regions of the world, further studies are required to define the optimum concentrations of 3-NOP that optimize reductions in enteric CH_4 emissions across a range of diets and ruminant production conditions. The development of systems to administer 3-NOP to grazing ruminants will be key, if meaningful reductions in CH_4 are to be achieved throughout the production system. Fortunately, recent studies have shown that administration of 3-NOP is unlikely to result in the release of residues into meat or milk (Thiel et al. 2019a) or cause toxicity (Thiel et al. 2019b).

4.1.1.5 Algae

Algae can be classified according to their size (i.e. microalgae, macroalgae), or based on their pigmentation (i.e. green, red, brown) and the habitat where they grow (i.e. freshwater, marine). All algae produce secondary metabolites that exhibit antimicrobial activity, such as halogenated methane analogues (HMAs) (Plaza et al. 2008; Blunt et al. 2011; Machado et al. 2018). The HMAs (e.g. bromochloromethane, bromoform or chloroform) exert antimethanogenic activity by binding to reduced vitamin B_{12}, blocking the cobamide-dependent methyltransferase reaction needed for the formation of methyl-coenzyme M, and thus consequently mitigating CH_4 emissions (Wood et al. 1968; Machado et al. 2018). Because of these antimicrobial properties, some algae (e.g. *Ascophyllum nodosum* and *Asparagopsis taxiformis*) have been tested in vitro and in vivo for their ability to reduce enteric CH_4 emissions (Wang et al. 2008; Machado et al. 2014; Li et al. 2018a). Machado et al. (2014) evaluated 20 species of tropical macroalgae through in vitro methods and concluded that marine algae were more effective than freshwater algae at inhibiting methanogenesis. Among the examined species, *Asparagopsis* spp. was the most effective at reducing enteric CH_4 production, with reductions as high as 98.9% in rumen fluid after 72 h-incubation (Machado et al. 2014). This result was attributed to secondary metabolites in *Asparagopsis* that inhibited both ruminal bacteria and protozoa (Paul et al. 2006; Genovese et al. 2009). Machado et al. (2018) reported that *Asparagopsis taxoformis* biomass containing 1.3 μM bromoform in vitro was similar to the addition of 5 μM bromoform in reducing CH_4 production, suggesting that bromoform was not the only CH_4 inhibitor in *A. taxiformis*. Li et al. (2018a) showed that addition of *A. taxiformis* at up to 3% of dietary DM lowered CH_4 emissions in sheep by as much as 80%, without impacting weight gain and by as much as 98% in steers with a 42% improvement in weight gain (Kinley et al. 2020). Supplementing *Asparagopsis armata* at 1% of dietary OM reduced CH_4 intensity (g/kg milk yield) in lactating dairy cows by 60% in the short term (Roque et al. 2019). Belanche et al. (2016) proposed that *Ascophyllum nodosum* possessed anti-protozoal activity and showed that it decreased CH_4 emissions from rumen fluid in vitro. Another study also reported that rumen bacteria and methanogens were linearly reduced, while protozoa were increased, when increasing levels (1%, 3% and 5 %) of sun-dried *Ascophyllum nodosum* were fed to sheep (Zhou et al. 2018). Although CH_4 emissions were not measured in this study, the 30–75% decline in total methanogens may have decreased enteric CH_4 emissions.

As can be observed, the effectiveness of algae in reducing rumen CH_4 emissions has been tested in several experiments, but investigations of their efficacy in large-scale beef and dairy production systems are needed. Harvesting of these aquatic plants from natural ecosystems may not be sustainable and scale-up of commercial production systems to a level that could satisfy demand could be both challenging and expensive. Drying and transportation of microalgae and macroalgae can also contribute to the GHG footprint of these additives.

4.1.2 Immunization

Vaccination against rumen methanogens has been studied for its ability to mitigate CH_4 emissions, an approach that is particularly appealing for use in grazing ruminants. Vaccines induce the immune system of the host animal to produce antibodies, which could potentially enter the rumen via saliva and bind to antigenic proteins located on the surface of methanogens, inhibiting their growth and activity (Williams et al. 2009; Wedlock et al. 2010, 2013; Subharat et al. 2016). Antibodies have been shown to be stable in the rumen for at least 8 h (Williams et al. 2008), but sufficient diversity and quantities of antibodies must enter the rumen so as to impact the diversity and the majority of the methanogens within the rumen.

Whole methanogen cells from different methanogen species have been investigated for their immunogenicity in grazing sheep in Australia and New Zealand, but results have been inconsistent (Wright et al. 2004; Leslie et al. 2008; Williams et al. 2009). Zhang et al. (2015) vaccinated goats with a new recombinant protein (*EhaF*, energy-converting hydrogenase A subunit F), which is a *Methanobrevibacter ruminantium* M1 adhesin-like protein responsible for hydrogenotrophic methanogenesis. The vaccine had no apparent impact on enteric CH_4 emissions or ruminal methanogens, although it did alter the composition of the bacterial community. Also, whole fixed protozoal cells have been evaluated as antigens in vaccines to control protozoa in the rumen of sheep, but this approach also was not shown to be effective (Williams et al. 2008). Improving the specificity of antibody targets against methanogens and enhancing immune responses so as to increase the concentration of antibodies that enter the rumen could improve the efficacy of anti-methanogen vaccines.

4.1.3 Defaunation

Defaunation is a process whereby ruminal protozoa are reduced or eliminated from the rumen by dietary, chemical or biological agents. Several chemicals (e.g. copper sulfate, dioctyl sodium sulfosuccinate and detergents) have been used to remove protozoa from the rumen (Becker and Everett 1930; Burggraaf and Leng 1980; Rowe et al. 1985). However, the most promising approach for removing protozoa from the rumen is through dietary manipulation as chemical agents may be harmful to host health (Williams and Coleman 1992; Ushida et al. 1997). Removal of protozoa from the rumen has been proposed as a strategy to reduce enteric CH_4, as 9–37% of total ruminal CH_4 emissions are attributed to interspecies hydrogen transfer between protozoa and methanogens (Newbold et al. 2015). Prolonged feeding of high grain and the resulting lower ruminal pH can inhibit the growth and reduce the diversity of protozoal populations (Whitelaw et al. 1984; Kreuzer and Kirchgessner 1987). This outcome could be one of the reasons why CH_4 emissions tend to be lower in ruminants fed high concentrate versus high forage diets. Addition of fat to the diet can also lower protozoa numbers. Coconut oil, in combination with high concentrate diets, has been recommended as an alternative feeding strategy that could reduce CH_4 emissions by up to 57% (Machmüller et al. 1998; Nguyen and Hegarty 2017). The effectiveness of defaunation at lowering CH_4 emissions depends on the composition of the diet, as suppression of protozoa in ruminants fed high-forage diets can significantly inhibit fiber digestion (Li et al. 2018b). Furthermore, most defaunation procedures do not remove all protozoa from the rumen, and if they do it is challenging to ensure that ruminants remain defaunated under practical production conditions. Some studies have suggested that programming microbial colonization in the neonate could result in life-long reductions in enteric CH_4 emissions (Hegarty et al. 2008; Yáñez-Ruiz et al. 2015). Although these studies have shown that these approaches can alter microbial community structure and/or activity post-weaning, they have yet to demonstrate a life-long reduction in enteric CH_4 emissions.

4.1.4 Genomic approaches in characterizing and reducing methanogenesis

It is challenging to find a universal approach for effectively mitigating enteric CH_4 production in different farming systems (housing or grazing) without influencing nutrient digestibility and animal productivity. Following the advancement of omics technologies, more in-depth information of the rumen microbiome has revealed remarkable host-microbe interactions and how they contribute to CH_4 production. Whole genome sequencing, as the basis of these technologies, plays a critical role in targeting methanogens and other ruminal microbes that produce substrates for methanogenesis. Culturomics is thought to be a useful technology for characterizing, as of yet, uncharacterized rumen microorganisms. A 'Hungate1000' project was launched in 2012 aiming to sequence 1000 cultured rumen microbial genomes to enhance our knowledge about the diversity and function of these microbes (Seshadri et al. 2018). Currently, 501 genome sequences of rumen microorganisms have been

Published by Burleigh Dodds Science Publishing Limited, 2021.

generated, of which 480 are bacterial genomes and 21 are archaea (Seshadri et al. 2018; Newbold and Ramos-Morales 2019). This includes members of 9 phyla, 48 families and 82 genera, with many species represented by only one or a few isolates. Although, multiple isolates of some polysaccharide-degrading genera such as *Butyrivibrio*, *Prevotella* and *Ruminococcus* were sequenced. Next-generation sequencing helps researchers predict rumen microbial function from metataxonomic data. In this context, the available rumen microbial genomics of a single species can be applied to identify and explain the process of methanogenesis based on microbial genomes (i.e. methanogens and other microbes-contributing substrates to methanogens) and the specific proteins that are expressed during methanogenesis (Huws et al. 2018). For example, Gilmore et al. (2017) reported that assembly and analysis of the methanogen genomes enabled the metabolism of four methanogens (*Methanobacterium bryantii*, *Methanosarcina spelaei*, *Methanosphaera cuniculi* and *Methanocorpusculum parvum*) to be predicted. They found all sequenced methanogens were enriched for genes in energy production and conversion, coenzyme transport and metabolism, but were lower in genes assigned to carbohydrate and lipid transport and metabolism. With a greater understanding of methanogen metabolism, CH_4 production may be modified by optimal designing of biochemical processes. Furthermore, with the revealing of the presence of a prophage (*peiR*) in the rumen methanogen (*M. ruminantium* M1) genome, another potential approach using the phage-encoded lytic enzyme (endoisopeptidase PeiR) to specifically target and lyse the pseudomurein cell walls of rumen methanogens could provide another viable strategy to reducing enteric CH_4 emissions (Leahy et al. 2013; Altermann et al. 2018; Gilbert et al. 2020). Microbial genomes can also enhance our understanding of microbial interactions that drive methanogenesis, such as the commensal relationship between methanogens and ciliates. However, to date, unlike rumen bacteria and archaea, our knowledge of the genomes of protozoa and fungi is limited as a result of their G-C rich genomes which are difficult to assemble.

Tapio et al. (2017) revealed that methanogenesis may be associated with the composition of rumen archaeal community but not archaea abundance, especially with the *Methanobrevibacterium gottschalkii* clade. Therefore, metagenomics would be a useful tool to understand methanogenesis mechanisms in the rumen by predicting microbial metabolic functions. By characterizing methanogens in the buffalo rumen through metagenomics, genes encoding key steps in the process of methanogenesis were identified (Singh et al. 2015). In a beef cattle study, the abundance of archaeal genes in rumen digesta differed between high and low CH_4-emitting steers, with eight genes being differentially abundant between these two populations (Wallace et al. 2015). *Succinovibrionaceae* were more abundant in the low CH_4 emitters, whereas *Methanobrevibacter* were more abundant in high CH_4 emitters.

Researchers have characterized the rumen microbiota of high CH_4-emitting and low CH_4-emitting sheep, finding that lactic acid-producing *Sharpea azabuensis* were more abundant in low CH_4 emitters (Kamke et al. 2016). These studies support the possibility of there being value in selecting ruminants for specific rumen microbiota that are associated with lower enteric CH_4 emissions.

McAllister et al. (2015) outlined several metagenomic and metatranscriptomic approaches that could be used to mitigate enteric CH_4 emissions. The chemogenomics approach is based on finding chemical compounds that inhibit specific proteins expressed by genes involved in methanogenesis. This methodology resulted in the development of 3-NOP (Duval and Kindermann 2012) as described above. Using genomics to identify extracellular proteins with improved antigenicity in the host could improve the efficacy of vaccines against methanogens.

4.2 Improved genetic selection

It has been reported that CH_4 yield (g/kg DMI) varies among individual ruminants fed the same diet. Pinares-Patiño et al. (2003) found that some pastured sheep were persistent-high or low CH_4 emitters in four separate measurement periods. This might be due to genetic differences in CH_4 production among individuals and variation in rumen methanogenic ecology (Zhou et al. 2009). This strategy aims to link genetic traits (e.g. weaning weight, dag score, muscle depth) with the rumen microbiota in order to predict CH_4 yield phenotypes across ruminant species (Kamke et al. 2016). Through the identification of rumen microbiome of these grazing sheep, they discovered that species closely related to the lactic acid-producing, *Sharpea azabuensis*, were more abundant in low CH_4-emitting sheep. In contrast, H_2 producing *Ruminoccocaceae*, *Lachnospiraceae* and *Verricomicrobia* were more prevalent in the rumen of high CH_4-yielding sheep (Kittelmann et al. 2014; Kamke et al. 2016). These findings suggest that the selection of ruminants that yield less CH_4 per unit of DMI may be a viable strategy to lower herd emissions. Residual feed intake (RFI), as an indicator of cattle feed efficiency, is the difference between actual feed intake and the expected feed intake estimated from body weight, growth rate and production over a specific period (Jones et al. 2011). Researchers have demonstrated that cattle with low RFI emit less CH_4 than animals with high RFI (Hegarty et al. 2007; Zhou et al. 2009). This finding promoted studies focusing on the genetic selection for low RFI animals (Weber et al. 2016). However, some studies have contradicted these findings, suggesting that CH_4 yields may actually be higher in low-RFI cattle (McDonnell et al. 2016; Velazco et al. 2017; Flay et al. 2019). It has been suggested that this strategy of selecting animals with low RFI for the suppression of CH_4 emissions could be more advantageous for systems that rely on the use of low-quality feeds in ruminant production (Patra 2012).

Nucleic acids have been used as genetic markers for rumen microbial processes (Huws et al. 2018) and those genetic markers related to ruminant CH_4 production have been studied in recent years. Golder et al. (2018) studied the genetic markers associated with rumen microbiome and metabolome of dairy heifers fed high grain diets. They observed that some metabolites (e.g. acetate to propionate ratio, lactate) and rumen microbial phyla (e.g. Actinobacteria, Euryarchaeota, Fibrobacteres) had associated markers and quantitative trait loci, which may enable selection for acidosis-resistant cattle with lower CH_4 emissions. A high genetic correlation between DMI and predicted CH_4 emissions was revealed by Pickering et al. (2015) using a data set that included 1726 dairy cows, where one single nucleotide polymorphism (SNP) on chromosome 7 was reported to be associated with CH_4 emission traits. Singh et al. (2015) identified the functional genes involved in rumen methanogenesis and acetogenesis pathways in Indian buffalo, which were key enzymes in CH_4 production. Their results also contributed new knowledge about acetogenic bacteria that compete with methanogens and thus may be useful to reduce CH_4 emissions. Roehe et al. (2016) suggested using archaeal abundance in ruminal digesta to genetically select animals for lower enteric CH_4 emission, avoiding the need for direct measurement of enteric CH_4 emissions. They also identified 20 genes (e.g. *mcrA* and *fmdB*) associated with CH_4 production through metagenomic analysis of rumen contents. These results contradicted with those of Carberry et al. (2014) where they found that diversity rather than abundance of methanogens determined the extent of enteric CH_4 emissions. Auffret et al. (2018) identified genes associated with the hydrogenotrophic methanogenesis pathway in beef cattle of different breeds fed different diets and suggested that they could be used as biomarkers of CH_4 emissions. The inconsistencies across these studies may reflect the challenges of comparing divergent data sets from different animals fed various diets as well as differences in sampling method, sample preparation and data analysis (Huws et al. 2018).

Nevertheless, as some rumen microbial features have been reported to be heritable and influenced by host genetics in beef cattle (Li et al. 2019), it has been suggested that it should be possible to genetically select for ruminants with low CH_4 emission traits. Wallace et al. (2019) collected samples from over 1000 dairy cows to investigate the relationship of host genomics and rumen microbiome as well as their interactions on CH_4 emissions. Difford et al. (2018) studied the individual variation in CH_4 production influenced by both host genetics and rumen microbiome in dairy cows. They reported that host genotypes can explain 21% of the individual variance while the cumulative effect of rumen bacteria and archaea was 13%, and these two were independent. The core rumen microbiome was found to be correlated with host genetics, and the possibly heritable rumen microbes raise the possibilities of selecting for low CH_4-emitting cattle. However, the complexity of measuring enteric CH_4 emissions may make it difficult to employ this approach in commercial ruminant production systems.

5 Conclusion

Research in the genetics, nutrition, microbiology, and physiology of ruminants has identified several strategies that are effective at reducing CH_4 emissions per unit of animal product (i.e. milk, meat or wool). Altering the composition of the diet and some feed additives are capable of reducing enteric CH_4 emissions, particularly in ruminants fed total mixed diets where additives can be easily administered. Some of these technologies only suppress CH_4 emission in the short term and almost all must be administered daily to be effective. Administration of these additives is notoriously difficult in more extensive grazing-based ruminant productions systems, which incidentally are often responsible for the largest portion of CH_4 emissions in ruminant production systems. Immunization and genetic selection are CH_4 mitigation approaches that could be applicable to grazing ruminants. However, evidence that vaccination can reduce enteric CH_4 emissions is still lacking and the complexities of measuring enteric CH_4 production has hampered the adoption of this selection criterion in commercial breeding programs.

Overall, a combined approach may be the best strategy to achieve a consistent decrease in CH_4 emissions in ruminants. For example, dietary management in a feed-efficient herd will help to reduce the intensity of enteric CH_4 emissions. Furthermore, novel strategies to reduce CH_4 production per unit of milk or meat in grazing systems need to be emphasized. Besides, consumers' preference regarding animal welfare, food quality and safety need to be taken into consideration while developing and selecting strategies that reduce enteric CH_4 emissions.

6 Where to look for further information

The Global Research Alliance harbors a livestock research group that is focused on reducing the greenhouse gas emissions intensity of livestock production systems and increasing the quantity of carbon stored in soils. It is home to a number of relevant networks including the Animal Health and Greenhouse Gas Emissions Intensity Network; Animal Selection and Genetic and Genomics Network; Feed and Nutrition Network; Manure Management Network and Rumen Microbial Genomics Network. The Global Rumen Census, Low Emission Livestock Development and Measuring, Reporting and Verifying Greenhouse Gases activities were also developed within this organization.

- https://globalresearchalliance.org/research/livestock/.

The Livestock Environmental Assessment and Performance Partnership has also produced a number of documents related to sustainability in livestock production systems. Particularly relevant documents would include guidelines on: Environmental performance of feed additives in livestock supply chains; Measuring and modelling soil carbon stocks and stock changes in livestock production systems; Environmental performance of animal feeds supply chains; Greenhouse gas emissions and fossil energy demand from small ruminant supply chains; Environmental performance of large ruminant supply chains.

- http://www.fao.org/partnerships/leap/resources/guidelines/en/.

The Intergovernmental Panel on Climate Change can also be a useful source on overall anthropogenic impacts on climate change. Some sections of the report are related to agricultural production and the role of livestock in greenhouse gas emissions. Searching the site using the term 'Agriculture' will bring up most relevant documents.

Ammonia Emissions from North Carolina Hog Operations' Animal Waste Management Systems to Produce Biogas

Dr. Viney P. Aneja
Department of Marine, Earth and Atmospheric Sciences
North Carolina State University
Raleigh, NC 27695-8208
vpaneja@ncsu.edu

January 20, 2022

As part of my on-going research on air quality issues surrounding concentrated animal feeding operations (CAFOs), I have been doing further analysis of ammonia emissions from hog operations, and have also revisited my own research papers. I wanted to share these findings with you promptly.

The hog industry in North Carolina is in the process of retrofitting existing animal waste management systems to produce biogas. The conversion of animal manure to biofuels (e.g. biogas) is often promoted as an environmentally beneficial management system, with a potential to reduce greenhouse gas emissions. Anaerobic digestion (AD) is a method for converting biomass into bioenergy. Livestock manure is a commonly used biomass material for production of bioenergy.

My 2008b research paper (attached) calculated the per-hog ammonia emission from combined sources (water-holding structure and barns) at a CAFO that used anaerobic digestion to produce biogas, and found that for the same ambient temperature, this emission increased by 12% relative to a comparable CAFO that does not produce biogas, that is, a CAFO employing traditional lagoon and sprayfield technology. My recent analysis has allowed me to determine the specific increase for the open lagoon (secondary lagoon) storing anaerobic digestate. I have determined that the per-hog ammonia emission from anaerobic digestate stored in an open water holding structure without additional treatment (i.e., an open secondary lagoon) increased by approximately 66 percent compared to the per-hog emission from a conventional anaerobic hog waste lagoon (primary lagoon).When a treatment module intended to reduce ammonia emissions was functioning in the cooler month of November 2002, the per-hog ammonia emission from the water holding structure decreased by approximately 59 percent compared to a conventional anaerobic hog waste lagoon. See table below.

Note that these figures represent the changes to the ammonia emissions rate from a given source (water-holding structure or house) as a percentage of the per-hog nitrogen-excretion rate (referred to in my paper (2008b) as %E, as discussed on page 1152) at conventional and biogas-producing facilities. The %E values in the table below represent the emissions at conventional and biogas-producing CAFOs, normalized to account for differences in the size of lagoons, the number and weight of hogs, and differences in feed and other factors affecting nitrogen excretion.

This information is drawn from my 2008b paper entitled "Characterizing Ammonia Emissions from Swine Farms in Eastern North Carolina: Part 2—Potential Environmentally Superior Technologies for Waste Treatment," which is discussed in more detail below. A copy of the paper is attached. This analysis updates the information I provided in an expert report in the N.C. Office of Administrative Hearings, which I understand was submitted to DEQ in December 2021 as an attachment to comments regarding the forthcoming biogas general permit.

The data from my 2008 research paper indicate that storage of waste from covered anaerobic digesters in open lagoons (i.e. secondary lagoon) without additional treatment increases lagoon emissions of ammonia significantly. Ammonia emissions are a serious concern for air quality and water quality. The data also indicate that additional treatment dramatically reduces these ammonia emissions.

Background

Anaerobic digesters do not significantly change the nutrient quantity in the waste as nitrogen and phosphorus are retained and only carbon is reduced through conversion and degassing of methane and carbon dioxide. However, the mass of organic nitrogen is decreased, and it is mineralized to TAN (Total Ammoniacal Nitrogen=NH_4^+ N + NH_3); i.e. NH_3 N expressed as a percentage of Total Kjeldahl Nitrogen (TKN) increases as manure is digested.

Thus, ammonia (NH_3) and ammonium (NH_4^+) are found at higher concentrations in liquid digestates than raw manure (Amon et al., 2005; Clemens et al., 2006; Weaver et al., 2012; Nkoa, 2014). Therefore, anaerobic digestates stored in open secondary lagoons and land-applied to fields have higher NH_3 emission than undigested animal manures and slurries (Strik et al., 2006; Aneja et al., 2008 a, b; (Harper et al., 2010); Alburquerque et al., 2012; Nkoa, 2014) especially as the temperature increases. Factors such as temperature and pH may alter the equilibrium between ammonia and ammonium. For example, increasing temperature and pH will enhance ammonia emissions (Angelidaki and Ellegaard, 2003; Weaver et al., 2012; Nkoa, 2014). Air movement across an open lagoon surface also enhances NH_3 loss (Dari et al., 2019).

An increase in NH_3 emissions relative to conventional open lagoons during the month of April from a secondary lagoon filled with digestate from a covered anaerobic digester at Barham Farm was documented in North Carolina in 2008 as part of the North Carolina State University Animal and Poultry Waste Management Center's evaluation of potentially environmentally superior technologies (ESTs) (Aneja et al., 2008 a, b).

Barham Farm (Aneja et al., 2008 b) (35.70 °N, 78.32 °W, 130 m mean sea level [MSL]) is located near Zebulon in Johnston County, NC. Field campaigns were conducted during April 1–12, 2002 and November 11–22, 2002, at this farm site. A schematic layout of the EST at Barham farm including the various sampling locations is given in Figure 2 of the attached paper (Aneja et al., 2008 b). This potential EST had an in-ground ambient digester comprised of a covered anaerobic waste lagoon. The primary lagoon was covered by an impermeable layer of 40-mm thick high-density polypropylene that prevented gaseous methane and other gases and odor from escaping into the atmosphere during the digestion process. Methane gas produced during the digestive process was extracted and burned into a biogas generator to produce electricity. Heat from the generator was captured and used to produce hot water that was used by the farm in its production activities. Effluent from the digester (covered lagoon) flowed into a storage pond with a surface area of 4459 m^2. This storage pond was formerly part of the primary anaerobic lagoon before the digester was built. A portion of this effluent was supposed to be further treated via biofilters, the purpose of which was to convert NH_4^+ to nitrate in the effluent. This nitrified effluent was then used to flush out the swine production facilities, and the excess effluent was channeled into the larger overflow pond with a surface area of 19,398 m^2. A heavy polymer baffle separated the overflow and storage ponds. The overflow pond was used to store rainwater and overspills from the storage pond. Water from the overflow pond was also pumped into a nitrification biofiltration system where the nutrients in the treated effluent were used to fertilize vegetables grown in greenhouses adjacent to the swine production facility. In this study, NH_3 flux measurements were made from the surfaces of the storage pond, the overflow pond, and from the covered anaerobic primary lagoon. Average NH_3 concentrations were measured using the OP-FTIR spectroscopy system across the forced ventilation fan openings, as well as along the sides of swine houses (barns) to estimate barn emissions during the experimental periods.

During the first measurement period in April, we were notified that the biofilter components of the EST were not operational during that time. These conditions and process make the Barham Farm results from April 2008 similar to the current biogas project developing in Eastern North Carolina. For the April results, the digestate was placed in an open water holding structure with no additional treatment, since the biofilters were not functioning. This means that the April 2002 sample results from the water-holding structure are functionally the same as an open secondary lagoon as is proposed for the recently-permitted North Carolina biogas project sites.

Analysis

Ammonia emission results for Barham Farm are presented in Table 4 of my 2008 paper (Aneja et al., 2008 b), “Summary of NH_3 emissions from the EST farms and percent reduction during the experimental periods,” and I have supplemented them with greater granularity as shown below in the right-hand column in bold. The percent reduction for the water-holding structure (lagoon) was calculated using the data in Table 4 of my 2008 paper and Formula 3 on page 1152 of the paper.

Barham Farm - Ammonia Emissions

Sampling Period	Emission Source	%E_{EST}	%E_{EST} (WHS + House)	%E_{conv}	%E_{conv} (WHS + House)	%Reduction (WHS + House)	%Reduction (WHS)
April 2002	WHS	18.8	39.4	11.3	35.2	-11.9	**-66.4**
	House	20.6		23.9			
November 2002	WHS	4.0	31.7	9.7	32.5	2.5	**58.8**
	House	27.7		22.8			

WHS = water-holding structure (lagoon)
House = animal confinement barns
E_{EST} = ammonia emissions at Barham Farms
E_{conv} = emissions at conventional CAFO employing lagoon and sprayfield technology

This detailed analysis shows the following:

1. Ammonia emissions for both the water-holding structure and the houses combined at Barham Farm during the warmer period, April 2002, when “we were notified that the EST was not fully functioning as designed, because the biofilters were not operational during that time,” shows an increase (i.e., a negative reduction) in ammonia emissions of 11.9% (WHS+House).

2. Ammonia emissions for the water-holding structure during April 2002 when “we were notified that the EST was not fully functioning as designed, because the biofilters were not operational during that time” showed an increase in ammonia emissions of approximately 66% (WHS only).

3. During the cooler period, November 2002, when the EST treatment system was functioning, there was a decrease in total ammonia emissions of 2.5% (WHS+House).

4. During the cooler period, November 2002, when the EST treatment system was functioning, there was a decrease in ammonia emissions from the water-holding structure of approximately 59% (WHS only).

This additional and detailed analysis of ammonia emissions leads me to conclude that the implementation of a biogas system using a covered anaerobic digester followed by an open secondary storage lagoon without additional treatment will have serious negative consequences at CAFOs in North Carolina by way of enhanced ammonia emissions and impact on the environment. These enhanced ammonia emissions could be eliminated, and the problem of overall ammonia emissions could be mitigated, by adding an effective treatment module.

ABSTRACT

Storage of slurry is an important emission source for ammonia (NH_3), nitrous oxide (N_2O), methane (CH_4), carbon dioxide (CO_2) and hydrogen sulfide (H_2S) from livestock production. Therefore, this study collected published emission data from stored cattle and pig slurry to determine baseline emission values and emission changes due to slurry treatment and coverage of stores. Emission data were collected from 120 papers yielding 711 records of measurements conducted at farm-, pilot- and laboratory-scale. The emission data reported in a multitude of units were standardized and compiled in a database. Descriptive statistics of the data from untreated slurry stored uncovered revealed a large variability in emissions for all gases. To determine baseline emissions, average values based on a weighting of the emission data according to the season and the duration of the emission measurements were constructed using the data from farm-scale and pilot-scale studies. Baseline emissions for cattle and pig slurry stored uncovered were calculated. When possible, it was further distinguished between storage in tanks without slurry treatment and storage in lagoons which implies solid-liquid separation and biological treatment. The baseline emissions on an area or volume basis are: for NH_3: 0.12 g m^{-2} h^{-1} and 0.15 g m^{-2} h^{-1} for cattle and pig slurry stored in lagoons, and 0.08 g m^{-2} h^{-1} and 0.24 g m^{-2} h^{-1} for cattle and pig slurry stored in tanks; for N_2O: 0.0003 g m^{-2} h^{-1} for cattle slurry stored in lagoons, and 0.002 g m^{-2} h^{-1} for both slurry types stored in tanks; for CH_4: 0.95 g m^{-3} h^{-1} and 3.5 g m^{-3} h^{-1} for cattle and pig slurry stored in lagoons, and 0.58 g m^{-3} h^{-1} and 0.68 g m^{-3} h^{-1} for cattle and pig slurry stored in tanks; for CO_2: 6.6 g m^{-2} h^{-1} and 0.3 g m^{-2} h^{-1} for cattle and pig slurry stored in lagoons, and 8.0 g m^{-2} h^{-1} for both slurry types stored in tanks; for H_2S: 0.04 g m^{-2} h^{-1} and 0.01 g m^{-2} h^{-1} for cattle and pig slurry stored in lagoons. Related to total ammoniacal nitrogen (TAN), baseline emissions for tanks are 16% and 15% of TAN for cattle and pig slurry, respectively. Emissions of N_2O and CH_4 relative to nitrogen (N) and volatile solids (VS) are 0.13% of N and 0.10% of N and 2.9% of VS and 4.7% of VS for cattle and pig slurry, respectively. Total greenhouse gas emissions from slurry stores are dominated by CH_4. The records on slurry treatment using acidification show a reduction of NH_3 and CH_4 emissions during storage while an increase occurs for N_2O and a minor change for CO_2 as compared to untreated slurry. Solid-liquid separation causes higher losses for NH_3 and a reduction in CH_4, N_2O and CO_2 emissions. Anaerobically digested slurry shows higher emissions during storage for NH_3 while losses tend to be lower for CH_4 and little changes occur for N_2O and CO_2 compared to untreated slurry. All cover types are found to be efficient for emission mitigation of NH_3 from stores. The N_2O emissions increase in many cases due to coverage. Lower CH_4 emissions occur for impermeable covers as compared to uncovered slurry storage while for permeable covers the effect is unclear or emissions tend to increase. Limited and inconsistent data regarding emission changes with covering stores are available for CO_2 and H_2S. The compiled data provide a basis for improving emission inventories and highlight the need for further research to reduce uncertainty and fill data gaps regarding emissions from slurry storage.

1. Introduction

Livestock production systems around the world generate slurry—a mixture of feces and urine from housed livestock, mixed with bedding material and cleaning water (Pain and Menzi, 2011). Storage of slurry is required to enable the spreading in the field at appropriate time to supply nutrients to crops. Thus, a major part of the slurry is transferred from housings to outdoor stores such as tanks (at or above ground level) or earthen lagoons. Stores have variable forms and dimensions (e.g. up to several hectares for lagoons) according to the required storage volume. They have been identified as important emission sources for ammonia (NH_3), hydrogen sulfide (H_2S) and greenhouse gases (GHGs) including nitrous oxide (N_2O), methane (CH_4) and carbon dioxide (CO_2) from livestock production. Slurry stores are complex systems which influence emissions in many ways (Sommer et al., 2006; VanderZaag et al., 2008; Sommer et al., 2013).

A thorough description on principal mechanisms influencing the release of NH_3, GHGs and H_2S from slurry stores can be obtained from several studies (Olesen and Sommer, 1993; Ni, 1999; Sommer et al., 2006; VanderZaag et al., 2008; Sommer et al., 2013). Some important basic principles are summarized here. Slurry stores have a defined area where the gas exchange with the atmosphere takes place. It is a diffusive process and is quantified by emission rate values with the unit mass per area and time. Dissolved species of the gases are produced through microbial breakdown of nitrogen or organic compounds in the bulk slurry. Depending on prevailing chemical equilibria (e.g. NH_3/NH_4^+ which shifts to NH_4^+ at a low pH-value) and absence of microbial consumption, the gases move towards the emitting surface driven by diffusion (i.e. movement due to concentration gradients) and convection where parcels of air or liquid induce a movement of the compounds in the slurry (Sommer et al., 2013). At the slurry-air interface, the compounds pass gas- and liquid-phase resistances and diffuse into the air where they are transported to the atmosphere by convection. Transport within the liquid phase is temperature dependent and the gas-phase transfer is dependent on both temperature and turbulence (VanderZaag et al., 2015). Depending on the dry matter content of the slurry or more precisely, the amount of particles in the slurry which is influenced by the slurry type, animal species, animal diets, the thickness of the slurry bulk layer in the stores and meteorological conditions (Smith et al., 2007), a natural crust at the slurry surface can develop. It constitutes a barrier to the gas molecules between the liquid and the air. NH_3 and CH_4 may be consumed due to microbial activity in the crust leading to an emission reduction (Petersen and Ambus, 2006; Nielsen et al., 2010) while N_2O production may be enhanced (VanderZaag et al., 2009).

Ammonia has a large variety of negative environmental impacts which encompass the quality of air, soil and water, ecosystems and biodiversity. Moreover, it contributes to the formation of particulate matter which impairs human health (Sutton et al., 2011). N_2O and CH_4 are strong GHGs (Myhre et al., 2013). H_2S is often related to odor nuisances and can be lethal to animals and humans at high exposure levels (Sommer et al., 2013). NH_3 and GHG emissions have been regulated by the 1999 Gothenburg Protocol to Abate Acidification, Eutrophication and Ground-level Ozone (UNECE, 1999) and by the Kyoto protocol arising from the UN Framework Convention on climatic change (UN, 1997), respectively. Member countries of these protocols are obliged to calculate and report their national emissions annually, to track changes and compare to national emission ceilings where applicable. The methods for emission reporting are defined in EEA (2016) for NH_3 and in IPCC (2006) for N_2O and CH_4.

EEA (2016); IPCC (2006) and UNECE (2014) provide emission factors for slurry storage or numbers for emission reduction related to mitigation techniques which are used for emission reporting in emission inventories. However, a considerable number of recent studies on emissions from slurry storage provide updated information. The present review paper aims therefore to collect the data on NH_3, GHGs (CH_4, N_2O, CO_2) and H_2S emissions from these recent but also from previous studies and to provide a comprehensive overview on emissions from cattle or pig slurry stored uncovered and emission changes due to slurry treatment and coverage of slurry stores. This information can be used for the purpose of guide values, e.g. for the evaluation of emission data, and for improving emission inventories (greater accuracy, reduced uncertainty), e.g. for the determination of baseline emissions or emission reductions due to slurry treatment or coverage of slurry stores. The compiled data is entirely provided in the Supplementary data 2 for tracking the present or conducting future analyses.

2. Material and methods

2.1. Data search and data selection

A literature research was carried out with Web of Science [5.3] using the following search terms: "storage", "slurry", "emission"; "lagoon", "slurry", "emission". These searches were done on January 10, 2018 and yielded 601 papers in total. In a first screening, 290 papers were eliminated because they did not encompass livestock slurry. The remaining 311 articles were retained. In addition, 58 papers were found in the reference list of the screened articles. Therefore, in total, 369 articles were retained for further screening according to the following criteria:

(i) The investigated slurry was produced in an animal operation and consisted of urine and feces excreted from the animals onto a floor of a barn, a hardstanding or a milking parlor. The slurry might contain solids like bedding material or feed residues and be diluted with water. The investigated slurry was untreated or submitted to a treatment such as solid-liquid separation, anaerobic digestion, addition of an acid (acidification), additives or co-substrates. The treatment occurred under real-world conditions or after slurry sampling in the laboratory. Studies based on synthetic slurry, e.g. urine and feces collected separately from animals and subsequently combined in the laboratory, were excluded since fresh animal excretions substantially differ in chemical composition from stored slurry (Table 6). Moreover, urine and feces deposited onto a floor can rapidly undergo processes leading to gaseous losses. Hence, synthetic slurries might induce different emission levels as compared to slurries submitted to real-world conditions.

(ii) The untreated or treated slurry was transferred from the animal operation to a storage tank or a lagoon outside of animal housings and then submitted to measurements under real-world conditions or the slurry as characterized under point (i) was collected from a floor, an underfloor pit or an outside store and subsequently transferred to an experimental vessel where emissions were measured at pilot- or laboratory-scale. Studies encompassing e.g. emissions from a pit below an animal confinement were excluded since such facilities provide an environment which substantially differs from outside stores (e.g. exposure to outdoor climate, disturbance of the slurry surface due to continuous addition of animal excretions over almost the whole area of a pit).

(iii) The reported emission data are based on experimental determination of emission rates as defined by VanderZaag et al. (2008). Studies providing gas concentrations only were excluded.

(iv) The article provides numerical data encompassing emission data or percent differences in emissions between a slurry submitted to a treatment or slurry stored with covering and a reference system with untreated slurry or uncovered storage, respectively.

After evaluation, 120 papers complied with criteria (i) to (iv). 93 papers did not provide numerical data or comply with these criteria but included substantial information on emissions from slurry storage, e.g. basic mechanisms driving emissions. The remaining 156 papers were excluded because they were out of topic or did not provide substantial information. An overview on the screened papers is in Supplementary data 1.

2.2. Data extraction

Data from the 120 papers were extracted. The parameters as shown in Table 1 were transformed, standardized or aggregated where necessary and then compiled in a database. Overall, 711 records were available for the analysis where one record is defined as an ensemble of entries listed in Table 1 (i.e. multiple records may be created from a single paper). Each record may differ in completeness according to the information provided in a paper.

2.3. Standardization of emission data

Emissions were reported in the papers using numerous units involving the gas molecule (i.e. NH_3, N_2O, CH_4, CO_2 and H_2S) or N, C or S included therein and various units for weight, time and surface or volume. Also, cumulative emissions were given over the entire experimental period. Overall, 36, 22, 31, 13 and 3 different ways for emission reporting were found for NH_3, N_2O, CH_4, CO_2 and H_2S, respectively. Standardization was performed in the present study to obtain comparable values over all records. For all emission rates, the unit g of molecules was used according to UNECE, (2015) and IPCC (2006). An emission on an area basis was applied for NH_3, N_2O, CO_2 and H_2S. For CH_4, the emission relative to the bulk volume was employed. Due to the availability of numerous additional records, data relative to the area were also provided for CH_4. For the area and the volume, the unit m^2

Table 1
Parameters extracted from the papers after transformation or standardization and transferred into the database. Explanations are given for parameters marked with symbols in the table footnote. The complete extracted data are provided in the Supplementary data 2.

Parameter	Explanation
Year	Date the study was published
Country	Location where the study was done
Slurry type	Cattle or pig
Slurry treatment	Untreated, solid-liquid separation, anaerobic digestion, acidification, aeration, addition of additives, dilution with water, addition of co-substrates (also denoted off-farm materials; mostly organic residues from e.g. food industry or energy crops) and combinations of treatments (e.g. solid-liquid separation and anaerobic digestion)
Slurry characteristics	Chemical analysis of the slurry: dry matter (DM), volatile solids (VS), total nitrogen (N_{tot}), ammonium (NH_4^+; TAN (total ammoniacal nitrogen) is often used instead of NH_4^+), total carbon (C), total sulfur (S) in g L^{-1}, pH
Type of study*	Farm-scale, pilot-scale, laboratory-scale
Type of store	For farm-scale studies: tank, lagoon according to Pain and Menzi (2011)**
Replicates	Number of replicates of real-world stores or experimental vessels
Store characteristics	Investigated store surface (m^2), depth (m), and volume (m^3); agitation of slurry (number of agitation events); other producer events or meteorological conditions; slurry temperature (°C)
Experimental conditions	Duration of storage of investigated slurry (days); duration of the study (days); number of measurement periods and total duration of the measurement (hours); season of measurements: cold, temperate, warm; for the determination of the season, the meteorological winter, spring or fall and summer were considered
Meteorological conditions	Air temperature during measurements (°C); air speed over the emitting surface during measurements (m s^{-1}); rainfall (cumulative amount during measurements in mm)
Measurement methods applied	Measurement method for the gases: dispersion modeling based on a backward Lagrangian stochastic (bLS) dispersion model or UK-ADMS atmospheric dispersion model, flux chamber method, flux gradient method, micrometeorological mass balance method (e.g. integrated horizontal flux, IHF; vertical radial plume mapping, VRPM), sampling at exhaust chimney, tracer gas method, method not further defined; instrument used for the concentration measurements of the gases
Cover type	Storage uncovered or covered; For covered storage: cover type according to VanderZaag et al. (2015): impermeable structural covers: lid (wood or concrete), tent covering; impermeable floating covers: plastic film; permeable synthetic floating covers: plastic fabrics, expanded clay, other materials such as expanded polystyrene, plastic tiles; permeable natural floating covers: peat, straw, vegetable oil, other organic materials (wood chips, sawdust etc.), other cover types such as storage bag
Occurrence of a natural crust at the store's surface	Formation of natural crust: yes or no, crust thickness (cm), time for natural crust formation (days)***
Measurement data****	NH_3 (g NH_3 m^{-2} h^{-1}, g NH_3 m^{-3} h^{-1}, g NH_3 AU^{-1} h^{-1}), NH_3-N in % TAN and in % N, N_2O (g N_2O m^{-2} h^{-1}, g N_2O m^{-3} h^{-1}, g N_2O AU^{-1} h^{-1}), N_2O-N in % TAN and % N, CH_4 (g CH_4 m^{-2} h^{-1}, g CH_4 m^{-3} h^{-1}, g CH_4 AU^{-1} h^{-1}), CH_4-C % VS, CO_2 (g CO_2 m^{-2} h^{-1}, g CO_2 m^{-3} h^{-1}, g CO_2 AU^{-1} h^{-1}), CO_2-C in % VS, CO_2eq (g CO_2eq m^{-2} h^{-1}, g CO_2eq m^{-3} h^{-1}, g CO_2eq AU^{-1} h^{-1}), H_2S (g H_2S m^{-2} h^{-1}, g H_2S m^{-3} h^{-1}, g H_2S AU^{-1} h^{-1}); Difference between untreated and treated slurry or between slurry stored uncovered and stored covered in percent for NH_3, N_2O, CH_4, CO_2, CO_2eq, H_2S

* Type of study: Farm-scale: measurements carried out at real-world storage facilities at a farm site. This information could be obtained from the description of the experimental setup given in the papers. Pilot-scale and laboratory-scale: measurements conducted under controlled conditions in experimental vessels. Due to a lack of definition for these study types, a discrimination according to the following characteristics was employed: Pilot-scale: volume of slurry investigated: ≥500 L with experimental vessels situated outdoors, with or without a shelter and submitted to ambient meteorological conditions. Laboratory-scale: volume of slurry investigated: < 500 L. Most of the studies defined as laboratory-scale studies were conducted indoors in a temperature-controlled room. Three studies deviated from the conditions regarding study situation or temperature control and for four studies, this information was not available (Supplementary data 2). Despite these gaps in information, the studies were retained.

** A tank is a large, normally open-top, in most cases circular vessel made from pre-fabricated vitreous enameled steel, concrete or wood panels charged from a reception pit and emptied using a pump. It is a facility constructed at or below ground level and may extend above ground with a depth of several meters. Earthen storage basins not designed for biological treatment of slurry are considered as stores equivalent to tanks. Like earthen storage basins, a lagoon is a large rectangular or square shaped structure with sloping earth bank walls and may be lined with water impermeable material. Lagoons are designed for both storage and biological treatment (Pain and Menzi, 2011). They are not emptied below a specific depth necessary for slurry treatment except for maintenance (Hamilton et al., 2001).

*** We did not consider a natural crust as a mitigation technique equivalent to covering of slurry stores. The significance of crusting and considerations regarding distinction between crusting and storage covering are specifically addressed in Section 4.2.4.

**** For units: see Section 2.3. Acronyms: AU: animal unit = animal with a live weight of 500 kg; CO_2eq: carbon dioxide equivalent. CO_2eq is a standardized unit for different greenhouse gases. The numbers reported rest on data provided by the authors of the papers which were mostly based on IPCC (2007); TAN: total ammoniacal nitrogen; N: nitrogen; VS: volatile solids.

and m^3 was used, respectively. For all gases, the time unit hour was applied (reasons are given in section 4.1). Where useful for inventories, the time unit year was additionally provided for emissions. In this paper, the emission data standardized as explained above are denoted emission on an area or volume basis.

Since emission inventories do usually not apply emissions on an area or volume basis but emission factors which express emissions as a proportion of a compound present in the slurry store, data were additionally scaled as follows: percent of TAN for ammonia (EEA, 2016), percent of N for N_2O (IPCC, 2006) and percent of VS for CH_4 (IPCC, 2006) and CO_2. To be consistent with the notion "emission on an area or volume basis" regarding terminology, we used the term flow-based emission. Flow-based emissions were either taken from the papers or determined based on the emission rate, the N, TAN or VS content of the slurry, the volume of the store and the duration of the experiment. Dividing the cumulative emission which was derived from the emission rate and the duration of the study by the amount of the compounds present in the store at the beginning of the experiment (derived from the slurry content of N, TAN or VS and the slurry volume) yielded the flow-based emission. It was only calculated if no slurry addition or discharge occurred during the experiment.

2.4. Data analysis

2.4.1. Descriptive statistics of the emission data

In a first step, descriptive statistics (number of records, minimum, 1 st quantile, median, average, 3rd quantile, maximum, standard deviation) were calculated over all records encompassing slurry stored uncovered. There were eight categories for data reporting resulting from the combination of two slurry types (cattle and pig) with four study types (farm-scale lagoon comprising solid-liquid separation and biological treatment of slurry; farm-scale tank, pilot-scale and laboratory-scale which include untreated slurry).

2.4.2. Baseline emissions

2.4.2.1. Definition. We define the term baseline emission as the average emission occurring with slurry storage according to the reference technology without emission control similar to VanderZaag et al. (2015). This implies uncovered storage in the following types of store: i) tanks or earthen stores without slurry treatment; ii) lagoons with solid-liquid separation and biological treatment occurring during storage (Hamilton et al., 2001). The baseline emission is considered as representative for average emissions over the whole course of a year. According to EEA (2016), baseline emissions are given separately for cattle and pig slurry. We further distinguished between storage in tanks (or earthen stores) and lagoons. Baseline emissions were calculated from uncovered slurry stores regardless of the occurrence of a natural crust because its formation can be only partially controlled and thus varies widely between stores (Smith et al., 2007). Moreover, there was insufficient information about the presence of crusts in the data impeding a distinction between crusted and non-crusted store's surfaces.

2.4.2.2. Determination. Baseline emissions were calculated using farm-scale and pilot-scale studies published in peer-review papers. For the calculation of representative emissions, important influencing factors should be considered such as the meteorological conditions (mainly air temperature, wind speed, precipitation) and operations at storage facilities (Sommer et al., 2013). Among these factors, we were able to include air temperature since the season used for emission measurements which can be used as surrogate for the temperature was available for more than 90% of the records. Records were dropped where conditions prevailed which are not representative for slurry storage in practice over a longer period, e.g. if daily agitation of slurry occurred. More detailed information on meteorological conditions and operations at storage facilities was not available and could not be included in the evaluation of emissions (e.g. only approx. 60% of records provided numerical air temperature data). Information on wind speed, precipitation and crust formation was available for less than half of the records.

We hypothesized that for generating emission data which are representative over the whole course of a year, emission values generated during the cold, the warm and the temperate season (spring, fall) should be equally covered. To achieve this, a weighting of the emission data for season was done. Values were aggregated according to the categorization "Season code" ("c": cold season = winter, "t": temperate season = spring or fall, "w": warm season = summer, "c,t": cold and temperate season, "c,w": cold and warm season, "t,w": temperate and warm season, "c,t,w": cold, temperate and warm season), "Slurry type" (cattle, pig), "Type of study" (farm-scale, pilot-scale) and "Type of store" (for farm-scale studies: lagoon, tank). For some papers, emission values for each individual season "c", "t", and "w" were provided and also the average value over the year, i.e. the "c,t,w" value. In these cases, the "c,t,w" value is denoted as redundant in the database (Supplementary data 2). It was used for the further calculations and not the values of the individual seasons. The aggregated values were averaged afterwards in the following manner:

i) Study duration varied considerably, i.e. individual experiments ranged from less than one day up to several months. The individual records were thus weighted according to measurement durations of records within each "Season code" category. The individual records were aggregated to four classes of measurement durations: a) ≥1 month, b) ≥1 week to < 1 month, c) ≥1 day to < 1 week, d) < 1 day. Weighting was done based on the square-root of the median of the measurement duration for each class to avoid over-emphasis of long-term measurements. The median values of the measurement duration for the 4 classes a, b, c and d were 146.5 days, 16.9 days, 4.5 days and 0.34 days, respectively. This implied the following respective weights 12.1, 4.1, 2.1 and 0.6. Therefore, a record based on a measurement of more than one month received a weighting 20.8 times higher than a record based on a measurement over less than a day.
ii) Average values for each season "c", "t" and "w" were calculated from all available values within one category (based on "Slurry type", "Type of study" and "Type of store"). Averaging was done in a way that values spanning over more than one season were attributed to the respective seasons, i.e. a value for "c,t" was attributed half to "c" and half to "t", a value of "c,t,w" was counted one fourth to seasons "c" and "w" and one half to season "t". For example, to average a "c" value based on a 2 weeks measurement (c_{2weeks}), a "c" value based on a 2 days measurement (c_{2days}) and a "c,w" value that based on a 2 months measurement ($cw_{2months}$) led to the following average "c" value: "c_{avg}" = (c_{2weeks}*$weight_{2weeks}$ + c_{2days}*$weight_{2days}$ + $cw_{2months}$*0.5*$weight_{2months}$)/($weight_{2weeks}$ + $weight_{2days}$ + 0.5*$weight_{2months}$).
iii) These average values were further averaged to annual emission rates "c,t,w" by weighting the value for season code "t" twice as high as the seasons "c" and "w" (i.e. "c,t,w_{avg}" = ¼*"c" + ½*"t" + ¼*"w") since the temperate season code "t" includes two seasons (spring and fall). These final averaged values are listed in column "Avg" in Tables 8, 9 and Supplementary data 4.

Numbers for baseline emissions are reported as average emission values if at least one record for each of the season "c", "t" and "w" was available. Included can be a record from an individual season (i.e. "c", "t" or "w"), or any kind of seasons combination (i.e. "c,t" "c,w" "t,w" or "c,t,w"). The lower and upper 95% confidence bounds (l95, u95) for baseline emissions were determined using bias-corrected and accelerated bootstrap intervals (Efron, 1987) if at least three individual records for each of the season "c", "t" and "w" were available. Again, this can be in the form of an individual season or any kind of seasons combination as for the calculation of the average. The bootstrapping was done as non-parametric bootstrapping with sampling stratified by season. To test whether there are significant ($p < 0.05$) differences in these baseline emission values, 95% confidence intervals were obtained from bootstrapping the differences between each combination of values. If a confidence interval of a difference did not include 0, the difference was marked as statistically significant.

The data resulting from this procedure related to emissions on an area or volume basis were aggregated according to the slurry type (cattle and pig) and the study types farm-scale tank and pilot-scale and for the two study types combined which were denoted as baseline emissions tank. The baseline emissions for lagoons are based on measurements carried out at farm-scale for lagoons. Baseline emissions expressed as flow-based emissions were given separately for cattle and pig slurry for tanks only due to a lack of appropriate data for lagoons. The calculation procedure is additionally illustrated based on an example in the Supplementary data 9.

2.4.3. Emissions and emission changes due to slurry treatment and covering of slurry stores

We determined the emission changes due to slurry treatment techniques and covering of slurry stores using records with a treatment or a cover and a reference system (uncovered storage with untreated slurry) to compare the emissions on an area or volume basis from both. Due to the limited number of available records, the restriction to peer review papers and exclusion of laboratory-scale studies was not applied. For storage covering, all records with less than 20 cm of slurry depth were excluded from the data analysis since it is likely that such conditions differ too much from the real-world and even more evident if the thickness of the cover material is similar to that of the bulk slurry layer. Studies where slurry depth was not provided were excluded.

Although a natural crust is often listed as abatement measure together with slurry store covers (Bittman et al., 2014) we did not consider it as a mitigation technique equivalent to covering of slurry stores. In contrast to coverings such as impermeable floating covers, it is not applicable for all stores since it does not form at each slurry type. Crusting was neither considered for the analysis on emission changes due to slurry treatment and covering of slurry stores because of insufficient information about the presence of crusts in the experimental data. The significance of crusting is specifically addressed in Section 4.2.4.

The numbers from different studies were aggregated without a weighting for season or measurement duration due to the limited number of records. We tested whether the differences between treatments or covers and the reference system (untreated slurry or uncovered storage) were significantly different from zero by a two-sided t-test.

3. Results

3.1. Characterization of the database

3.1.1. General characteristics

The literature review yielded a total of 711 records. Among them, 13% were from before 2000. The period between 2000 and 2010 contributed 43%, and 44% were published after 2010 (Table 2). US and CA generated 28% and 19%, respectively, of the records while 11 European countries provided 48%. Two countries from Asia and Oceania contributed 3% and 2% of the records. Ammonia was studied in 38% of the records, while 59% were on GHGs, and 3% on H_2S. Among GHGs, CH_4 was most often investigated with a share of 30% of all records. 47% of the records included one gas and 53% several gases.

Table 3 shows the types of studies. A share of 46% of the records are based on studies conducted at farm-scale. Pilot-scale studies contributed 31% and laboratory-scale 23% of the records. Records from pilot-scale studies are similarly represented over all three periods before 2000, between 2000 and 2010 and after 2010. In contrast, data from farm-scale studies and conducted in the laboratory occur more frequently from 2000 onwards.

An overview of the investigated slurry types is shown in Table 4. Cattle and pig slurry each account for about 50% of the investigated slurries. Cattle slurry mostly originated from dairy cows while for pig slurry fattening pigs and breeding pigs or a mixture of both was studied. Other types of slurry were included in measurements as well, but these occur much less. The proportion of untreated slurries is 65% and 87% for cattle slurry and pig slurry, respectively. Solid-liquid separation occurs for 16% (cattle slurry) and 3.7% (pig slurry) of the records. Anaerobic digestion of unseparated slurry applies for 7.2% (cattle slurry) and 3.7% (pig slurry) of the records while for anaerobically digested and separated slurry, the numbers are 8.1% for cattle slurry and 0.6% for pig slurry, respectively. Other treatments encompass acidification, aeration, supplementation with additives or dilution of slurry, but these treatments occur less.

Approximately 140 records compare the emissions between covered and uncovered storage. More than 80% of these data are from pilot and laboratory studies. Straw covers and other natural materials such as wood chips or maize stalks were most often investigated (51 in total). Also, cover types such as a lid, plastic film and fabrics were frequently addressed resulting in approximately 15 records for each.

Measurement methods employed in the experiments are shown in Table 5. Roughly, two thirds of all measurements were carried out using a flux chamber method. While this is almost the only option for pilot- and laboratory-scale studies, this system was also used for approximately 30% of the measurements conducted at farm sites. Methods like dispersion modeling or micrometeorological mass balance method make up about 60% of the records from farm-scale studies. Other methods e.g. using a tracer gas were rarely applied.

Slurry analyses are shown in Table 6. Not all studies provided analytical data of the slurry (e.g., only 84% of NH_3 studies presented TAN values). While most laboratory studies analyzed TAN, only 67% of the studies carried out at farm sites reported this parameter. Pilot-scale studies lie in between with 92% of records reporting TAN data. The availability of analytical data is similar for other parameters (e.g. DM) as for TAN but with somewhat lower numbers. The composition of the mixture of urine and feces as excreted by animals published by ASAE (2005) and Richner et al. (2017) is added at the bottom of Table 6. They provide numbers for cattle on DM, VS and TAN in the range of 80 to 90 g L^{-1}, 53 to 70 g L^{-1} and 1.4 to 2.1 g L^{-1}, respectively. For pigs, the values for DM, VS and TAN are in the range of 50 to 90 g L^{-1}, 36 g L^{-1} and 3.4 to 5.0 g L^{-1}. The slurry analyses given in the records show substantially lower numbers for DM and VS contents for untreated slurries which is most likely due to dilution with water from farm operation and rainfall at the farms (Table 6). Studies at farm-scale based on tanks, at pilot-scale and at laboratory-scale exhibit DM contents which are in a similar range within cattle and pig slurry. Numbers for DM are lower for pig slurries compared to cattle slurry except for laboratory scale studies. Pig slurry exhibits higher N_{tot} and TAN contents than cattle slurry. Within farm-scale studies, the numbers for all analytes strongly differ between slurry from tanks and from lagoons. Values for DM, VS, N_{tot} and TAN are lower for lagoons by a factor of approximately two to eight as compared to slurry stored in tanks. Slurries from lagoons compare better with slurries after solid-liquid separation (Table 6) than with untreated slurries.

3.1.2. Descriptive statistics of emission data from cattle and pig slurry stored uncovered

Descriptive statistics are shown in Table 7 for NH_3, N_2O, CH_4, CO_2 and H_2S over all records encompassing untreated cattle and pig slurry stored uncovered from studies conducted at farm-, pilot- and laboratory-scale (farm-scale studies with lagoons include biologically treated and separated slurry; see section 2.4.2.1). Data from measurements conducted during warm, temperate and cold seasons are unevenly

Table 2
Number of records listed by country and year of publication and share of total records by country.

distributed over all records (Supplementary data 3). The minimum and maximum emission values differ by one to several orders of magnitude for all gases. The average often exceeds the median by a factor of two or more which is most pronounced for N_2O. This indicates a distribution of data being right skewed by high values. The variability of data and the occurrence of high maximum values is most pronounced for laboratory-scale studies. Striking high values exceeding the median by at least one order of magnitude for NH_3, CH_4 and CO_2 are reported in the laboratory-scale study of Guarino et al. (2006). For N_2O, high values were found from three studies conducted at farm- and pilot-scale (Clemens et al., 2006; Amon et al., 2007; Leytem et al., 2011) (Supplementary data 2,8,11). For H_2S, one figure from a laboratory-scale study stands out which exceeds all other values by two orders of magnitude (Hobbs et al., 1999).

Table 6
Number of records of a slurry type (cattle, pig), type of study (f: farm-scale; p: pilot-scale; l: laboratory-scale), type of store for farm-scale studies, and slurry treatment (untreated, sol-liq sep: solid-liquid separation) in the database. Number of records (n) with analytical data on DM, VS, N_{tot}, TAN and average contents of DM, VS, N_{tot}, TAN in g L^{-1} for untreated slurry.

3.2. Baseline emissions

3.2.1. Emissions on an area or volume basis

Table 8 shows emissions on an area or volume basis from cattle and pig slurry stored uncovered in tanks at farm-scale and at pilot-scale without slurry treatment and in lagoons with solid-liquid separation and biological treatment for NH_3, N_2O, CH_4 and CO_2. Average NH_3 emissions from farm-scale studies conducted at lagoons are higher than those from tanks for cattle slurry but lower for pig slurry. Pilot-scale studies exhibit similar emissions as farm-scale studies conducted at tanks, but they differ when compared to measurements from lagoons. The range between the lower and upper 95% confidence bounds is relatively small for cattle slurry but large for pig slurry with the greatest range for farm-scale studies from tanks (0.13 to 0.37 g NH_3 m^{-2} h^{-1}). The baseline emission for lagoons is 0.12 g NH_3 m^{-2} h^{-1} and 0.15 g NH_3 m^{-2} h^{-1} for cattle and pig slurry, and for tanks 0.08 g NH_3 m^{-2} h^{-1} and 0.24 g NH_3 m^{-2} h^{-1} for cattle and pig slurry, respectively. Baseline emissions given as a yearly average emitted amount for lagoons are 1.1 kg NH_3 m^{-2} y^{-1} and 1.3 kg NH_3 m^{-2} y^{-1} for cattle and pig slurry, and for tanks 0.67 kg NH_3 m^{-2} y^{-1} and 2.1 kg NH_3 m^{-2} y^{-1} for cattle and pig slurry, respectively. The differences between baseline emissions for cattle slurry and pig slurry, and the difference between lagoons and tanks are both statistically significant ($p < 0.05$).

Values for N_2O emissions mostly originate from pilot-scale studies. The data from the three studies which exhibit high values mentioned in section 3.1.2 were excluded for the calculation of baseline emissions. The N_2O losses shown in Table 8 are very low and often close to the limit of detection. Negative fluxes are reported e.g. in VanderZaag et al. (2009) or values lower than the limit of detection in Misselbrook et al. (2016). Pig slurry exhibits a large range between the lower and upper 95% confidence bounds (< 0.001-0.005 g N_2O m^{-2} h^{-1}). Baseline emissions are 0.002 g N_2O m^{-2} h^{-1} for cattle and pig slurry stored in tanks. Storage in lagoons for cattle slurry is 0.0003 g N_2O m^{-2} h^{-1} while for pig slurry no baseline value is available. Statistically significant differences were not found for N_2O.

Farm-scale studies exhibit higher CH_4 emissions than pilot-scale studies (Table 8). For both study types, pig slurry has a higher emission level as compared to cattle slurry. The baseline emission values for lagoons are 0.95 g CH_4 m^{-3} h^{-1} (cattle slurry) and 3.5 g CH_4 m^{-3} h^{-1} (pig slurry), and for tanks 0.58 g CH_4 m^{-3} h^{-1} (cattle slurry) and 0.68 g CH_4 m^{-3} h^{-1} (pig slurry), respectively. The baseline emission for lagoon storage of pig slurry is based on one record only. But its distinctly higher emission level as compared to the baseline for tank storage and relative to the baseline emissions of cattle slurry stored in lagoons and tanks is confirmed by the area based CH_4 emissions where the data basis is much larger and statistically significant differences ($p < 0.05$) were found (Supplementary data 4).

For CO_2, the number of observations is relatively small. Some studies exhibit high values for cattle slurry which are greater than 20 g CO_2 m^{-2} h^{-1} (Leytem et al., 2011; Minato et al., 2013; Misselbrook

Table 9
Flow based baseline emissions for tanks from untreated cattle and pig slurry stored uncovered for NH_3 given in percent of total ammoniacal nitrogen (TAN), N_2O in percent of nitrogen (N), CH_4 and CO_2 in percent of volatile solids (VS). The average (Avg) and the lower and upper 95% confidence bounds (l95, u95) are shown. The numbers are mainly based on pilot-scale studies. Cells denoted with "-": value is not available; #: values denoted with different letters are significantly different ($p < 0.05$). Detailed information is provided in Supplementary data 4.

	n	Avg	l95	u95	#
		NH_3% TAN			
Cattle	31	16%	14%	19%	a
Pig	17	15%	9.2%	23%	a
		N_2O% N

Cattle	27	2.9%	2.3%	3.7%	a
Pig	14	4.7%	2.1%	10%	a
		CO_2% VS			
Cattle	4	11%	–	–	–
Pig	3	9.2%	–	–	–

Cells denoted with "-": value is not available.

et al., 2016). The baseline emissions for lagoon storage are 6.6 g CO_2 m^{-2} h^{-1} and 0.30 g CO_2 m^{-2} h^{-1} for cattle and pig slurry, respectively, and for tank storage, 8.0 g CO_2 m^{-2} h^{-1} for both slurry types. Data on H_2S emission are sparse and a calculation of baseline emissions is only feasible for lagoon storage which are 0.04 g H_2S m^{-2} h^{-1} for cattle slurry and 0.01 g H_2S m^{-2} h^{-1} for pig slurry (Supplementary data 4).

3.2.2. Flow-based emissions

Flow-based emissions, i.e. emissions given in percent of TAN, N or VS present in the store are shown for NH_3, N_2O, CH_4 and CO_2 in Table 9. Almost all data originate from pilot-scale studies (Supplementary data 4) which can be used for baseline emissions for tanks but not for lagoons. Baseline emission values for NH_3 are 16% of TAN for cattle slurry and 15% of TAN for pig slurry, respectively. N_2O emissions are 0.13% of N for cattle slurry and 0.10% of N for pig slurry. Baseline emissions for CH_4 are 2.9% of VS for cattle slurry and 4.7% of VS for pig slurry. Emissions for CO_2 reach 11% of VS and 9.2% of VS for cattle and pig slurry, respectively, but the data basis is limited. The ranges between the lower and upper 95% confidence bounds are large in most cases and are partially skewed to high values, especially for N_2O and CH_4 from pig slurry. There were no statistically significant differences.

3.3. Emission changes due to slurry treatments

Acidification clearly reduces NH_3 emissions by ca. 70% during storage compared to untreated cattle and pig slurry (Table 10). The effect is even higher for CH_4 (61%–96%) but lower for CO_2. For NH_3 and CH_4, the differences are statistically significant ($p < 0.05$). An emission reduction also occurs for digested slurries and slurries after solid-liquid separation combined with acidification for all gases except for N_2O (Supplementary data 6). In contrast, the emissions are enhanced for N_2O emissions compared to untreated cattle and pig slurry although limited data are available and the differences not statistically significant. Data on H_2S emissions are sparse. Fangueiro et al. (2015) state in their review that H_2S emissions were either unaffected or decreased following acidification.

The number of studies on emission changes due to anaerobic digestion is limited. Where more than one observation is available, both an increase and a decrease in emissions occur for storage after anaerobic digestion as compared to untreated slurry (Supplementary data 6). NH_3 and N_2O exhibit on average greater emissions from anaerobically digested slurry. Most studies comparing anaerobically digested and untreated slurry exhibit lower emissions of CH_4 for the former. An emission increase is observed for N_2O and CO_2 for pig slurry, although this is based on only one observation for both gases. Statistically significant differences do not occur for anaerobic digestion.

Average NH_3 emissions during storage from the liquid fraction are significantly ($p < 0.05$) higher as compared to untreated cattle slurry (Table 10). But for pig slurry, only a slight effect of solid-liquid separation on NH_3 release can be observed which is statistically insignificant. CH_4 and CO_2 exhibit lower emissions from the liquid fraction as compared to untreated slurry with a statistically significant difference for CH_4. A statistically significant reduction ($p < 0.05$) in N_2O emissions occurs for cattle slurry. But the release of N_2O is greater for pig slurry compared to untreated slurry where the difference is statistically not significant.

Five studies examined the effect of slurry dilution with water and found an average reduction of all investigated gases in the range of approximately 30–50%. Statistically significant effects occurred for cattle slurry for NH_3 and N_2O. Maximum abatement effects of 88% and 86% were found for N_2O and CH_4, respectively (Supplementary data 6).

3.4. Emission changes due to covering of slurry stores

The average NH_3 emission percent reduction due to covers ranges between approximately 50% up to ca. 90% for most cover types (Table 11). However, the variability of values is large. Minimum values can be around 15% and maximums higher than 95% (Supplementary data 7). The emission mitigation does not systematically differ between cattle and pig slurry on a percentage basis. Emission reductions lie in a similar range for structural covers, impermeable floating covers, permeable floating covers and the other cover materials. The differences are statistically significant ($p < 0.05$) for the following covers and

Table 10
Percentage emission change (i.e. % change of emissions on an area or volume basis) during storage due to acidification, anaerobic digestion, solid-liquid separation and dilution of cattle and pig slurry for NH_3, N_2O, CH_4 and CO_2 relative to untreated slurry. both slurry types: lid, plastic film, straw cover, vegetable oil; other organic materials for cattle slurry; plastic fabrics, expanded clay, expanded polystyrene for pig slurry.

For N_2O, an increase in emissions is observed in many cases. But reduced emissions occur as well (Supplementary data 7). However, the number of records providing emission changes from slurry storage due to store covers is sparse and the effects are statistically insignificant. CH_4 emissions being lower by approximately 10% to 60% occur for impermeable covers (lid and plastic film), plastic tiles and vegetable oil compared to uncovered storage (Table 11). For plastic fabrics, expanded polystyrene and peat, the emissions are higher by 2% to 33%. The other cover types (expanded clay, straw and organic materials such as corn stalks or wood chips) show both increases and reductions in CH_4 emission (Supplementary data 7). On average, CH_4 emissions from slurry stores covered with permeable materials moderately differ in emission levels as compared to uncovered storage. The differences in CH_4 emissions are statistically not significant ($p < 0.05$) except for pig slurry covered with a lid. Stores covered with plastic fabrics, expanded clay and expanded polystyrene emit less CO_2 while higher emissions are observed for peat and straw covers than for the uncovered controls, but the differences are statistically not significant. Plastic fabrics induce a significant ($p < 0.05$) emission reduction for pig slurry by 50% for H_2S. Data on both CO_2 and H_2S emissions are sparse.

4. Discussion

4.1. Variability in emissions

The high variability of emission levels as shown by descriptive statistics (Table 7) may be due to different meteorological conditions, disturbance of the slurry surface induced by operations at the stores and slurry characteristics. The enhanced variability in laboratory-scale studies compared to the other study types is striking. In laboratory-scale studies, the environment is expected to be largely uniform since the experiments were mostly conducted in a temperature-controlled room with ambient temperatures lying in a narrow range and the slurry being undisturbed. As most of the laboratory-scale studies aimed at a comparison of different techniques or systems, the representativeness of the resulting emission rates for real-world conditions was not the primary focus and discrepancies between different approaches are very likely present. A thorough evaluation of potential biases of the laboratory studies is not possible due to missing information on the measuring systems and is beyond the scope of this paper (see Liu et al. (2020) and the related discussion). Also, for other study types, the occurrence of methodological biases cannot be ruled out which may lead to implausible results. Detection of striking values might be hampered due to the multitude in units used in the papers. Therefore, a standardization as used here and providing guide values are important issues. For this, a favorable option is the unit g m^{-2} h^{-1} or g m^{-3} h^{-1} of a molecule. It is equally suitable to illustrate an emission pattern within one day, also in combination with important influencing factors such as temperature or wind speed which can change over short time periods and to compare them with e.g. average emissions over one year. If a yearly amount of a gas release is required, data can be obtained from Table 8. Alternatively, the unit mol m^{-2} h^{-1} could be used to facilitate the comparability between different molecules, even if to date, it is generally not used in the context of emission inventories.

4.2. Important factors influencing emissions

The relevance of important influencing factors on emissions from slurry stores is discussed in this section in order to support interpretation and understanding of the data used to determine baseline emissions and emission changes due to slurry treatment and coverage of slurry stores. It should be noted that a part of these influencing factors could not be included in the data processing such as the weighting or the statistical analysis of emission data due to insufficient information in the records. This data limitation applied for operations at stores, the meteorological parameters rain and wind speed and the natural crust.

4.2.1. Type of slurry

Records from the same study where both cattle and pig slurry have been investigated using the same approach were compared. Eight studies (De Bode, 1991; Sommer et al., 1993; Husted, 1994; Kaharabata et al., 1998; Balsari et al., 2007; Dinuccio et al., 2008; Mosquera et al., 2010; Misselbrook et al., 2016; Baral et al., 2018) with a total of 14, 2, 8 and 3 pairs of records on NH_3, N_2O, CH_4 and CO_2 emissions, respectively, were available. For NH_3, 85% of data pairs, exhibited higher emissions for pig slurry than for cattle slurry. Similar for N_2O, CH_4 and CO_2, pig slurry exceeds emissions of cattle slurry in most cases. These findings agree with the data reported in Table 8 (except for CO_2) and with data previously published by Sommer et al. (2006) and VanderZaag et al. (2015).

4.2.2. Operations at stores

Operations at the storage tank, such as agitation, filling and removing of slurry are necessarily related to real-world storage systems. Their effects are usually reflected in farm-scale measurements using non-intrusive methods but rarely included in pilot studies or farm-scale studies using chamber systems. A series of studies specifically investigated such processes (see Supplementary data 10). They showed consistent results and provided evidence that disturbance of the manure surface due to slurry agitation, filling and discharging of the stores induces large episodic emissions for NH_3, CH_4, CO_2 but not for N_2O. While emissions of CH_4 and CO_2 rapidly decline after cessation of the operations and can even drop to levels below the previously undisturbed stores, increased emission levels persist for NH_3. Due to the relatively short time duration of agitation over the year and the subsequent drop below average levels for CH_4, this operation per se does not substantially contribute to annual NH_3 and GHG emissions from slurry (VanderZaag et al., 2009). A more detailed overview on emissions during and following operations at stores is given in the Supplementary data 10.

4.2.3. Meteorological conditions

Increasing air temperature and wind speed enhance the emissions since they directly affect diffusion and convection of gases near the emitting surfaces (Sommer et al., 2013). The relationship between the temperature as represented by the season of measurements and the emission level could be demonstrated in the present study (Supplementary data 5). It must be considered however, that the air temperature is a simplistic surrogate for the slurry temperature which is a determinant factor for GHG emissions. Rennie et al. (2018) demonstrated that slurry store design and operations (i.e. filling level, agitation) influence the slurry temperature and the emission level of gases such as CH_4. In 25 studies, slurry temperatures during different seasons are available. Slurry temperatures increase as expected in the order cold < temperate < warm for 94% of the cases. The effects of temperature and wind speed are not discussed further in the present study because this topic has been previously covered by e.g. Ni (1999) or Sommer et al. (2006). In contrast, emission changes related to the influence of rain events and thawing of the slurry surface are summarized here since they have been less frequently addressed in the literature. Petersen et al. (2013) found lower NH_3 emission from uncovered storage of pig slurry with precipitation than from the treatment without rain although the differences are not statistically significant. It was shown that ammonia emissions can decline towards zero during rain events after slurry spreading (Hafner et al., 2019) due to sorption of NH_3 onto wet surfaces. Moreover, the TAN-concentration at the emitting surface may decrease with precipitation due to dilution or transport of TAN from a crusted slurry surface into the bulk liquid. Overall, it can thus be assumed that NH_3 emissions from slurry storage during rain events are low. In contrast, an increase in emissions of CH_4 has been observed. Balde et al. (2016b) reported average emissions of 1.8 g CH_4 m^{-2} h^{-1} for digested slurry while peak emissions during rain events reached 10 g CH_4 m^{-2} h^{-1}. This was likely due to bursting of bubbles at or near the surface. Elevated emissions were also observed by Balde et al. (2016a) from storage of the liquid fraction of cattle slurry which confirms earlier findings from Kaharabata et al. (1998) and Minato et al. (2013) on slurry stored in open tanks or lagoons. Kaharabata et al. (1998) suggested that the emission increase is due to more disturbance at the slurry surface induced by rain and thus enhancement of the CH_4 exchange through the liquid surface area and of incidental outburst of gas bubbles (ebullition). Petersen et al. (2013) found a drop of N_2O emissions to zero as a result of rewetting of the crust after rainfall inducing a shift towards anaerobic conditions. Grant and Boehm (2015) did not find a relationship between H_2S emissions and rain events.

VanderZaag et al. (2011) observed important bubble flux events in late winter/early spring that coincided with surface thawing which were probably due to a release of previously produced CH_4 that was trapped under the frozen slurry surface. In the study of VanderZaag et al. (2010a) which encompassed winter and spring, N_2O release was only recorded during spring thaw. A moderate increase in CH_4 emissions was observed during the same period at slurry temperatures above 0 °C while NH_3 and CO_2 flows were unaffected by spring thaw. Elevated CH_4 emissions due to thawing of the manure store were also reported by Leytem et al. (2017).

4.2.4. Natural crust

There is agreement that crusting impacts the gas release in many ways: enhanced resistance to mass transfer (Olesen and Sommer, 1993), oxidation of NH_3 (Nielsen et al., 2010) and CH_4 (Petersen et al., 2005) and formation of N_2O related to nitrification and denitrification occurring in liquid–air interfaces near air-filled pores present in crusts (Petersen and Miller, 2006). Several studies investigated the effect of a natural crust on the emission level (Sommer et al., 1993; Misselbrook et al., 2005; Aguerre et al., 2012; Wood et al., 2012). All studies showed that a natural crust provided an efficient barrier leading to an emission reduction for NH_3. Baldé et al. (2018) confirmed these findings by measurements conducted under farm conditions at tanks and earthen basins containing slurries with differing ability to form natural crusts (i.e. raw cattle slurry, the liquid fraction of cattle slurry produced by solid-liquid separation, digested slurry with and without solid-liquid separation). They confirmed that slurry stored with a thick surface had lower NH_3 losses. Grant and Boehm (2015) found that crusting of a lagoon surface containing dairy cow slurry reduced NH_3 but not H_2S emissions. Nielsen et al. (2010) showed that NH_3-oxidizing bacteria may contribute to a significant reduction of NH_3 emissions if a natural crust is present on a slurry store. Grant and Boehm (2018) found emissions from a tank containing pig slurry to be greater by 10% when the surface was covered with a crust than without crusting (difference not statistically significant). They explained their findings by the higher TAN content of the crusted slurry surface as compared to a non-crusted one. Sommer et al. (2000) and Husted (1994) found higher emissions of CH_4 from slurry without than from slurry with a natural surface crust. Wood et al. (2012) investigated the emissions from dairy slurry with varying DM contents and thus natural crusts with different thicknesses and coverage of the storage surfaces. They were not able to relate the CH_4 fluxes to the presence of a natural crust. N_2O production was found to be enhanced after build-up of a natural crust (VanderZaag et al., 2009).

In the literature (e.g. Vanderzaag et al., 2015), a natural crust is often classified as abatement measure for NH_3 similar as slurry store covers. However, crust formation can only be controlled to a limited extent. Crusts are of variable thickness, coverage of the store and durability. Their effectiveness for emission abatement has therefore be considered as inconsistent (Vanderzaag et al., 2015). Crusts only develop for slurry types with a high content of fibrous material (Bittman et al., 2014). This applies mainly for cattle slurry (Smith et al., 2007) and less for pig slurry (Sommer et al., 2006). Crusting is likely to occur at a slurry DM content of more than 20 g L^{-1} (Sommer et al., 2006; Wood et al., 2012) which mostly does not apply for slurry stored in lagoons (Table 6). Consequently, they have much less ability to form a natural crust as shown by e.g. Balde et al. (2018).

We therefore did not consider crusting as an emission mitigation technique equivalent to slurry store covers but rather as a parameter influencing emissions from stored slurry and thus excluded it from the analysis of emission changes due to covering of stores. But we stress that if a natural crust is present, it is likely to significantly contribute to an emission reduction and, therefore, should be preserved by e.g. reducing slurry agitation and addition of manure below the surface.

The limited information in the data impedes our ability to clearly distinguish between crusted and non-crusted stores. This may be relevant for (i) the calculation of baseline emissions and (ii) emissions changes due to slurry treatments and covering of stores: (i) baseline emissions determined here may include stores with variable occurrence of a natural crust. For lagoons, information on crusting was available for 45% (cattle slurry) and 19% (pig slurry) of the records, respectively. Among these, 62% of the lagoons containing cattle slurry were fully or partly covered by a crust during the emission measurements. For pig slurry, this applies for 21% only. Among records used for the determination of baseline emissions for tanks, 78% and 50% included information regarding crusting for cattle and pig slurry, respectively. Of these, 83% (cattle slurry) and 48% (pig slurry) had a fully or partly crusted surface. This complies with findings that crusting occurs less on lagoon surfaces and stores containing pig slurry. The proportion of crust occurrence for cattle slurry stored in tanks is in line with earlier findings (Smith et al., 2007). We thus suggest that the baseline emissions determined here are based on studies which appropriately reflect the range of store surface crusts occurring at farms. (ii) A natural crust may occur in combination with a storage cover and thereby be enhanced (Chadwick et al., 2011) since the slurry surface is less exposed to wind turbulence. In experiments comparing uncovered and covered storage, it is thus difficult to stringently distinguish between the effect of covering and of crusting. Moreover, this information is not always available: only 60% of the records used to determine the emission change due to covering included information on crusting. From these, about half had crusted surfaces and the other half not. This might partly explain the variability of emission changes due to covering found here. These considerations should be taken into account for the discussion in the Sections 4.4 and 4.6.

4.3. Study types to be included for baseline emissions

Data should only be included for the calculation of baseline emissions if they can be considered as representative or typical for gas flows occurring at farm conditions. In principle, this applies for farm-scale studies. Pilot-scale studies imply some aspects of farm-scale studies due to measurements conducted in outdoor facilities and a slurry volume in the order of several cubic meters. But there are concerns extrapolating data from pilot-scale studies to real-world systems. VanderZaag et al. (2009, 2010a, 2010b) who performed pilot-scale studies state that although measured fluxes were reported, emission trends and treatment differences or temporal trends were the focus of their analysis. Moreover, almost all pilot-scale studies are based on flux chambers. VanderZaag et al. (2010b) argued that steady-state chambers alter the enclosed environment and concluded that absolute fluxes measured might deviate from emissions that would occur without chambers. Nevertheless, several studies conducted in pilot-scale facilities similar to that of VanderZaag et al. (2009, 2010a, 2010b) quantified emissions of NH_3 and GHGs and derived emission factors for slurry storage (e.g. Amon et al., 2006, 2007; Rodhe et al., 2012). Petersen et al. (2009) presented a pilot-scale facility and suggested to use the obtained results for better documentation of emission data for GHG and ammonia inventories. Pilot-scale studies have occasionally been conducted with simulation of real-world conditions by including mixing of the slurry or filling of tanks during the experiment (VanderZaag et al., 2009; Rodhe et al., 2012).

Emission peaks for CH_4 were observed in several studies (VanderZaag et al., 2011; Balde et al., 2016a) due to ebullition. They may remain unrecorded (Rodhe et al., 2012) unless the gas measurements are continuous with a high temporal resolution. This shortcoming may apply for pilot-scale studies where e.g. a flow chamber is used which is moved between several experimental tanks (e.g. Amon et al., 2006). Intermittent gas sampling can hamper measurements at a farm-scale as well. Grant et al. (2015) assumed differences in emission levels between two locations due to under-sampling of ebullition events given the short measurement periods. Sampling large storage areas using chambers might be hampered if the sampled surface areas are not representative for the entire store. Balde et al. (2016b) found average emissions of CH_4 measured at an earthen storage containing liquid digestate with a floating chamber which were about four-fold greater than measured at the same time with a non-intrusive bLS technique. The authors explained this by the limited area covered by the chamber and by disturbances induced by the chamber causing bubble formation and bursting thereby increasing emissions.

To summarize, it can be hypothesized that farm-scale measurements using non-intrusive methods are a preferential option. Still, data from such studies are limited at present time. Therefore, inclusion of records from pilot-scale and farm-scale studies appears to be the best opportunity for the determination of baseline emissions. This approach provides a larger data basis as if only farm-scale studies were included. Moreover, Table 8 shows that emissions from pilot-scale studies comply with farm-scale studies tank for NH_3 but less for CH_4. On the other hand, we excluded laboratory-scale studies for the determination of baseline emissions. They are mostly not designed for generating emission rates. Their experimental conditions strongly deviate from an environment that occurs under practical conditions. The enhanced variability found in emissions level from laboratory-scale studies (section 3.1.2) points to severe methodological shortcomings which might bias baseline values.

4.4. Baseline emissions

4.4.1. Emissions on an area or volume basis

NH_3 emissions from pig slurry are higher as expected due to its higher TAN content and its lower ability to form a natural crust compared to cattle slurry. Sommer et al. (2006) and VanderZaag et al. (2015) suggested lower emissions on an area basis from pig slurry stored in lagoons than from storage in tanks. This complies with the results of this study (Table 8). Lagoons are the prevailing system for slurry storage in the US (Sorensen et al., 2013). They usually have a greater surface area than tanks which would imply more exposure to the ambient air turbulence suggesting a higher emission potential. Slurries from lagoons have on average a lower dry matter and TAN content as compared to tanks. This might be due to a stronger dilution with water: e.g. five out of six lagoons investigated by Leytem et al. (2017) collected parlor wash water and not slurry from a pit of a livestock housing. We assume that solid-liquid-separation was applied at the farms studied which have lagoons although this was not always clearly defined in the papers. This is supported by the low contents in DM and TAN in slurry from lagoons as shown in Table 6. The lower solids content would enhance the emission potential due to less ability for formation of a natural crust at the slurry surface (Wood et al., 2012). But the lower TAN content induces the opposite effect on NH_3 emissions (Sommer et al., 2006). The overall impact of these effects combined on the emission level is difficult to assess. The present data suggest higher emissions from lagoons than from tanks containing cattle slurry but the opposite for pig slurry.

The baseline emissions (lagoons: 0.12 g NH_3 m^{-2} h^{-1} and 0.15 g NH_3 m^{-2} h^{-1} for cattle and pig slurry, tanks: 0.08 g NH_3 m^{-2} h^{-1} and 0.24 g NH_3 m^{-2} h^{-1} for cattle and pig slurry, respectively), are mostly lower than numbers given by VanderZaag et al. (2015), Sommer et al. (2006) and Bittman et al. (2014). VanderZaag et al. (2015) suggested emissions for crusted and non-crusted cattle slurry of 0.11 and 0.19 g NH_3 m^{-2} h^{-1}, respectively, from tanks or lagoons. For pig slurry stored in a lagoon, they give 0.12 g NH_3 m^{-2} h^{-1}, and stored in a tank, 0.40 g NH_3 m^{-2} h^{-1}. Sommer et al. (2006) provided similar values. Bittman et al. (2014) gave baseline emissions between 0.19 and 0.40 g NH_3 m^{-2} h^{-1}. They attributed the lower value to slurry which is frozen in the store for several months, and the higher value applies to warm countries. For N_2O, most studies exhibit emissions clearly below 0.01 g N_2O m^{-2} h^{-1} (Supplementary data 8). In contrast, three papers reach values from 0.02 to 0.06 g N_2O m^{-2} h^{-1} and N_2O losses ranging between 25% and 160% of the NH_3 emissions determined concomitantly (Clemens et al., 2006; Amon et al., 2007; Leytem et al., 2011). Unless at very low levels of NH_3 emissions, flows of both NH_3 and N_2O in the same order of magnitude do not occur in other records and have not been reported in the livestock sector (e.g. EEA, 2016). Therefore, the data from the three studies were excluded for the calculation of baseline emissions. If they were kept, the baseline emissions for N_2O would be higher by a factor of two and three for cattle and pig slurry stored in tanks, respectively. Chadwick et al. (2011) stated in their review that N_2O emission from slurry stores without a surface cover are negligible which supports the baseline emissions shown in Table 8.

For CH_4, higher emissions occur for farm-scale studies than for pilot-scale studies (Table 8; statistically significant differences for emissions on an area basis; $p < 0.05$; Supplementary data 4). This could be due to the temperature dependency of methanogenesis (Elsgaard et al., 2016). Pilot-scale studies exhibit lower slurry volumes as compared to farm-scale stores which suggests faster cooling of the slurry and therefore a lower methane conversion rate. Another reason could be the batch-filling of vessels used for pilot-scale studies which differs from continuous filling and incomplete removal of slurry at farm-scale stores. Under such conditions, aged slurry may act as inoculum which was shown to enhance emissions of CH_4 (Wood et al., 2014). Overall, the lower emission level for CH_4 measured at pilot-scale included for the determination of baseline emissions tank could lead to an underestimation thereof.

The review of Owen and Silver (2015) reported CH_4 emission data from lagoons and tanks of dairy systems being 2.3 and 2.7 g CH_4 m^{-2} h^{-1}, respectively. This is higher than data from farm-scale studies reported here which are 1.2 and 1.3 g CH_4 m^{-2} h^{-1} for cattle slurry stored in lagoons and tanks, respectively (Supplementary data 4). However, the data basis of Owen and Silver (2015) is smaller and measurements carried out in the warm season tend to be overrepresented. The higher CH_4 emissions from pig slurry as compared to cattle slurry are expected due to the higher methane production potential of pig slurry (Triolo et al., 2011). Both cattle and pig slurry exhibit lower losses from tanks than from lagoons. Moreover, lagoon storage produces a solid fraction which includes a large proportion of the slurry VS generating additional emissions. According to VanderZaag et al. (2010b), a CO_2-C:CH_4-C ratio of 50:50 is expected from stores. Looking at records which include emission data of both CH_4 and CO_2, a large variation occurs. The average CO_2-C:CH_4-C ratio is approximately 65:35 which also differs from the CH_4 to CO_2 relationship expected from anaerobic digestion of livestock slurries (ca. 55%–70% CH_4 content of dry biogas; Triolo et al., 2011). This could be due to a tendency for greater CO_2-C:CH_4-C ratios in pilot-scale studies which increases the average CO_2-C:CH_4-C ratio of all records included. The greater ratios were also linked to studies with low CH_4 fluxes. This is likely because pilot-scale studies had less ability to provide appropriate conditions for CH_4 production as mentioned above. On the other hand, CO_2 seems to be emitted more consistently in all studies.

As the aim of all studies considered for the calculation of baseline values in the present paper was the determination of emission rates we think that the baseline emissions are robust and reflect the current state of knowledge. But the confidence intervals shown in Table 8 may be substantial. This suggests an inherent variability in the systems which can be due to differing conditions regarding meteorological conditions, operations at stores and occurrence of a natural crust. Baseline values must be considered as average numbers. In a specific situation and e.g. for representative regional values, deviations from the presented baseline values can occur. Moreover, methodological biases cannot be ruled out and different experimental approaches might entail systematic differences in results (e.g. possibly CH_4 emissions from pilot-scale studies). Such effects have been observed for experimental data on NH_3 emissions from slurry application (Hafner et al., 2018).

4.4.2. Flow-based emissions

The determined baseline emission values for NH_3 of 16% of TAN and 15% of TAN for cattle and pig slurry, respectively, which are mostly based on pilot-scale studies exhibit similar values as the emission factors of EEA (2016) which give 20% of TAN and 14% of TAN as Tier 2 default values for cattle and pig slurry. Data from farm-scale studies have comparable numbers for storage in tanks for cattle slurry: 16% of TAN (Baldé et al., 2018) and 13% of TAN (McGinn et al., 2008) but lower emissions for pig slurry (Dinuccio et al., 2012) with 2% and 5% of TAN. Flow-based emissions are not available for lagoons. IPCC (2006) and EEA (2016) suggest an N_2O emission factor being zero for slurry storage without a natural crust. For a crusted store, IPCC (2006) and EEA (2016) give EFs of 0.5% of N and 1% of TAN entering the store, respectively. These values are higher than the values determined in this study which are 0.13% of N and 0.10% of N for cattle and pig slurry, respectively (Table 9). The eight highest values for flow-based N_2O emissions originate from records that include slurry stores with a crust which supports the occurrence of N_2O emissions with crusted store surfaces. This complies with Sommer et al. (2000) who suggest that N_2O is produced in drying of natural crusts where aerobic and anaerobic zones exist. Drying enhances convection of liquid upward through the cover, where dissolved ammonium can be oxidized by nitrifying bacteria in an aerobic environment and under such conditions, molecules produced from nitrification can be denitrified. During ammonium oxidation and denitrification, N_2O is released as an intermediate or final product. At limited oxygen availability, formation of N_2O is enhanced.

For CH_4, a direct comparison between the suggested baseline emissions with default emission factors used in models for emission inventories is not possible. A simplified application of the approach of Mangino et al. (2001) and IPCC (2006) using the methane conversion factor (MCF) for slurry in a cool climate with an annual average temperature of 14 °C results in a CH_4 emission of ca. 4.0% of VS and 7.5% of VS for cattle slurry and pig slurry, respectively. These figures are somewhat higher than the baseline emissions suggested (Table 9) which are 2.9% of VS and 4.7% of VS for cattle and pig slurry, respectively. It should be noted that emission values for CH_4 derived from such model approaches can strongly deviate from measured values as shown by several studies (e.g. Kariyapperuma et al., 2018).

For the determination of flow-based emissions, analytical data of the slurry, the flow volume of slurry into storage and its residence time in the store must be known. Determining these three parameters is not straightforward which might explain the high degree of absence regarding flow-based emissions in farm-scale studies. This particularly applies for lagoons where extended slurry residence times, accumulation of solids over long time periods and repeated recycling of liquids used for flushing or recharging pits of livestock housings represent additional challenges. Generally, lagoons have a greater surface to volume ratio and longer slurry residence times as compared to tanks. These two factors will lead to higher flow-based emissions for lagoons as compared to tanks if identical emissions on an area basis are assumed for both storage systems.

For inventory purposes, emission factors could be calculated using the baseline emissions on an area or volume basis and an assumption of the surface or volume of the storage system, the average values for the residence time of the slurry in the store and the slurry contents of TAN, N or VS. These values are specific for different countries and production systems. A further assessment thereof is outside the scope of this paper. The calculation of flow-based emissions (and emission factors) is subject to additional uncertainties as compared to emissions on an area basis due to the requirement of further parameters.

4.5. Emission changes due to slurry treatments

The pH value has a strong effect on gaseous emissions from slurry stores (Sommer et al., 2013). This is appropriately reflected by the data on emission changes due to slurry acidification through addition of inorganic acids shown in Table 10. The variability in the achieved reduction is likely related to the degree of acidification and the different pH values in slurry (Dai and Blanes-Vidal, 2013). The emission reductions found for NH_3 and CH_4 are in line with the review of Fangueiro et al. (2015). Similarly, Petersen et al. (2012) observed significant reduction effects for NH_3 and CH_4 due to acidification. The data point at an increase in N_2O emission but this is based on limited data. Bastami et al. (2016) concluded that self-acidification of slurry induced by addition of substrates rich in carbon may be a promising alternative to slurry acidification using concentrated acids for abatement of CH_4 emissions. Additives other than acids to reduce gaseous emissions or odor nuisance from manure storage have been investigated in some studies (Martinez et al., 2003; Sun et al., 2014; Owusu-Twum et al., 2017). A clear emission reduction due to other additives did not occur. Similarly, Van der Stelt et al. (2007); Wheeler et al. (2011) and Holly and Larson (2017a) found little evidence that manure additives other than acids have a clear influence on the release of ammonia and GHGs. Still, individual investigations have shown an emission reduction potential for certain additives (Bastami et al., 2016).

The number of studies allowing a direct comparison of emissions from storage of untreated slurry and anaerobically digested slurry is limited since biogas plants are mostly fed with manure and off-farm organic feedstock material which hampers a direct comparison with unamended untreated slurry. The increase of NH_3 emissions due to anaerobic digestion complies with studies which include anaerobic digestion with addition of organic feedstock material. Baldé et al. (2018) measured NH_3 emissions from two stores at different farms containing untreated livestock slurry and liquid digestate obtained from livestock slurry and organic feedstock materials under farm conditions. Emissions from the untreated slurry were lower. Koirala et al. (2013) suggested that anaerobic digestion of dairy slurry significantly increased the NH_3 volatilization potential. The most important factor was the enhanced ammonium dissociation. Anaerobic digestion seems to reduce CH_4 emissions during slurry storage. Maldaner et al. (2018) found lower CH_4 losses from the liquid fraction of anaerobically digested slurry amended with organic feedstock material compared to unamended raw slurry from the same farm before the installation of anaerobic digestion. This is likely due to the reduction of the VS load after digestion but also a consequence of solids removal with solid-liquid separation of the major part of the digestate. Furthermore, Maldaner et al. (2018) suggested that VS remaining in the digestate was less degradable which leads to a reduced CH_4 production. VanderZaag et al. (2018) showed the CH_4 emission potential (B_0) from digestate was 35% lower than the B_0 of untreated manure. In contrast, Sommer et al. (2000) and Rodhe et al. (2015) measured higher emissions from anaerobically digested slurry as compared to untreated cattle slurry. They explained this by the presence of a larger and more active microbial community in digested slurry. However, most storage tanks are never completely empty. Residual aged slurry may act as inoculum and enhance the production of CH_4 (Sommer et al., 2007; Ngwabie et al., 2016). Although, the microbial population in aged slurry may be less efficient for methane production as compared to microbes present in anaerobically digested slurry, the higher amount of degradable organic carbon available in untreated slurry might compensate this. It can therefore be hypothesized that untreated slurries as occurring in real-world stores imply a higher potential for CH_4 emissions than anaerobically digested slurry.

Solid-liquid separation reduces the solids content of the slurry and thus the potential to develop a natural crust. This enhances NH_3 emissions during storage which complies with the increasing emissions of cattle slurry due to solid-liquid separation. Pig slurry exhibits a lower ability to form a natural crust which could explain why almost no effect of solid-liquid separation on NH_3 emissions can be observed (Table 10). Baldé et al. (2018) investigated the NH_3 emissions from two stores situated at different dairy farms containing untreated slurry and separated liquids under farm conditions. They measured higher emissions from the liquid fraction than from the untreated slurry and reported similar findings for the separated liquids from digestate derived from livestock slurry and organic feedstock materials. In contrast, Hjorth et al. (2009) found significantly higher NH_3 emissions from raw and digested slurries than from the corresponding liquid fractions. They explained their findings by the higher ammonium and N contents of the unseparated raw and pre-digested slurries compared with the liquid fractions, which increased the potential for NH_3 volatilization. The lower N_2O storage emissions of the liquid fraction for cattle slurry as compared to raw slurry is in line with the conclusions of the review paper published by Chadwick et al. (2011). The reduced emissions of CH_4 due to solid-liquid separation results from the reduction of the total solids content in the slurry which can be considered as a surrogate for the available VS pool. This leads to a lower amount of organic matter which can be degraded to CH_4 and CO_2 (Wood et al., 2012). However, yearly average CH_4 emissions of 1.4 g CH m^{-3} h^{-1} and 2.2 g CH m^{-3} h^{-1} for the first and second year of measurements were reported for dairy slurry from a farm-scale study conducted at a tank (Balde et al., 2016a). These numbers exceed the baseline emission and emissions from farm-scale studies from tanks for cattle slurry given in Table 8. Balde et al. (2016a) explained the elevated emission levels by the high biodegradability of the liquid fraction and the limited crust development. VanderZaag et al. (2018) showed that the speed of CH_4 production was much higher for the separated liquid fraction, compared to untreated slurry. Grant et al. (2015) found CH_4 emissions on an area basis from the liquid fraction of cattle slurry stored in a lagoon which are similar to the baseline emission for cattle slurry (Supplementary data 4). The discrepancy between the emission changes given in Table 10 and the high emissions found in these two studies is difficult to explain.

Dilution of slurry with water changes its DM content. DM of slurry can be considered as an indicator for the N/TAN- and VS-content which influences the potential production of NH_3, N_2O, CH_4 and CO_2, respectively (Wood et al., 2012). However, DM affects the formation of a natural crust as well (section 4.2.4). Overall, dilution leads to a reduction of all investigated gases which complies with the findings of Ni et al. (2010) for NH_3 and CO_2 and of Habetwold et al. (2017) for CH_4. But this conclusion is based on pilot-scale studies where the slurry volume is identical for the diluted and untreated slurry. Under practical conditions, addition of water leads to a higher amount of slurry. If the area of manure stores is thereby increased due to requiring larger storage capacities, the reduction might be overcompensated due to a rise in emitting surface (Ni et al., 2010).

Aeration of slurry is a technique which is used to remove excess N from slurries. It induces nitrification and denitrification that converts TAN in the slurry to nitrite/nitrate with the aim of a complete denitrification to N_2. If the process is not properly controlled aeration can produce substantial amounts of NH_3 and N_2O (Loyon et al., 2007). The effect of aeration was investigated in several laboratory- and pilot-scale studies. Amon et al. (2006) found a strong increase of NH_3 emissions by up to a factor of five. Molodovskaya et al. (2008) reported NH_3 emissions of up to 50% of total slurry N. Losses were increased at greater aeration rates. Many studies found a strong increase in emissions for N_2O with aeration (Beline et al., 1999; Beline and Martinez, 2002; Amon et al., 2006; Loyon et al., 2007). Low emissions for both NH_3 and N_2O were achieved from low flow phased oxic/anoxic treatment (Molodovskaya et al., 2008). A reduction of CH_4 by ca. 50% to almost 100% emissions was observed by Martinez et al. (2003) and Amon et al. (2006) if slurry aeration was applied. Concomitantly, CO_2 emissions were reduced (Martinez et al., 2003).

An increase in emissions of a specific gas during slurry storage due to a treatment technique does not necessarily indicate a conflict related to emission mitigation. Enhanced losses during storage can be reduced by e.g. storage covering and might be overcompensated by reduced emissions during subsequent field application. The overarching goal of manure management is the reduction of gaseous losses between the excretion by livestock and uptake by arable and fodder crops. Therefore, the discussion on effects of slurry treatments on emissions from slurry storage must consider the context of good management practices along the whole manure management chain (Sajeev et al., 2018).

4.6. Emission changes due to coverage of slurry stores

Almost all types of covers induce a substantial emission reduction for NH_3 which complies with the review of VanderZaag et al. (2008). Emission reductions lie in a similar range for all categories of covers and for both cattle and pig slurry. This contrasts to Bittman et al. (2014) who give distinct values for the different cover types and lower values for “Low technology” floating covers such as permeable natural floating covers. VanderZaag et al. (2015) give an emission reduction of 80% for impermeable structural covers and for impermeable synthetic floating covers which is in the range of the values given in Table 11. A larger layer thickness of natural floating covers leads to a higher emission reduction (Guarino et al., 2006; VanderZaag et al., 2009). This is probably due to a more efficient barrier for the gas transport between the slurry and the ambient air (VanderZaag et al., 2009). Other cover types not included in the data analysis according to section 2.4.3 also efficiently reduce NH_3 emissions. Organic materials such as steam-treated wood or biochar were shown to exhibit similar effects as floating covers consisting of straw or peat (Holly and Larson, 2017b). Minerals like perlite or zeolite were also found to be efficient in NH_3 emission reduction (Hörnig et al., 1999; Portejoie et al., 2003).

The increase in emissions observed for N_2O in many cases agrees with the previously published literature (VanderZaag et al., 2008; Chadwick et al., 2011). Petersen et al. (2013) observed lower N_2O flows with a straw cover exposed to precipitation as compared to straw covers where wetting by precipitation was excluded. Sommer et al. (2000) suggested that N_2O is only produced in periods with drying surface layers. Storage covers can influence the formation of a natural crust (Chadwick et al., 2011). A natural surface crust on slurry can provide sites with aerobic conditions where nitrification occurs which produces N_2O (Sommer et al., 2000). Therefore, the variability in emission changes due to slurry storage covering could be driven by differing moisture contents of the manure surfaces and differing formation of a natural crust due to covering. However, the number of records related to emission changes for N_2O due to store covers is sparse and these findings can be uncertain.

The observed increase in CH_4 emissions for plastic fabrics, expanded polystyrene and peat complies with the review of VanderZaag et al. (2008). Straw covers provide additional carbon but might reduce ebullition and increase aerobic microbial activity at the upper storage layer (VanderZaag et al., 2009). This induces contrasting effects on CH_4 net emissions. VanderZaag et al. (2009) suggested that the reduction of CH_4 emissions due to a straw cover is related to areas in a crust where microbial breakdown of CH_4 might occur. It can be assumed that the enhanced CH_4 consumption overcompensates the increased potential for CH_4 production due to the additional carbon supply with straw. An opposite effect can occur if straw is incorporated into the bulk slurry during storage due to e.g. agitation. Petersen et al. (2013) found that an elevated CH_4 concentration in the gas phase above the slurry surface is required for a significant stimulation of methane oxidation. This would support the preponderant emission reduction found for impermeable covers. For other cover types, the CH_4 concentration above the emitting surface might have been inconsistent in the experiments which could explain the contrasting emission changes for CH_4 due to storage covering. Similar to NH_3, a larger layer thickness of straw covers leads to a higher emission reduction for CH_4 although the differences of the emissions are low (Guarino et al., 2006; VanderZaag et al., 2009).

The contribution of the different gases to the total of GHG emissions is largest for CH_4 with a proportion of ca. 80% (VanderZaag et al., 2009; Petersen et al., 2013). Therefore, the changes of GHG equivalents due to effects of covers is moderate with a slight trend towards lower total GHG emissions.

VanderZaag et al. (2010b) have shown that a permeable synthetic floating cover was more efficient regarding emission reduction of NH_3 and CH_4 when slurry is agitated as compared to undisturbed slurry. VanderZaag et al. (2009) found that agitation increased NH_3 losses from straw covered tanks less than from the uncovered reference. CH_4 emissions from covered and control tanks were similarly changed.

Although found efficient in emission reduction, low cost floating covers such as straw covers are probably not efficient for emission mitigation in practice since they may be destroyed when the slurry surface is disturbed due to strong winds or operations at a store. Therefore, we consider impermeable structural covers or synthetic floating covers as most reliable for emission mitigation.

4.7. Recommendations for further research

The emission data provided in records from different studies range over several orders of magnitude even for the same slurry type, the same type of study and identical seasons of measurement. This may be partly due to varying conditions related to manure management and meteorological conditions occurring during the measurements. In addition, different study designs and measuring methods are likely to contribute to the variability in emissions. An important issue in future research should thus focus to identify and quantify potential experimental biases. This aspect requires the simultaneous use of independent approaches to determine emissions.

Farm-scale studies using non-intrusive methods such as micrometeorological mass balance (Wagner-Riddle et al., 2006) or dispersion modeling (Flesch et al., 2009) are likely to be a preferential option. Such approaches avoid interactions with emitting processes and determined emission rates best reflect the emissions occurring under conditions at farm-scale. They have the ability to cover large area sources (Gao et al., 2008) and can thus integrate the large inhomogeneity of emissions over space and time. For dispersion modeling, the limiting factor is the requirement of a simple topography allowing for representative turbulence measurements. Most of the micrometeorological methods require a minimum wind speed. Many sensors, e.g. for NH_3, have a minimum detection limit which may be higher than gas concentrations occurring under conditions with low emissions (Balde et al., 2019). Consequently, farm-scale studies using non-intrusive methods have a risk to overestimate the true average emissions (Baldé et al., 2018). This risk can be minimized by using recently developed sensors such as DOAS systems (Volten et al., 2012; Bell et al., 2017). Moreover, it would be important to quantify such potential biases by an assessment of gap filling procedures used for missing data due to e.g. non-detection at low concentration levels as done by Voglmeier et al. (2018). For reliable results from farm-scale studies, extended measurement periods are required covering all seasons of a year. Moreover, recent research has demonstrated that the history of the storage may play an important role for CH_4 emissions (Kariyapperuma et al., 2018) pointing at the necessity of measurement campaigns over several years for an adequate determination of representative emission rates. This implies a large effort in labor and costs. In addition, thorough recording of the operations at the storage facilities (agitation, filling, discharging of the stores by using e.g. a webcam, continuous measuring of the slurry volume stored), of crusting at the stores surface (thickness, structure, coverage of the surface), of slurry temperature at several depths, of meteorological conditions as well as slurry sampling and analyses are required. A few studies comply with these requirements (e.g. Baldé et al., 2018; Kariyapperuma et al., 2018). Still, collection of such data can be challenging or even hardly feasible (e.g. representative slurry sampling at large lagoons). Also, operations at stores can largely differ between individual farms and consequently, it is difficult to select an experimental site at farm-scale which is appropriate to generate baseline emissions. Therefore, several measurement campaigns that consider the variety of different conditions occurring at slurry stores are required.

Pilot-scale studies are indispensable for studying principal mechanisms and influencing factors driving emissions or to evaluate the effectiveness of emission mitigation techniques. Facilities allowing for continuous measurements e.g. as presented by Petersen et al. (2009) are probably the best option. Further advantages of pilot-scale studies are the possibility to conduct experiments in replicates and a better control of the experimental conditions. There is also a potential to generate bases for modeling which could be used to complement data from farm-scale studies. Further progress for the quantification of emissions from slurry storage could be achieved by an analysis of individual measurement intervals from several experiments and model construction on this basis as e.g. done for slurry application by Hafner et al. (2019). The measurement intervals should include the relevant information regarding influencing factors. For this, we recommend that the researchers provide the emission data along with parameters as given in the Supplementary data 2. For indistinct parameters such as crusting, we suggest the elaboration of a standardized procedure to achieve a definition which reliably reflects its influence on the emission level.

5. Conclusions

The present article provides a comprehensive overview on published emission data from slurry storage which serves as a basis to determine guide values and baseline emissions for NH_3, GHGs and H_2S. Standardization of the emission data is an important issue in the present study due to the use of a large variety of units in the studies. Accompanying parameters (e.g. data on slurry analyses) were only partly available in the papers and could thus not be used for a more advanced data analysis. However, the season of the experimental period which served as a surrogate for the temperature was provided in most studies. Descriptive statistics of the emission data revealed a large variability for all gases. Data generated during warm, temperate and cold seasons are unevenly distributed over all records. Therefore, the calculation of an average annual value completed with a confidence range based on a weighting of the emission data according to the season and measurements duration was done. The baseline emissions on an area or volume basis determined for cattle and pig slurry stored in lagoons and tanks (Table 8) are mostly lower than existing reference values. NH_3 baseline emissions for tanks related to TAN are 16% of TAN (range: 14%–19% of TAN) and 15% TAN (range: 9.2%–23% of TAN) for cattle slurry and for pig slurry, respectively, and thus similar to emission factors used in emission inventory models. The flow-based baseline emissions for N_2O and CH_4 are lower than current emission factors. Total GHG emissions from slurry stores based on the global warming potential using a 100-year time horizon are dominated by CH_4.

Techniques for slurry treatment exhibit contrasting effects on emission levels during storage. Acidification was found to be efficient in reducing the emissions of NH_3 and CH_4 but less for CO_2 while the release of N_2O was enhanced in few studies. Solid-liquid separation causes higher losses for NH_3 and a reduction in CH_4, N_2O and CO_2 emissions. Anaerobic digestion promoted NH_3 emissions in most studies. In contrast, emission changes during slurry storage were less explicit for CH_4, although there is evidence toward an emission reduction. The effect of anaerobic digestion on N_2O and CO_2 emissions is unclear. It is essential to consider the context of good management practices along the whole manure management chain when the effect of slurry treatments on emissions from slurry storage is assessed.

All storage cover types reduce emissions of NH_3 while the effect is small for CH_4 and CO_2 with a trend toward a reduction. Permeable covers increase emissions of N_2O. Total GHG emissions tend to be lower with coverage of slurry stores. Overall, coverage of slurry is efficient to abate NH_3 emissions involving a minimum risk of pollution swapping.

The present study provides a robust data basis for the determination of baseline emissions except for flow-based baseline emissions for lagoons which could not be calculated. The emission data in the records from different studies may vary over several orders of magnitude even for the same slurry type, the same type of study and identical seasons of measurement. For future research, appropriate study designs are required to generate baseline emissions appropriate to improve emission inventories. For this, farm-scale studies using non-intrusive methods are likely to be a preferential option. Pilot-scale studies are important to complement results from farm-scale studies.

Declaration of Competing Interest

Abstract: Livestock manure is a major source of the greenhouse gases (GHGs) methane (CH_4) and nitrous oxide (N_2O). The emissions can be mitigated by production of biogas through anaerobic digestion (AD) of manure, mostly together with other biowastes, which can substitute fossil energy and thereby reduce CO_2 emissions and postdigestion GHG emissions. This paper presents GHG balances for manure and biowaste management as affected by AD for five Danish biogas scenarios in which pig and cattle slurry were codigested with one or more of the following biomasses: deep litter, straw, energy crops, slaughterhouse waste, grass–clover green manure, and household waste. The calculated effects of AD on the GHG balance of each scenario included fossil fuel substitution, energy use for transport, leakage of CH_4 from biogas production plants, CH_4 emissions during storage of animal manure and biowaste, N_2O emissions from stored and field applied biomass, N_2O emissions related to nitrate (NO_3^-) leaching and ammonia (NH_3) losses, N_2O emissions from cultivation of energy crops, and soil C sequestration. All scenarios caused significant reductions in GHG emissions. Most of the reductions resulted from fossil fuel substitution and reduced emissions of CH_4 during storage of codigestates. The total reductions in GHG emissions ranged from 65 to 105 kg CO_2-eq ton^{-1} biomass. This wide range showed the importance of biomass composition. Reductions were highest when straw and grass–clover were used as codigestates, whereas reductions per unit energy produced were highest when deep litter or deep litter plus energy crops were used. Potential effects of iLUC were ignored but may have a negative impact on the GHG balance when using energy crops, and this may potentially exceed the calculated positive climate impacts of biogas production. The ammonia emission potential of digestate applied in the field is higher than that from cattle slurry and pig slurry because of the higher pH of the digestate. This effect, and the higher content of TAN in digestate, resulted in increasing ammonia emissions at 0.14 to 0.3 kg NH_3-N ton^{-1} biomass. Nitrate leaching was reduced in all scenarios and ranged from 0.04 to 0.45 kg NO_3-N ton^{-1} biomass. In the scenario in which maize silage was introduced, the maize production increased leaching and almost negated the effect of AD. Methane leakage caused a 7% reduction in the positive climate impact for each percentage point of leakage in a manure-based biogas scenario.

1. Introduction

Emissions of nitrous oxide (N_2O) and methane (CH_4) from livestock manure management contribute around 10% of the total non-CO_2 greenhouse gas (GHG) emissions globally calculated as CO_2 equivalents [1]. N_2O and CH_4 have global warming potentials for time horizons of 100 years (GWP100) of 298 and 25 times, respectively, higher than

GWP100 per kg of carbon dioxide (CO_2) [2]. Ammonia (NH_3) emission and leaching losses of nitrate (NO_3^-) are important indirect sources of N_2O [3,4].

Globally, manure management contributes about 10% of agricultural CH_4 emissions [5], but in confined livestock production systems (e.g., dairies and piggeries) with liquid manure management, this proportion can exceed 50% depending on climate [1]. Animal manure applied to soil contributes to maintenance of soil carbon (C) insofar as a fraction of the manure C is sequestered. The Danish Energy Agency has calculated that of the Danish GHG emissions from livestock production, manure management contributes 22%, manure and mineral fertilizers applied to soil contribute 39%, and enteric fermentation contributes 39% to total agricultural GHG emissions [6].

Emissions of CH_4 and N_2O are regulated and accounted under the UNFCCC as part of the Paris Agreement. The reduction target for the EU on GHG is 55% by 2030 with reference to the year 1990 [7]. The Danish parliament has decided that GHG emissions from Denmark must be reduced by 70% with reference to 1990 by 2030 [6], and agriculture must contribute to this reduction. This calls for the implementation of technologies that cost-effectively reduce GHG emissions from the livestock slurry management chain. Slurry is in focus because 80% of Danish livestock manures are managed in the form of slurries [8].

GHG emissions from slurry management systems can be reduced by AD treatment, frequent export of slurry from livestock buildings to colder outside stores, acidification, or separation of slurry combined with incineration [9–13].

In Denmark, more than 25% (weight basis) of animal manure is today anaerobically codigested on centralized biogas plants with organic wastes from the food industry, slaughterhouses, dairies, and the fish industry with the aim to produce CH_4 for bioenergy. The residues from AD must be recycled as fertilizer and meet the requirements for content of pathogens, heavy metals, and environmentally harmful substances. Biogas plants use almost all industrial residues available in Denmark, and increasing amounts of straw, grass, deep litter, etc. are used in the codigestion of slurry.

The economy is critical when making decisions about the introduction of technologies in farming aiming to reduce GHG emissions, and socioeconomic impacts of different types of biomass for AD have been calculated [14,15]. In scenarios with codigestion of slurry with fibre fraction from slurry separation, maize silage, grass, and sugar beet, NO_3^- leaching was assessed, but the effects of the AD treatment on GHG emissions and NO_3^- leaching were not well documented [14]. More recently, a refined model of CH_4 from manure management that accounted for different storage conditions was used to calculate the effects of biogas and frequent export of slurry from livestock housing to an outside storage tank [16]. However, no biomasses other than slurry were accounted for, nor were any other effects, such as energy and environmental impacts.

When assessing the effect of AD as a potential mitigation measure, a whole-farm approach is needed to estimate GHG emissions from the pig or dairy farm, and calculations must include evaluation of side effects in the form of increased NH_3 emissions, reduced C sequestration, leakage of CH_4 from the biogas plant, etc. [17]. It is relevant to improve estimates of the potential of AD to reduce the negative GHG balance of livestock farming. Therefore, in the present study, the effect of AD on the GHG gas balance was calculated using a "system analysis approach", which included substituting CO_2 emission from power and heat production using fossil fuel; leakage of CH_4 from biogas production plants; CH_4 emissions during storage of animal manure and organic waste; N_2O emissions from stored and field applied manure, organic waste, and digestate; N_2O emissions related to NO_3^- leaching and NH_3 emission; N_2O emission from cultivating energy crops; and effects on soil C sequestration (Figure 1).

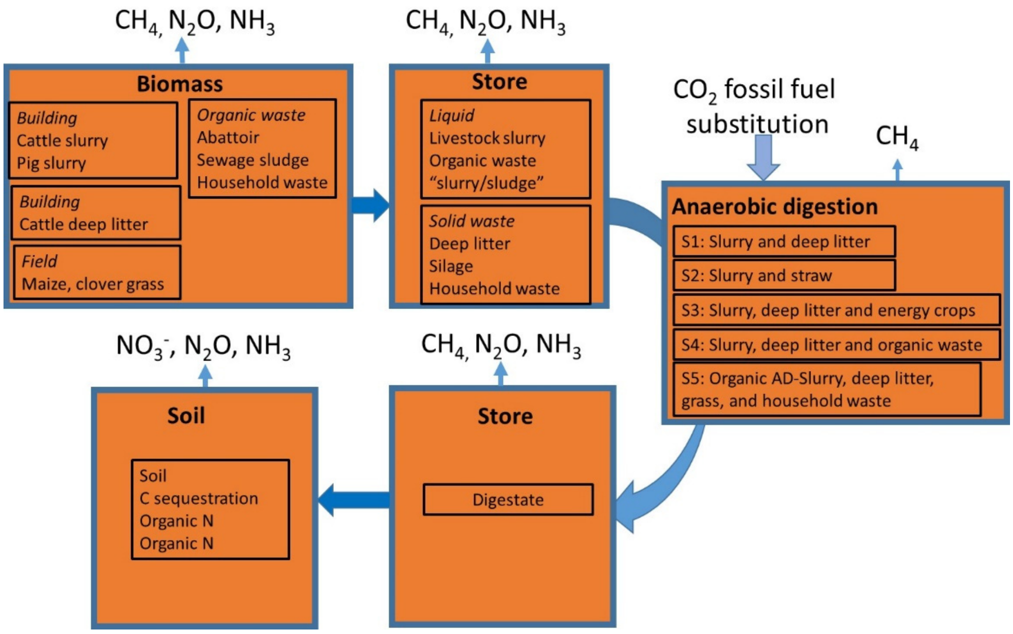

Figure 1. Flow diagram depicting the transfer of biomass among the five compartments of the biomass transfer continuum or system.

This quantification of the climate and environmental effects of biogas production constitutes an important basis for designing and targeting future biogas subsidies to optimize the climate and environmental benefits of production. In this study, assessments are reported for five biomass scenarios in a Danish biogas context with different retention times and biomass compositions. The assessment was based on the best technologies currently used by the Danish biogas sector.

2. Materials and Methods

The calculated climate and environmental effects of introducing centralized codigestion AD in the livestock sector were compared with typical reference management of slurry and waste biomasses. Environmental impacts of introducing AD in five manure management systems (Figure 1; Table 1) were calculated with a whole-system calculation approach for each scenario using one ton of dry matter of biomass as the functional unit. The calculations included CH_4 and N_2O emissions from each scenario (AD and reference farm without AD), the effect on soil C storage, and AD effects on N_2O emissions related to NO_3^- leaching and NH_3 emission. GHG and environmental effects were calculated using the models applied in the Danish national inventory. Global warming potentials for a 100-year time horizon (GWP100) of CH_4 and N_2O at 25 and 298 CO_2-eq kg^{-1}, respectively, were used [18].

2.1. Slurry and Biowaste Management

In this study, the starting point was the collection of excreta and urine in slurry channels. The retention time was set at 20 days for cattle and 19 days for pigs [16], and the average slurry temperature was set at 13.8 °C for cattle and 18.6 °C for pigs. From the channels, slurry was transferred to an outside store and subsequently applied to grassland or arable land between March and August. In the outdoor storage tank, the temperature of untreated slurry was calculated based on monthly mean temperatures [16]. Untreated slurry and digestate must be stored according to national regulations to minimize ammonia emissions [19]. About 80% of untreated slurry was covered by a floating layer of natural crust, straw, or clay pebbles, and 20% was covered by a tent cover. Solid manure was stored for an average of 5 months in heaps covered by a PVC sheet. The deep litter in the reference system was covered with PVC and stored for an average of 5 months.

Table 1. Model plants used in the five scenarios. Distribution of biomass input is given in weight percentage. The slurry input was a mixture of 50% cattle slurry and 50% pig slurry, except in S5, where only cattle slurry was used.

Scenario	Input	Input g DM kg^{-1} Biomass	Reactor g DM kg^{-1} Biomass	Reference Scenario
1	Slurry (80%) + deep litter (20%)	112	95	Animal slurry is stored in a slurry tank and then applied by injection or trailing hose. Deep litter is stored in covered stacks/manure piles for five months and applied before sowing spring cereals.
2	Slurry (80%) + straw (20%)	220	95	Straw is cut and incorporated.
3	Slurry (80%) + deep litter (8%) + energy crops (12%)	94	51	The land farmed with energy crops is used for cereal crops.
4	Slurry (70%) + deep litter (10%) + organic waste (20%)	141	53	The organic waste is stored as slurry and then spread directly on the field (slaughterhouse waste), incinerated (glycerine), or composted and then applied (biowaste).
5	Organic grass–clover (25%) + cattle slurry (50%) + deep litter (20%) + biowaste (5%)	97	95	At an organic farm without a biogas plant, the grass–clover is managed as green manure.

Slurries were applied by injection to bare soil and grassland and by trail hoses to autumn-sown crops such as winter cereals, whereas deep litter had to be incorporated within 4 h after application to soil.

In the reference system, slaughterhouse waste was stored together with livestock slurry and then spread on fields in the growing season. Glycerine was used for energy production by incineration, and source-separated household and industrial organic wastes were composted and used as fertilizer. The maize grown for codigestion in S3 was assumed to substitute a cereal crop in the reference system, and the grass–clover grown for codigestion in the organic farming scenario (S5) was assumed to be cut and mulched in the reference system.

In the AD concepts, liquid manure was transferred from livestock buildings to stores on the farm, as in the reference system (Figure 1). Every 3–30 d, the slurry in the outside store and slurry channels within the building were assumed to be emptied and transferred to stores on the AD plant and covered according to regulations. Deep litter was assumed to be transferred from the farms to biogas plants, where it was stored in covered heaps until used for biogas production. Straw was used for biogas production, and in the organic farm scenario, grass–clover crops were fed to the digester as silage. Organic waste in the form of abattoir waste was fed to the biogas reactors after storage in concrete stores similar to those used for animal slurry, and glycerine was assumed to be stored in containers until use. Source-separated household waste and industrial organic waste were assumed to be stored in covered heaps.

In the five scenarios examined in this study (Table 1), biomass was fed to centralized biogas plants with 45 d hydraulic retention times (HRT) in primary thermophilic reactors (53 °C) and an average retention time of 45 d. In newly built biogas plants in Denmark, HRT tends to be longer, and therefore, the calculations included scenarios with retention times of 60 and 90 days. Digestate was defined to be cooled by heat exchange to 25 °C and then stored at the plant for 20 d in a storage tank with CH_4 gas collection. In all model plants, digestion took place by serial operation in two reactors with the same retention time in each unit, and the biogas was assumed to be upgraded and transferred to the natural gas distribution network by removal of CO_2 in the biogas.

The digestate was transferred from the AD plant to farmer concrete stores, where 50% of the digestate was assumed to be covered with a tent and the rest by a floating cover, straw, or natural surface crust. The digestate was applied by injection to bare soil and grass crops (mandatory in Denmark) and by trail hoses to other growing crops.

2.2. Calculations

Greenhouse gases, NH_3 emissions, and leaching of NO_3^- from different farm compartments in the reference and AD biomass management continuum are depicted in Figure 1. An overview of the calculation of biogas production, emissions, leaching, and soil C storage is given in the following. Short reviews about the algorithms used to calculate emissions, transformation, and leaching losses are presented in Supplementary Materials, which also contain tables with parameters for the algorithms and emission factors.

2.2.1. Biogas Production

The CH_4 production from the different biomasses was estimated from our own experiments and other studies (Supplementary Materials, Table S1). The ultimate CH_4 yield in terms of volatile solids (VS) is the yield achieved at a retention time of more than 90 days, and to determine the yield at shorter retention times, the CH_4 produced in the biogas reactor was determined for each biomass through modelling using the Gompertz equation [20]. The gas potential at a given time was calculated as follows:

$$M(t) = B_0 \cdot \left(1 - e^{-k \cdot t}\right) \tag{1}$$

where M is the cumulative CH_4 yield (mL g^{-1} (VS)), B_0 is the theoretical CH_4 yield (mL g^{-1} (VS)), k is a first-order kinetic rate constant representing the hydrolysis constant, and t is retention time (days). The biogas production was calculated from this equation and thus determined by the amount and quality of biomasses and the retention time in the biogas reactor.

2.2.2. Energy Production and Consumption

The calculations of CO_2 substitution from energy production were based on the displacement of natural gas, in which CH_4 substituted CO_2 corresponding to 0.057 kg CO_2-eq MJ^{-1} [21]. The electricity demand for agitators, pumps, etc. at the plant was assumed to be covered by a mix of the Danish electricity production, which in 2019 was estimated at 0.150 g CO_2 kWh^{-1}, as calculated using data from [22]. The volume of biomass transported in one truckload to and from the biogas plant varied among the different biomass types, and diesel consumption was given per kilometre driven. The distances were calculated as the average additional transport of biomass compared to the reference scenario without AD and varied from 0.8 kg CO_2-eq ton^{-1} for grass and maize silage to 11.6 kg CO_2-eq ton^{-1} for glycerol. The effect on GHGs of replacing mineral N fertilizer due to higher N availability in the digestates was estimated by assuming that the long-term N availability equivalent of total N was 5% higher in the treated than in untreated manure [23]. The potential reduction in N fertilizer use was assumed to give a reduction in GHGs of 5.6 kg CO_2 kg^{-1} N [24], equivalent to 0.28 kg CO_2 kg^{-1} treated N in the biogas plant.

2.2.3. Methane Emission from Slurry and Digestate

Daily methane emissions from slurry and digestate during storage were estimated from the volumes of readily degradable (VS_d, kg kg^{-1}) and slowly degradable organic matter (VS_{nd}, kg kg^{-1}) as proposed by Sommer et al. [9]:

$$F_t = (VS_d + 0.01VS_{nd})e^{(lnA - \frac{E_\alpha}{RT})} \tag{2}$$

where F_t is the methane production rate (g CH_4 kg^{-1} VS h^{-1}), E_α is the process activation energy (J mol^{-1}), lnA (g CH_4 kg^{-1} VS h^{-1}) represents the methanogenic potential of the substrate, R is the universal gas constant (J K^{-1} mol^{-1}), and T is the temperature (K). Equation (1) assumes that the amount and degradability of biomass organic matter, and storage temperature, are main controlling variables.

E_α was set to 81,000 J mol^{-1} [25]. The parameter lnA was highly variable and depended on slurry origin, treatment, storage conditions, and age [4]. Petersen et al. [26] estimated

lnA for slurry collected in pig and cattle barns by measuring CH_4 production rates at the storage temperature and calculating lnA from Equation (1) after rearrangement:

$$lnA = ln\left[\frac{F_t}{(VS_d + 0.01VS_{nd})}\right] + \frac{E_\alpha}{RT} \quad (3)$$

The degradability of VS in slurry changes during storage, and no data were available from outside storage tanks. Instead, a different approach was used in which lnA estimates were related to total VS:

$$lnA' = ln\left[\frac{F_t}{VS_{total}}\right] + \frac{E_\alpha}{RT} \quad (4)$$

Note that the parameter value derived from total VS is referred to as lnA' to distinguish from the original calculation of lnA with reference to degradable VS. A limited number of studies were identified for which information about storage temperature and VS content were available to allow estimation of lnA' in pig and cattle slurry, as well as digestate (Supplementary Materials, Table S4). For the present study, the lnA of pig and cattle slurry in barns reported by Petersen et al. [26] were recalculated to lnA'; Table 2 summarizes the values used.

Table 2. Values of the parameter lnA' used in scenario analyses to represent methanogenic potential; for derivation, see text. In the table, $\bar{x} \pm$ s.e. refers to average and standard error.

Category	Storage Period	lnA' g CH_4 kg^{-1} VS h^{-1}	Reference
Cattle slurry	Barn	30.1	[20]
	Outside store	29.2 ± 0.1	[25,27,28]
Pig slurry	Barn	30.6	[20]
	Outside store	30.3 ± 0.4	[25,27,28]
Digestate	Outside store	27.9 ± 0.4	[28,29]

Methane emissions were calculated separately for cattle and pig slurry in barns and for untreated slurry, digestate, and other biomasses assumed to be stored in outside storage tanks. Assumptions regarding retention time, storage temperatures, etc. are given in Supplementary Materials.

After field application, manure environments are predominantly at a redox level at which little, if any, CH_4 is produced. Transient emissions have sometimes been reported; these are probably due to release of dissolved methane produced during storage [30,31].

2.2.4. Methane Emission from Solid Manure

Methane may be emitted from solid manure (deep litter, fibre fraction from separated slurry or digestate) during storage. The emission level is determined by VS degradability, air- and water-filled porosity, and coverage, which in turn determine biological oxygen demand, gas exchange rates, temperature, and anaerobic volume developing during storage. The Danish emission inventory estimates this source with a model proposed in [4]:

$$EF = BMP * MCF * 0.67 \quad (5)$$

where EF (kg CH_4 kg^{-1}(VS)) is the CH_4 emission factor, BMP (m^3 CH_4 kg^{-1}(VS)) is the biochemical methane production potential, and MCF (%) is a country-specific CH_4 conversion factor. For deep litter, an MCF of 3% is assumed if manure is exported at 1-month intervals or less, and an MCF of 17% is assumed if manure is removed at longer intervals. With a BMP of 0.24 m^3 kg^{-1}(VS), the overall CH_4 emission from barns and during outside storage were as shown in Table 3.

Table 3. Emission factors for CH_4 and N_2O from deep litter in housing and storage facilities (IPCC 2006) as well as emission factors used for the storage period in this report. BMP was 0.240 m^3 (CH_4) kg^{-1} (VS).

Categories	Methane		Nitrous Oxide
	IPCC (housing and outside storage)		
	MCF (% of BMP)	kg CH_4 kg^{-1} (VS)	N_2O-N % of total N
<1 month in housing	3	0.005	1
>1 month in housing	17	0.027	1
	This study (outside storage)		
	kg CH_4 kg^{-1} (C)	kg CH_4 kg^{-1} (VS)	% of total-N
Storage in covered heaps	0.015	0.0075	0.5
Composting	0.03	0.015	2.2

We assumed that half of these emissions would come from outside stores, corresponding to 0.005 and 0.027 kg CH_4 kg^{-1}(VS) for short- and long-term storage periods, respectively (Table 3). Recent studies have shown that emission of CH_4 from uncovered and uncompacted manure heaps are at a level of 0.027 kg CH_4 kg^{-1}(VS) [32–34], and we therefore assumed that the emission factor was 0.03 kg CH_4 kg^{-1}(VS) for uncovered manure heaps and half as much for heaps with PVC tent covers (i.e., 0.015 kg CH_4 kg^{-1}(VS)) (Table 3) [34].

In organic farming, animal manure is often actively composted by turning the heap. This reduces the development of anaerobic volumes in the heap and contributes to lower CH_4 emission compared to undisturbed heaps. Based on a CH_4 emission from actively composted organic waste corresponding to 3% C [32], and assuming the same C/VS ratio in organic waste and deep litter, CH_4 emissions from deep litter were estimated (Table 3).

2.2.5. Nitrous Oxide Emission

Nitrous oxide may be emitted from slurry and digestate, as well as solid manure, during storage and after field application. Nitrous oxide emissions are associated with nitrification and denitrification, two interdependent processes occurring under aerobic and anaerobic conditions, respectively. Oxic–anoxic gradients occur in slurry storages with surface crusts and in the outer layers of manure heaps.

Nitrous oxide emissions during storage of slurry or digestate depend on the development of a floating crust where populations of nitrifying and denitrifying bacteria live. The IPCC guidelines give a default emission factor for storage tanks with a surface crust of 0.5%, i.e., 0.5% of total N entering the storage tank is converted to N_2O [4]. Danish pilot-scale measurements indicated lower emissions, 0.2–0.4% [35], but the level of emissions is influenced by climatic conditions, especially the water balance (rain and evaporation). The emission factor of 0.5% of N in the total flow of slurry was used here even though only the surface can be a source of N_2O. Without a surface crust, the emission factor for N_2O was set to 0 for both untreated slurry and digestate.

For cattle deep litter, IPCC [4] recommends a N_2O emission factor for barn and storage of 1% regardless of retention time in the barn. Assuming half of these emissions occur during outdoor storage, this effectively corresponded to 0.5% of total N. In a review by Pardo et al. [32], N_2O-N emissions from compost heaps with organic waste corresponded to 2.2% of total N (Table 3).

The default emission factor for nitrous oxide emissions from N in field-applied liquid and solid manure is 1% [4]. In soil with organic amendments, be they manure, digestate, or crop residues, the balance between oxygen (O_2) demand and O_2 supply is an important control of denitrification and N_2O emissions [36]. While anaerobic digestion reduces the availability of degradable VS, and hence O_2 demand, the net effect on N_2O emissions depends on the interaction with specific soil conditions. A review of field studies [37] reported mostly reductions in N_2O emissions with AD, but increases have also been reported. In the present study, no effect of anaerobic digestion on N_2O emissions was assumed. Nitrous oxide emissions related to NH_3 emissions and nitrate (NO_3^-) leaching were accounted for with emission factors of 1% and 0.75%, respectively, in accordance with the national inventory of Denmark [18].

2.2.6. Ammonia Emission

The emissions of NH_3 from slurry storage tanks and solid manure heaps were calculated using emission factors estimated by [38]. These were within the ranges given in the recent review by Kupper et al. [39]. The NH_3 emission factor for composting of source separated organic waste was taken from the review by Pardo et al. [32]. When deposited, the emitted NH_3 contributes to N_2O emissions [4], and this indirect source of N_2O was included in the calculations. Ammonia emission factors for applied livestock liquid manure given by [38] were used in this study, while emission factors for each month were calculated with the ALFAM model [40] using average monthly weather conditions and average slurry compositions for Denmark. Based on a review of recent studies, we assumed that NH_3 emission from digestate would be higher than emission from untreated slurry (Supplementary Materials, Table S6).

Data from studies on emissions of NH_3 from deep litter applied to soil were limited in 2008 [38], and only one emission factor for application during different months was given. The evidence about the effects of climatic conditions on emission of NH_3 from solid manure applied to soil is still limited, and emission factors cannot be assessed at a monthly scale [41]. We therefore used the same emission factor for applied deep litter regardless of whether the application took place in the spring or autumn. Deep litter must, in Denmark, be incorporated into the soil within 4 h of application, and it was assumed that within this timespan, 25% of total ammoniacal N (TAN) was emitted as NH_3.

2.2.7. Crop Production and Nitrate Leaching

AD processing of animal slurry and biowaste affects NO_3^- leaching from crop production in both direct and indirect ways. The direct effects are through the effects of applied N in both the first and following year after application of fertilizer or manure; here, AD affects the quality and quantity of N applied. The indirect effects of AD on NO_3^- leaching occur through AD effects on NH_3 volatilization, which affects the N available for plants through both the N loss and the deposited N.

Nitrate leaching during the first year after fertilizer or manure application was assumed to be proportional to the amount of total N (mineral N + organic N) applied [23,42,43]. Total N application was assumed to be similar before and after AD, in accordance with Danish fertilizer regulations, despite more N being plant available after AD. This means that more N is taken up in the first crop and less organic N is left in the soil from digestates. In the scenario with an energy crop (S3), total N application increased by AD, as the energy crop contributed with extra organic N to the system, and the N derived from the energy crop was assumed to replace only mineral N fertilizers with an efficiency of 40% as in the Danish legislation. In the other scenarios, total N application remained the same before and after digestion.

The effect of AD on NO_3^- leaching over a 10-year period was calculated using a model based on the principles described by Sørensen et al. [23]. It was assumed that about 40% of the organic N input would be mineralized during years 2–10 after application, and that 34% of the mineralized N would be leached as nitrate [23]. Because of the lower N mineralization after AD, NO_3^- leaching was also slightly reduced after digestion. The model uses information on soil and climatic conditions, and it was assumed that 80% of the manures were used on sandy soils with precipitation above average Danish levels [44].

The direct and indirect effects of increased NH_3 volatilization after AD on NO_3^- leaching were calculated separately. It was assumed that increased NH_3 emission caused a net reduction in NO_3^- leaching [8] as estimated with the following assumptions. The empirical NLES5 model estimates an average marginal leaching of 17% during the first three years after mineral N application in spring under Danish conditions and at N rates near the economic optimum [44]. In Denmark, 80% of livestock manure is applied to sandy soils [45] with higher-than-average marginal leaching, and therefore, 20% of NH_4^+-N in applied manure/digestate was assumed to be lost by leaching over a 3-year time period. Furthermore, NH_4^+-N applied to soil contributes to organic N from plant residues that may give an extra NO_3^- N leaching equivalent to 2% of the N input in years 3–10 after application [8]. The total reduction in NO_3^- N leaching from NH_4^+-N was therefore 22% of the increase in NH_4^+-N volatilization loss over a 10-year period. However, part of the lost NH_3 would be deposited on agricultural land where part of that pool is leached. It was estimated that 10% the NH_4^+-N lost by volatilization was land deposited and leached as nitrate [8]. Thus, the net effect of increased NH_3 loss on reduction in NO_3^- N leaching was set to 22% − 10% =12% of the increase in NH_3-N loss over a 10-year period. This factor was used to calculate the leaching reduction due to increased ammonia volatilization.

2.2.8. Soil Carbon Storage

The effect of biogas treatment of slurry and other livestock manure on soil C storage is still relatively poorly quantified, but a study based on laboratory incubations measured slightly smaller soil C storage in connection with AD treatment [46]. Based on Thomsen et al. [46], the amount of C digested in the biogas plant was assumed to have contributed to C storage by 25% of the effect achieved when adding C in fresh plant material and straw, i.e., 0.25 × 15% = 3.75% of the C transformed to CO_2 and CH_4 in biogas during the digestion process would alternatively have been stored after a 20-year period, assuming retention in the soil of 15% of the C added in plant material over 20 years [46].

3. Results

3.1. Biogas Production

The largest biogas production was achieved in the scenarios in which slurry was codigested with straw or grass, which were the scenarios with largest energy output. In the energy balances showing reduced CO_2-eq emissions, it was assumed that the CH_4 produced substituted natural gas (Figure 2). Power is used in biogas plants for heating, pumping, and mixing, which reduces the net energy production, but most Danish biogas plants limit the energy consumption using heat exchangers, reducing the digestate temperature to 25 °C. Without heat exchange, the digestate would be stored at higher temperatures and be a significant source of CH_4 emissions. In the calculations, the use of heat exchangers reduced the need for process heat and thereby enhanced the CO_2 balance by around 10% (Figure 2).

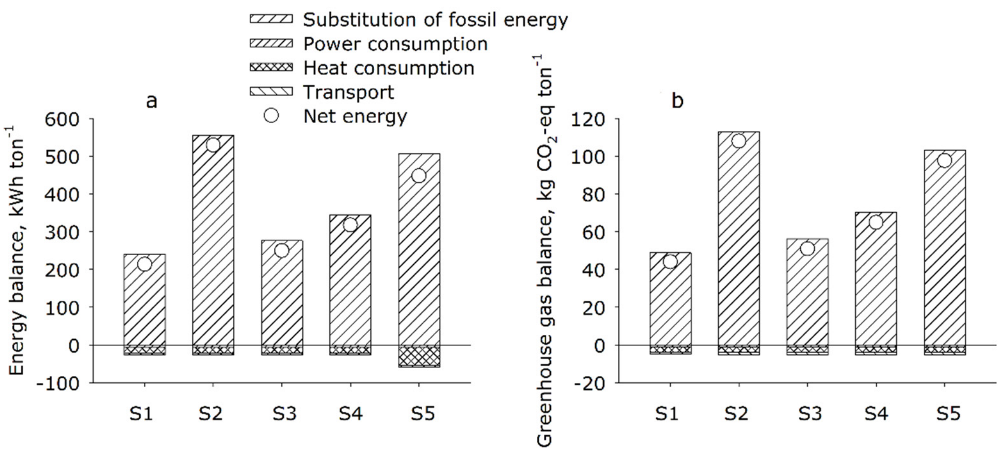

Figure 2. The energy (**a**) and GHG (**b**) balances of the energy production at model plants with heat exchangers installed. Scenarios were (S1) slurry and deep litter; (S2) slurry and straw; (S3) slurry, deep litter, and maize silage; (S4) slurry, deep litter, and organic waste; and (S5) slurry, deep litter, organic waste, and organic grass–clover.

The use of diesel for transport of biomass had little influence on GHG balances (Figures 2 and 3) in the biogas plants and constituted less than 3% of the energy produced.

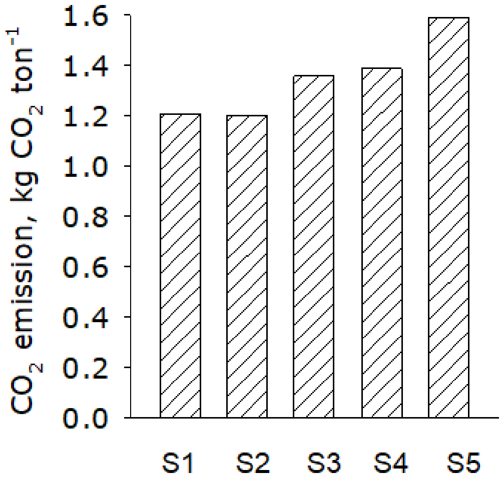

Figure 3. CO_2 emissions from biomass transport in model plants in which slurry was codigested with the following biomasses: (S1) deep litter, (S2) straw, (S3) deep litter and maize silage, (S4) deep litter and organic waste, and (S5) deep litter, organic waste, and organic grass–clover.

3.2. Methane Emissions

Whereas experimental data were available for the estimation of daily CH_4 emissions from cattle and pig slurry in barns, parameters representing the methanogenic potential during storage had to be extracted from published storage experiments. The lnA' values (Table 2) indicated that the methanogenic potential in stored digestate was around 70% lower than that in cattle slurry and 90% lower than that in pig slurry. This was in accordance with the assumption that anaerobic digestion would remove 90% of the degradable VS. With these differences in methanogenic potential, the five biogas scenarios showed reductions in CH_4 emissions from barns and subsequent outside storage that varied between 41 and 56% (Figure 4).

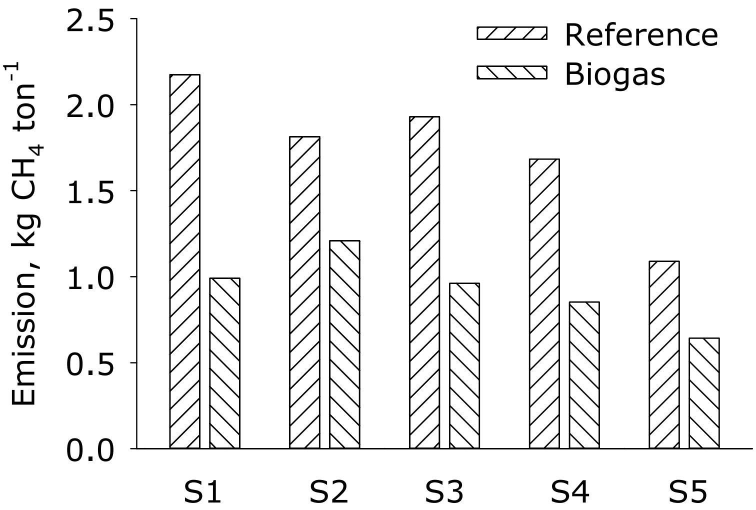

Figure 4. Calculated CH_4 emissions from barn and slurry storage tanks for the five reference and biogas scenarios. The model plants included slurry codigestates as follows (S1): deep litter, (S2) straw, (S3): deep litter and maize silage, (S4) deep litter and organic waste, and (S5): deep litter, organic waste, and organic grass–clover.

In the model calculations, the relationship between VS degradation and CH_4 production depended on assumptions regarding the proportions of C in VS converted to CH_4 and

CO_2, a ratio that is subject to large uncertainty (cf. Supplementary Materials). In the scenario calculations, the CH_4/CO_2 ratio was set at 25:75 for untreated slurry and codigestates stored anaerobically and 10:90 for digestates. The importance of these ratios was evaluated in a sensitivity analysis calculating the effects of reducing by half, or doubling, the share of CH_4 produced in pig and cattle slurry (Table 4). Untreated pig slurry was sensitive to the assumption regarding CH_4 share, with 21% lower CH_4 emissions if the assumed CH_4 share was reduced by half and 17% higher emissions if the assumed CH_4 share was doubled. All other relative changes were negligible. Experimental data on CH_4 emissions from slurry and digestate were the reference for model calculations, and as a consequence, a lower or higher CH_4/CO_2 ratio would lead to less or more residual VS, respectively, being exported and available as substrate for CH_4 emissions from the outside storage. The limited effect of changing the CH_4/CO_2 ratio for digested slurry was due to the fact that pretreatment emissions in barns were identical, and the CH_4 emissions following biogas treatment were greatly reduced.

Table 4. Sensitivity analysis of the importance of the CH_4/CO_2 ratio in the gas produced from VS degradation of untreated and digested slurry for the cumulated CH_4 emissions from barn and outside slurry storage (relative differences with scenario results as basis).

Untreated Slurry			Digested Slurry		
CH_4/CO_2	**Cattle**	**Pig**	**CH_4/CO_2**	**Cattle**	**Pig**
12.5:87.5	0.99	0.79	5:95	0.98	0.99
25:75	1.00	1.00	10:90	1.00	1.00
50:50	1.01	1.17	20:80	1.01	1.00

For each scenario, the CH_4 emissions were calculated using 45, 60, and 90 days of HRT in the reactor, which may affect the predicted CH_4 emissions during subsequent storage of the digestate. This is exemplified in Figure 5b, which shows the sources of CH_4 for scenario S5 (organic biogas) with cattle slurry, deep litter, grass–clover silage, and biowaste, as well as CH_4 emissions without treatment (HRT 0 d) for reference. It was mainly the emission of CH_4 from cattle slurry that was affected by increasing HRT, the emission being 16% less at 90 than at 45 days HRT. The reduction for deep litter was 5–6%, and the changes for grass silage and biowaste were <1%.

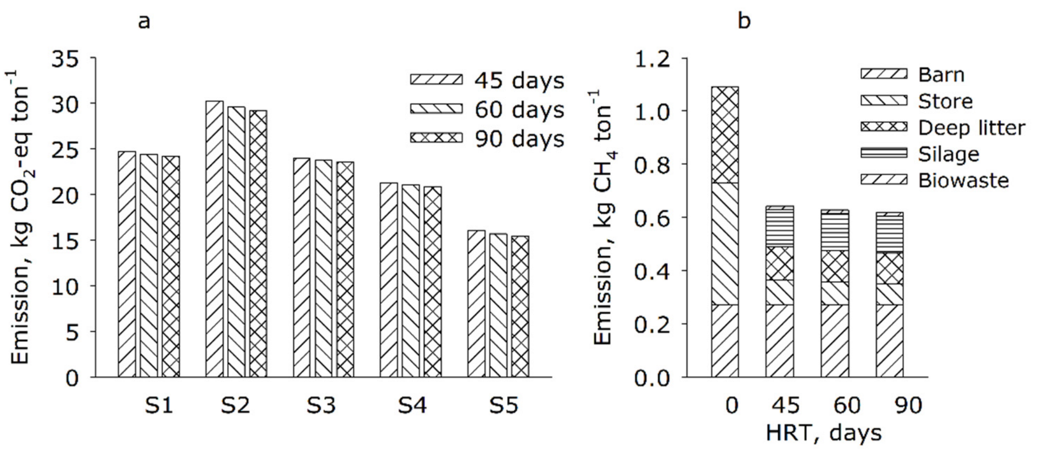

Figure 5. (**a**): Total GHG emissions in each of the five scenarios with 45, 60, and 90 d HRT calculated as CO_2-eq. (**b**): Methane emissions from stored biomasses without biogas treatment (HRT 0 d) or (S5) with biogas treatment at increasing hydraulic retention time (HRT). In the biogas scenarios, livestock slurry was codigested with (S1) deep litter, (S2) straw, (S3) deep litter and maize silage, (S4) deep litter and organic waste, and (S5) deep litter, organic waste, and grass–clover.

The total CH_4 emissions for scenarios with HRT at 45, 60, or 90 d, expressed as CO_2 equivalents, are shown in Figure 5a. All scenarios showed the same trend, with 2–3% lower GHG emission at 90 than at 45 d HRT.

Overall GHG balances were calculated for biogenic CH_4 and N_2O emissions from barns and outside storage, and after field application (Figure 6). While biogas treatment gave a substantial reduction in CH_4 emissions, ranging from 41% to 56%, as described above, no effect on N_2O emissions was assumed, and N_2O emissions are therefore directly proportional to the N content of the biomasses used in each scenario, which were identical in reference and biogas scenarios. As a result, the overall GHG balances corresponded to reductions through biogas treatment ranging between 21% and 40%.

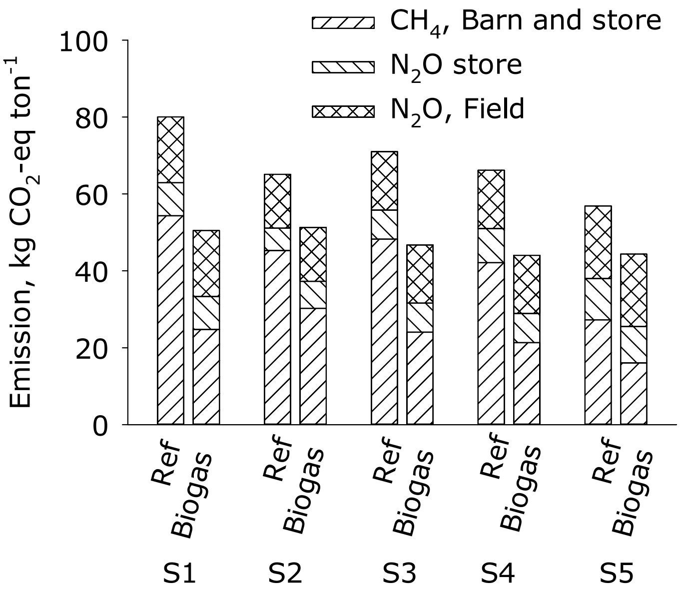

Figure 6. Total biogenic CH_4 and N_2O emissions, calculated as CO_2-eq, from stored slurry and other biomasses in the reference (Ref) and biogas scenarios (Biogas). The scenarios were (S1) slurry and deep litter; (S2) slurry and straw; (S3) slurry, deep litter, and maize silage; (S4) slurry, deep litter, and organic waste; and (S5) slurry, deep litter, organic waste, and organic grass–clover.

3.3. Ammonia Emission

The digestion of animal slurry, crops, and biowaste increases emission of NH_3 because of the higher emission potential of digestate due to its higher pH and TAN to N ratio. Consequently, AD increased NH_3 emission in all five scenarios. The highest increases were in scenarios S3 and S5, in which slurry was codigested with maize silage and grass–clover, which increased the N content in the digestate. This was, in the scenarios with deep litter, to some extent counteracted by reduced emissions from the solid manure management, as emissions were lower from the fraction of digested solid manure than from the solid manure managed in the reference scenarios (Table 5).

Table 5. Changes in NO_3^- leaching, NH_3 emission, and NO_x emission by introducing AD in manure management. In the model plants, pig and cattle slurry was codigested with (S1) deep litter, (S2) straw, (S3) deep litter and maize silage, (S4) deep litter and organic waste, and (S5) deep litter, organic waste, and organic grass–clover.

Source	Scenarios				
	S1	**S2**	**S3**	**S4**	**S5**
NO_3^- (kg NO_3^--N ton^{-1} (biomass))	−0.19	−0.13	−0.04	−0.18	−0.45
NH_3 (kg NH_3-N ton^{-1} (biomass))	0.19	0.18	0.21	0.14	0.30
NO_x (g NOx ton^{-1} (biomass))	2.49	2.48	2.30	3.97	2.13

3.4. Crop Production and Nitrate Leaching

The change in NO_3^- leaching by implementing AD was estimated for a mixture of the most common crops in Denmark and calculated with and without the inclusion of NH_3 emission after digestion. The increase in NH_3 emission reduced NO_3^- leaching by only 0.02–0.04 kg NO_3^--N ton^{-1} (biomass) (data not shown). In the reference scenario, slaughterhouse waste was assumed to be applied to crops as untreated biofertilizer hygienized and mixed with slurry. The source-separated organic household waste would in the reference system be composted and applied to a spring-sown crop as an alternative to digestion. The reduction in NO_3^- leaching by AD was 0.04–0.45 kg NO_3^--N ton^{-1} (biomass), with the lowest reduction in the scenario with an energy crop (S3) and the largest in the organic system with digestion of a grass–clover green manure crop that would alternatively be cut and mulched in the field (S5). The reduction in NO_3^- leaching was lowest in S3 because the overall input of N increased in this scenario. We did not include the effect of a crop change to maize in the leaching effect because of the uncertainty of which crop was being replaced by maize, although it was expected to be mainly cereals. Nitrate leaching is higher from maize than from most other crops [44], and if this effect had been accounted for, or if a higher proportion of maize had been applied in S3, then an increase in NO_3^- leaching would be expected by AD [47].

3.5. Soil Carbon Storage

For the scenario including straw as a cosubstrate, the alternative was assumed to be incorporation of straw into the soil. For one ton of straw with a dry matter content of 85%, and 45% C in the dry matter, this corresponded to reduced soil C storage of 7.7 kg C, equal to 28.1 kg CO_2-eq. It was assumed that substituting cereals for silage maize would not affect soil C storage [48] and that changes from mulching grass–clover to a cutting regime with return of the digestate would also have little effect [49].

3.6. GHG Emissions

Introducing AD in the five different scenarios reduced the net GHG emissions of livestock farming by 67–111 kg CO_2-eq ton^{-1} of biomass at 60 d HRT (Table 6). The corresponding effect in terms of DM was 479–613 kg CO_2-eq ton^{-1} DM. Most of this reduction was ascribed to substitution of fossil energy in energy production and avoided CH_4 emission during storage of biomass. The difference in biogas production in the five scenarios was due to the different amounts of dry matter and biogas potentials in the substrates supplied to the plants.

The biogas plants in scenarios S2 and S5 were supplied with biomasses with high dry matter concentrations, which contributed to a high amount of energy produced per ton of biomass and thus a considerable GHG reduction. If the comparison were to be made independently of these differences in dry matter content, the assessment should be based on the GHG effect per GJ or dry matter input. For example, scenario S2 with straw had a significantly higher GHG effect per ton of biomass than S1 with deep litter. The reason is that considerably more dry matter was supplied in the straw scenario. If the same amount of dry matter had been supplied in the straw scenario as in the deep litter scenario, then the straw scenario would have had a lower GHG effect. This was reflected in the lower GHG effect per GJ of straw than of deep litter. The model plant with the greatest GHG reduction per ton of biomass was the scenario in which 20% straw was added (S2). However, this was also the scenario with the lowest GHG effect in terms of dry matter.

Table 6. Calculated GHG emissions per ton of biomass and per kg of dry matter (DM) (values in brackets) for five model plants at 60 d HRT and 1% methane leakage from the biogas plant. The model plants were (S1) slurry and deep litter; (S2) slurry and straw; (S3) slurry, deep litter, and maize silage; (S4) slurry, deep litter, and organic waste; and (S5): slurry, deep litter, organic waste, and organic grass–clover. Positive values indicate lower emissions, and negative values indicate higher emissions, from biogas.

Source	Unit	S1	S2	S3	S4	S5

* Methane and N_2O from storage relate to emissions from storage of biomasses, especially slurry, deep litter, and slaughterhouse waste.

4. Discussion

The analysis presented here showed that anaerobic codigestion of slurry with biowaste, crop residues, and crops primarily reduced GHG emissions by substituting fossil fuel for power and heat production and reducing CH_4 emission during postdigestion storage. The main environmental benefits from biogas energy systems compared to fossil fuel energy systems occurred in terms of reduced GHG emissions and reduced resource consumption [50]. The impact of utilizing animal manure for biogas production is important in this respect, since avoided emissions from the reference system of conventional manure management could be credited to the biogas system [50], which was not the case for energy crops and straw that would not be sources of GHGs in a non-AD scenario.

In our study, AD was assumed not to affect N_2O emissions, in contrast to calculations presented in a previous study by Sommer et al. [9], in which the removal of degradable organic matter during AD was assumed to reduce N_2O emissions from digestate applied to soil by reducing the potential for denitrification. However, experimental results on this aspect have conflicted [37], and recent studies have made it clear that the amount and composition of denitrification products depend on complex interactions between digestate and soil properties. Thus, accounting for the effect of AD on N_2O emissions would probably require considering the composition of residual VS in digestates, as modified by codigestates and soil gas exchange controlling the exchange of oxygen and denitrification products [51]. The consideration of specific site and weather conditions was beyond the scope of this study, but this should be investigated further.

In our study, the total impact on GHG was 67–111 kg CO_2-eq ton^{-1} of biomass at 60 d HRT, which demonstrates that the biomass mix played an important role. In a study by Poeschl et al. [52] the GHG impact was 75 kg CO_2-eq ton^{-1} for a small-scale plant and 120 kg CO_2-eq ton^{-1} for a large-scale plant. In this study, liquid manure accounted for 55% in the small-scale plant, while in the large-scale plant, only wastes from industry and household were included [53]. Including corn silage had a high positive GHG impact, while grass silage had a negative GHG impact. This was in contrast to our study, in which the scenario with maize had the lowest GHG impact while the scenario with glass–clover had significantly higher impact. However, in a study by Hijazi et al. [50], nonleguminous perennial grass was used. In organic farming, leguminous perennial grass is used as a source for N fertilizer because of its ability to fix atmospheric N [53]. This type of grass might be better than nonleguminous perennial grass in terms of the savings of direct N_2O emission from N input in the form of mineral or organic fertilizers [53].

4.1. Biomass Sources for Biogas

The GHG impacts calculated in our study were based on a Danish territorial perspective; in general, only impacts on Danish national GHG emissions were included. However, the production of commercial N fertilizer was taken into account with a minor climate impact corresponding to 0.28 kg CO_2-eq per kg biomass N, or about 1.5 kg CO_2-eq per ton of biomass. The fertilizer replacement value of biomass is increased after digestion. However, Danish legislation with quotas on mineral N fertilizer application does not account for this, and it is uncertain whether farmers take the higher N availability into account. Therefore, this effect is uncertain in practice but has potential to be utilized. Since there is no fertilizer production in Denmark, such emissions are not included in Denmark's national GHG inventory and therefore were not considered. Neither were the possible effects of changed land use elsewhere on the planet (iLUC) considered. This was relevant only for scenario S2, in which the cultivation of maize as an energy crop was set to replace the production of cereals and could, thus, potentially have iLUC impacts. The iLUC impacts are uncertain, but they may potentially exceed the calculated positive climate impacts of biogas production [53]. In the inventory of biofuels under the EU's Renewable Energy Directive (RED), iLUC impacts are included, although they are not included in the EU requirements for compliance with the RED II [54]. For maize for biogas production, the iLUC impact in a RED context was most recently calculated as 21 kg CO_2-eq MJ^{-1} [55].

Besides livestock manure, the model plants used different types of biomasses from the agricultural sector. Addition of 20% straw to the slurry (S2) gave the largest GHG reduction per ton, but the smallest reduction in terms of DM. The Danish biogas sector is considered a cornerstone in Danish green energy production, and there is increasing demand for more biomass for codigestion with slurry. While there is plenty of unused straw available as cosubstrate, the amount of straw added in scenario S2 cannot be managed with existing biogas technology because of problems related to pumping and agitating the biomass. However, the Danish biogas industry has projected that future technologies in form of pretreatment, pumps, and agitators will be able to manage this amount of dry matter. The calculations in this report assumed that the alternative to the use of straw for biogas was incorporation in the field. If the alternative had been incineration for combined heat and power, the climate impact would have been considerably lower. On the other hand, biogas from straw has the advantage that plant nutrients and part of the slowly degradable C in the straw is returned to the field.

Substituting some of the deep litter (S1) with maize silage (S3) improved the GHG emission reduction per ton slightly. The high degradability of the organic matter in maize contributes to high biogas production per ton of biomass, and energy production was therefore higher for S3 than for S1. In a study from 2013 [14], the GHG emission by codigestion of slurry and 10% maize was reduced by 72 kg CO_2-eq ton^{-1} (wet basis), which was about 10 kg CO_2-eq ton^{-1} (wet basis) more than in our study. In the mentioned study [14], the fibre fraction from separation of slurry was included in the calculation, and it was assumed that it had a higher CH_4 emission potential during storage than deep litter.

Glycerol can be used for energy production in power plants and Otto engines [56], and it is also a useful raw material for biogas production. When glycerol is used in conventional heat and power (CHP) production, the CO_2 reduction effect is 690 kg CO_2 ton^{-1} when it substitutes natural gas, and when producing biogas substituting natural gas, it reduces GHG emissions with an equivalent of 558 kg CO_2 per ton. When compared to incineration in power plants, biogas is considered a high-value energy carrier that can be stored and converted to electricity.

Among the biogas plants, the GHG effect was lowest in the plant with deep litter (S1), since CH_4 emissions during storage increased because of the higher CH_4 emission from digestate than from heaps of deep litter. In S4, with added glycerol, it was assumed that the glycerol would otherwise have been used efficiently for heat and power production. This assumption has not previously been used and is one of the reasons why the GHG reduction potential of an "industrial waste plant" was lower than in the study by Nielsen et al. [57], in which the total GHG effect was a reduction at 90 kg CO_2-eq ton^{-1}.

The organic farming biogas plant (S5) had, next to the deep litter and straw model plant (S2), the largest GHG reduction potential per ton (102 CO_2-eq ton^{-1}), which may be attributed to the high biogas yield as a result of the high proportion of grass, deep litter, and biowaste. In a previous analysis from 2013, the GHG reduction calculated for the introduction of AD in an organic farming system was 83 kg CO_2-eq ton^{-1} [15], but lower effects of both energy production and CH_4 emission during storage was assumed. In our study, the effect of substituting fossil fuels contributed more to the overall GHG impact than in previous studies, in which the importance of reducing CH_4 emissions was greater and a reduction in N_2O emissions was included in the calculations [57].

Energy crops, such as maize, are still a significant source of substrates used by Danish biogas plants, but the amount that can be used is constrained by restrictions under subsidy schemes. Compared with cereal crops such as wheat, there are only limited negative effects of growing maize and other energy crops. However, grass and sugar beets have better environmental and GHG profiles for biogas production than maize [58], and in the future, cover crops are also expected to be used for biogas production. This may reduce the N_2O emissions currently seen after the incorporation of cover crops [59] while at the same time maintaining and possibly improving soil C storage potential. Cover crops and straw together provide a promising source of biogas while at the same time increasing the recycling of nutrients in crop production [60]. Utilization of the expanding area with cover crops as a source of biomass for biogas production would not have the negative iLUC effects that are associated with the cultivation of energy crops for biogas.

4.2. Biogas Plant Configuration

Increasing the reactor size and hydraulic retention time (HRT) reduced net GHG emissions via an increase in the production of biogas and a reduction in the amount of degradable VS in digestate transferred for downstream storage, which will reduced CH_4 emissions from the digestate (Figure 7). The effect of increasing HRT was related to the degradability of the organic matter in the biomass used, and the highest effect was calculated when adding straw or deep litter, which feature high concentrations of slowly degradable biomass. There were increases in the GHG reduction potential by increasing HRT from 45 to 60 days in all scenarios, whereas the effect of extending HRT further was positive only for scenarios S1 to S4, because the positive effect in S5 was outweighed by greater consumption of process energy.

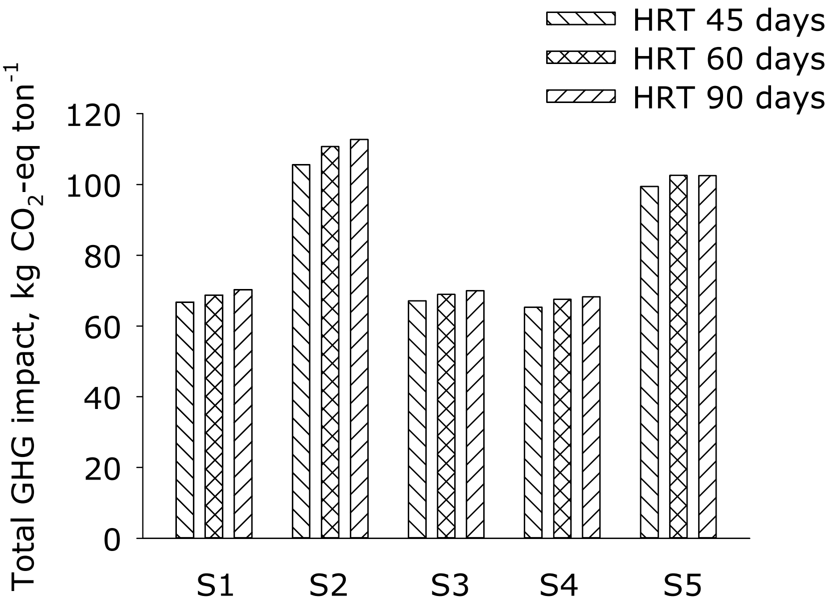

Figure 7. Effect of hydraulic retention time in AD reactor on total GHG impact.

Methane leakage may have a significant effect on total climate impact, which would mainly be due to the global warming potential of CH_4 and, to a lesser extent, the unrealized energy production (Figure 8). The total climate impact was almost linearly reduced with increasing CH_4 leakage (Figure 8). The total impact was reduced by about 5 kg CO_2-eq per ton of biomass from scenario S1 at a methane leakage of 1% to about 10 kg CO_2-eq ton^{-1} of biomass at a methane leakage of 2%. This means that about 7% of the positive climate impact of the plant was lost for each percentage point of leakage. For a leakage of 15%, biogas no longer had a positive effect for scenario S1. Release and leakage of CH_4 from small, unheated digesters may, in a scenario in which biogas energy substitutes coal, negate the GHG-reducing effect of biogas production if 40% of the biogas produced is emitted to the atmosphere [61].

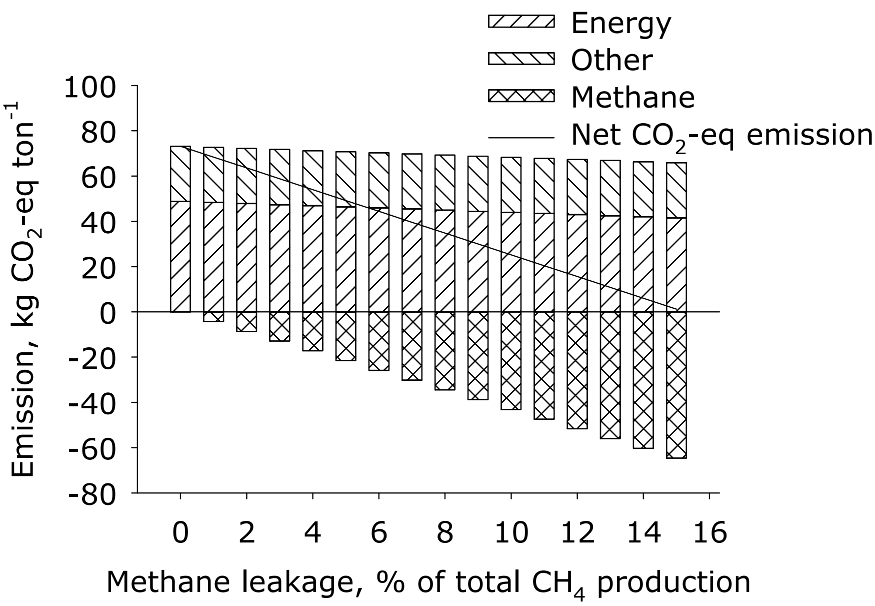

Figure 8. Effect of methane leakage on the climate impact for model plant (S1) with 45 days HRT. Methane and nitrous oxide emissions shown are from storage of livestock manure and biogas slurry.

Nielsen et al. [57] assumed that the organic waste used as codigestate would be stored under anaerobic conditions in the reference scenario and therefore be a significant source of CH_4 emissions. Compared with [57], the biogas scenarios in the present study used a greater diversity of biomasses as codigestates. The relevant alternative management of these biomasses was incorporation (straw), ensiling (maize), storage in a heap (deep litter), or composting (biowaste), and only the slaughterhouse waste included in scenario S4 was assumed to be stored under anaerobic conditions if not digested. To the extent that codigestates were not stored anaerobically in the reference scenarios, this reduced the CH_4 mitigation potential of biogas treatment compared with that in the previous analyses.

4.3. Nitrogen Losses

The reduction in NO_3^- leaching from the AD scenarios was lowest in the system with energy crops (S3), because the overall N input increased in this system with the introduction of more organic N from plant material. If 12% maize silage was used, the effect of digestion on leaching was close to zero, in accordance with previous estimates by Sørensen and Børgesen [23]. Nitrate leaching is typically greater for maize cultivation than for most other crops [44], and if this effect could be included, or if a higher proportion of energy crops were applied in S3, then an increase in NO_3^- leaching would be expected with AD compared with the corresponding reference scenario. However, since the effect is much affected by the assumption about which crop would be replaced by maize, we did not include the effect of a crop change to maize. On organic farms, AD of plant biomass from green manure crops, as in S5, increased the average plant availability of N [60]. This meant that less organic N was left in the soil to contribute to leaching by mineralization in the following years, and the effect of AD in such a system was estimated to reduce NO_3^- leaching by 0.45 kg N ton^{-1} biomass.

The NH_3 emission potential of digestate applied in the field was higher than that of cattle slurry and pig slurry because of the higher pH of the digestate. This effect, and the higher content of TAN in digestate, contributed to higher emission from the AD systems. The effect of higher TAN concentration contributed 60–70% of the increase in NH_3 emission from AD systems, and most of this increase was due to higher emission from digestate applied to soil. The relatively small increase in NH_3 emission in scenario S3 was due to the emissions from storage and application of deep litter and biowaste being large in the reference system. Ammonia emission in the organic scenario, S5, was high because of the increase in the TAN content of digestate originating from N in the codigested grass–clover and the low NH_3 emission from the reference system. This increase in NH_3 can be avoided if organic farms inject slurry into the soil, which is feasible because of the high share of spring crops in organic crop rotations for which slurry can be injected prior to seeding or on grassland during the growing season.

In Denmark, slurry acidification is an alternative to incorporation and injection, but this technology is not suitable for digestates, because the high pH buffer capacity of the digestate results in high demand for acid and thus high cost for this treatment; furthermore, acidification with sulfuric acid is not allowed in organic farming.

4.4. Uncertainties

The calculations were based on the current knowledge about energy production in the form of biogas from different types of biomasses and their related environmental and GHG impacts. Biogas technology is constantly developing, and so is the alternative use of biomasses. This leads to uncertainty with respect to the representativeness of the biogas plants defined and their composition of biomasses. However, the model plants analysed in this study represent the types of biomasses currently used for biogas production in Denmark.

Other uncertainties are associated with the way in which impacts were quantified. The study was based on the models and data used in Denmark's inventories of environmental and GHG impacts. These models are constantly being developed, particularly to better account for variation in environmental controls of the biological processes that determine the impacts and in the properties of biomasses and how they are managed in practice. With the current knowledge, it is not possible to quantify those uncertainties, but a qualitative discussion follows.

The gas potentials of the different biomasses, and the rate at which the gas was produced, are significant sources of uncertainty, especially in the assessment of the effect of retention time in the biogas reactor. The degradation profiles used were, therefore, essential for the estimates of gas yield with different retention times and for the assessment of residual VS in the digestates. The degradation profiles further influenced the CH_4 emissions during the subsequent storage. There is a considerable need for documentation of the rate at which biogas is produced and identification of any interactions between biomasses that may give rise to synergies and/or antagonism. Moreover, it is necessary to provide better documentation of the correlation of CH_4 production between batch tests and continuous systems. These sources of uncertainty may have affected the reported differences among the effects of 45, 60, and 90 d retention time.

Our study assumed that electricity for the process energy used in biogas production was covered by a mix of Danish electricity production, which was estimated to be 0.150 g CO_2 kWh^{-1} in 2019. It may be argued that such emissions could have been 0 g kWh^{-1} if only renewable energy had been used. If it were assumed that no CO_2 was emitted from the production of process energy, the total positive climate impact would increase by about 0.97 kg CO_2 ton^{-1} of biomass at 45 d retention time, increasing the total climate effect by a maximum of 1.7%. Hence, the emission factor assumed for electricity for process energy was less important.

The estimation of CH_4 emissions and the related degradation of organic matter during storage of biomasses was based on simplified input data and assumptions. Firstly, CH_4 emissions were assumed to be a product of VS and temperature alone, but this does not always well explain temporal dynamics [62], and the composition and growth of methanogenic communities would probably be part of an improved model [63]. Furthermore, CH_4 emissions were calculated from total VS and not degradable VS because of a lack of relevant experimental data regarding VS composition. In the analysis presented here, increasing the retention time in biogas reactors from 45 to 90 days showed only a limited effect on CH_4 emissions during subsequent storage, with a 15% reduction in posttreatment emissions from cattle slurry being the most significant effect. A possible reason for the limited sensitivity to HRT could be that CH_4 emissions were estimated on the based on total VS and using the same lnA' value for digestate regardless of retention time. This parameter also represents the slowly degradable parts of VS for which anaerobic degradation was small whether HRT was 45, 60, or 90 days. It is likely that a model in which the VS degradability of each biomass was defined would better capture differences among digestates from the five scenarios with very different feedstocks.

Biogas treatment of pig and cattle slurry (and codigestates) reduces the availability of easily degradable organic matter. All other factors being equal, the resulting decline in demand for oxygen to degrade residual organic matter after field application should reduce the extent and lifetime of anoxic conditions with a potential for N_2O production in well-drained soil. There are, however, confounding effects. For example, soil compaction and periods with rainfall reduce soil oxygen status and change the conditions for N_2O production in untreated manure and digestates applied to soil [36]. Furthermore, fibre-rich codigestates such as maize silage or deep litter may change the distribution of degradable VS in the soil of digestates compared with that of untreated manure [64]. A systematic investigation is needed to elucidate interactions among manure and digestate properties, soil conditions, and N_2O emissions before the effect of anaerobic digestion on N_2O emissions can be included in biogas assessments.

The calculations included an assumption that digestion of slurry and biomasses reduced soil C storage compared with direct field application of those biomasses. Only very limited documentation exists of this effect [46], which is very difficult to determine experimentally. Therefore, the effect is also uncertain, and further studies are needed.

In our calculations, the higher content of TAN in the digestate caused a significant increase in NH_3 emissions in the scenario calculations, corresponding to 60–70% of the higher NH_3 emission. However, there is great uncertainty in these estimates due to a lack of knowledge about how the different combinations of substrates and slurry in the biogas scenarios would affect digestate physical characteristics and infiltration in the soil. Ammonia emissions from slurry or digestates are reduced with faster infiltration, which is a function of viscosity, dry matter content, and adhesiveness. It is poorly understood how infiltration of digestate is affected by the substrates used for AD.

Regardless the types of biomasses used for biogas production, the following measures are important to achieve the potential environmental and climate benefits:

- CH_4 leaks from the biogas installation should be minimized.
- Digestate storage should be covered, and low-NH_3-emission technology should be used for field application.
- Heat exchangers should be employed to cool down the digestate to ambient temperature before storage to improve the energy balance and reduce GHG and NH_3 emissions.

5. Conclusions

Environmental and climate assessments were conducted for different biogas scenarios to evaluate the sustainability of this treatment technology and identify potential improvements of environmental and climate impacts. The scenarios were analysed considering (i) biomass composition; (ii) process temperatures; (iii) hydraulic retention time; (iv) methane leakage from biogas installations; and (v) digestate storage and field application. With respect to energy production, only upgrading for the natural gas grid and substitution of natural gas with biogas were considered.

On the basis of this study, the following conclusions were drawn:

(1) The scenarios investigated resulted in GHG mitigation ranging from 65 to 105 kg CO_2-eq ton^{-1} biomass. Reductions per ton of biomass were greatest when straw or grass–clover was used for codigestion, whereas reductions per unit energy produced were highest with deep litter and deep litter plus maize silage.
(2) The ammonia emission potential of digestate applied in the field was higher than that from untreated cattle and pig slurry because of digestates' higher pH, resulting in an increase in ammonia emission of 0.14 to 0.3 kg NH_3-N ton $^{-1}$ biomass. The use of low-emissions application technology for a larger share of the digestate should limit these higher emissions.
(3) All scenarios reduced nitrate leaching (0.04 to 0.45 kg NO_3-N ton^{-1} biomass). However, introducing maize silage almost eliminated this reduction.
(4) Increasing the hydraulic retention times led to higher climate impact via increased energy production and lower amounts of volatile solids available for degradation and subsequent CH_4 emission during digestate storage.
(5) Methane leakages can have a significant effect on the total climate impact, with about 7% of the positive climate impact being lost for each percentage point of leakage in a manure-based biogas scenario.
(6) The methodology used predicted significant reductions in CH_4 emissions but assumed there was no reduction in direct emissions of N_2O from digestates, which is not always true. Furthermore, iLUC, which was ignored which for bioenergy use, may have a negative impact on the GHG balance.

These and other examples given above show the importance of the assumptions chosen for this type of analysis. Still, it was concluded that biogas treatment of livestock slurry and biowastes has the potential to reduce GHG emissions, improve N use efficiency, and reduce nitrate leaching losses. However, the risks of higher ammonia emission and CH_4 leakage during AD need to be managed.

Supplementary Materials: The following supporting information can be downloaded at: https://www.mdpi.com/article/10.3390/su14031849/su14031849/s1, Table S1: Assumptions on dry matter content and gas potential of different biomasses used in biogas production. The ultimate CH_4 yield is the yield achieved at a retention time of more than 90 days. The CH_4 yields after 45 and 60 days and ultimate gas yield are based on data from tests at the Foulum biogas plant Aarhus University. Sources; (1) Average of 50 analyses of slurry supplied to two biogas plants, (2) Olesen et al. (2018), (3) Data from Foulum biogas plant, Aarhus University and (4) Data from tests at Foulum biogas plant, Aarhus University; Table S2: Data used for the calculation of energy consumption on a standard Danish biogas plant; Table S3: Energy use and CO_2 emission due to transportation of biomass. CO_2 emissions of 2.7 kg per litre of diesel is assumed; Table S4: The methane production potential values, lnA', for digestate, cattle slurry and pig slurry were calculated based on information extracted from published studies about methane production rate, total VS and temperature. In the table, $\overline{x} \pm$ s.e. refers to average and standard errors, Table S5: Ammonia emission factors for stored liquid and solid manure (Hansen et al. 2008) and organic food waste (Pardo et al. 2015); Table S6: Ammonia emission factors for cattle and pig slurry applied to soil (Hansen et al. 2008), and the novel estimates emission from digestate; Table S7: Assumptions about plant available N (NH_4^+-N) in biomasses before and after biogas treatment during the first crop growing season after application of manure, required N use efficiency for manures and organic wastes (by Danish legislation), and calculated reduction in NO_3^- leaching due to AD of manure—not accounting for changed NH_3 loss. The share of NH_4^+-N in manure is based on Sørensen and Børgesen (2015). Organic N expected to be transformed to NH_4^+ within the first season is included in the NH_4^+-N share of total N; Figure S1: Average cumulative net N mineralisation from organic N applied in livestock manure over a 10-year period after application.

Dinitrogen and methane gas production during the anaerobic/anoxic decomposition of animal manure

Lowry A. Harper · Kim H. Weaver · Alex De Visscher

Received: 14 February 2014 / Accepted: 10 July 2014 / Published online: 31 July 2014

Abstract Trace-gas emissions from animal feeding operations (AFOs) can contribute to air quality and global change gases. Previous and current estimated gas emissions from AFOs vary widely and many do not consider all forms of carbon (C) and nitrogen (N) emissions. Studies have found that as methanogenesis in the lagoons increased, conversion of ammonium (NH_4^+) to dinitrogen (N_2) also increased. The purpose of this research was to measure N_2 and CH_4 emissions from swine AFOs in three locations of the U.S. and to evaluate the possible universal relationship between lagoon methanogenesis and the conversion of NH_4^+ to N_2 gas. This relationship was tested by measuring N_2 and CH_4 emissions in two climates at 22 different farms. Methanogenesis was correlated with NH_4^+-to-N_2 conversion by a near-constant N_2 to CH_4 emissions ratio of 0.20, regardless of C loading and climatic effects. The process is shown to be thermodynamically favored when there is competition between NH_4^+ oxidizing reactions. Under methanogenic conditions (redox potentials of methanogenesis) N_2 production is favorable and nitrification/denitrification is not. Thus, N_2 production is stimulated in methanogenic conditions. Evaluation of NH_3 gas emissions from AFOs must consider other N emissions than NH_3. Finally, a statistical model was developed to estimate methane and N_2 emissions (kg gas ha^{-1}) given feed input per lagoon surface area (kg feed ha^{-1}) and local air temperature. Further studies are needed to investigate the mechanisms involved in manure processing and isolate the favorable mechanisms into engineering improved manure processing.

Keywords Ammonium · Methane · Methanogenesis · Thermodynamics · Lagoon · Dinitrogen

Introduction

Ammonia (NH_3) is a significant air pollutant, especially in combination with acid gas production from fossil fuel combustion, because the resulting acid–base reaction potentially leads to an air quality problem in the form of haze and respirable particulate matter (PM). The link between PM and increased mortality is well established (Pope et al. 2002; Cohen et al. 2005). Ammonia emissions' estimates from swine manure treatment lagoons, as a percent of feed nitrogen (N) input, have been reported to vary from 36 to 71 % (Doorn et al. 2002a; Hatfield et al. 1993; USEPA. 2004). From a systems' analysis approach using the *USEPA National Emissions Inventory* (USEPA, 2004), the addition of all NH_3 emissions' components, such as from housing (22 %), lagoons (43 %), field application of manure (23 %), N leaving as animal protein (30 %, from host data), suggest that more than 100 % of the N entering the farm system is leaving the farm as NH_3 volatilization plus animal product. Recent studies in North Carolina (NC) (Harper et al. 2004b), the Georgia Coastal Plains (GA) (Harper and Sharpe 1998; Harper et al. 2000), and the Central Great Basin (CGB) (Harper et al. 2010; Weaver et al. 2012) regions have shown that swine lagoons emit significantly less NH_3 than previously and currently thought. Much of the N estimated as NH_3 gas emissions has been found to be converted to dinitrogen gas (N_2) (Harper et al. 2000, 2004b; Weaver et al. 2012), representing an even larger discrepancy for the N balance of farm systems suggested by the USEPA. This aspect of dinitrogen emissions, not considered in most of the estimates of NH_3 emissions from animal feeding operations (AFOs), highlights the fact that the N cycle in lagoons is not fully understood. Benign N_2 emission from lagoons is a pathway of N emissions is that is significant and must be considered in the total N balance of AFOs. When the National Emissions Inventory (USEPA 2004) NH_3 emissions values are combined with published (measured) N_2 emissions (Harper et al. 2000, 2004a, b; Weaver et al. 2012), in many cases more N as NH_3 plus N_2 is emitted than is excreted by the animals, suggesting the need to reevaluate emissions' estimates.

Many of the current NH_3 emissions' estimates are based upon chamber measurements. A number of studies using dynamic chamber measurements (Aneja et al. 2000; Blunden and Aneja 2008) have led to higher emission estimates than found by micrometeorological measurements (Harper and Sharpe 1998; Harper et al. 2000, 2004b, 2010). Doorn et al. (2002b) pointed out that studies with dynamic chambers led to emission factors 2.3 times higher than studies with micrometeorological techniques, while others (Shah et al. 2006; Rochette et al. 1992; Harper 2005; Harper et al. 2010; 2011) stated that chamber techniques are not even suitable for developing emission factors as they create conditions at the water surface that overestimate NH_3 emissions. Based on all of the evidence (Harper et al. 2000, 2004b; Weaver et al. 2012) and discussions regarding the physical chemistry of highly anaerobic systems (van Clemput 1972, 1997), it seems very plausible that NH_3 emissions from lagoons are lower than indicated by current emission factors and a significant fraction of N is emitted as N_2.

There are complex interactions between carbon (C) and N compounds during manure processing by microbial and chemical processes. While little emissions' research for methane (CH_4) and carbon dioxide (CO_2) has been accomplished (Sharpe et al. 2001; DeSutter and Ham 2005) in AFOs, Harper et al. (2000; Table 1; 2010) found interesting correlations between emissions of NH_3, CH_4, nitrous oxide (N_2O), and CO_2 from manure-processing lagoons. These and other studies (Harper et al. 2010) show that manure management aimed at reducing the emissions of one gas could have the undesired consequence of increasing emissions of other gases. In these studies, manure lagoons with a high rate of methanogenesis also converted significant amounts of ammonium (NH_4^+) to benign N_2 gas with little or no N_2O produced [in the lagoons with the highest rate of methanogenesis, atmospheric N_2O was actually absorbed by the lagoon (Harper et al. 2000)]; however, when methanogenesis decreased, smaller emissions of N_2 occurred and higher rates of N_2O were produced. Harper et al. (2010) also showed that removing organic material from swine production farms for biogas production reduced CH_4 emissions by 47 % (the reduction resulted in a 44 % decrease in radiative forcing gases) from the biogas farms while increasing NH_3 emissions from the biogas farms by 46 %, a substantial increase in air-quality emissions. Weaver et al. (2012) also showed similar results. The above studies suggest there is a relationship between the amount of methanogenesis and conversion of NH_4^+ to N_2 gas in manure-processing lagoons. Thus, the main purpose of this study was to measure biological gas emissions from six manure-processing lagoons within a three-county area of eastern NC, a farm in GA, and in a large swine operation in the CGB (15 farms), and to evaluate the relationship between methanogenesis (CH_4 production) and conversion of organic and inorganic N to N_2 gas (N_2 production).

Table 1 Summary of lagoon ebullition studies for methane, carbon dioxide, and dinitrogen gases used in this report

Materials and methods

In the 22 swine lagoons studied from all regions, undecomposed organic material (manure) from animal production houses is pumped to lagoons where the organic materials settle to the bottom forming a layer of semi-solid organic material which is anaerobically decomposed producing gas. Gas bubbles emitted from the sludge layer in each of the lagoons, were trapped in six collectors (Fig. 1) randomly located within each of six areas of the lagoon. These gas collectors do not interfere with the emission process, as with NH_3 chambers (Harper, 2005). On a short-term basis ($<$ $\sim$2 weeks), ebullition gases, the result of biological and thermodynamic processes, are emitted from the lagoon bottom and are not affected by climatic events at the lagoon surface; however, NH_3 emissions are highly influenced by the physical processes of water surface turbulence and temperature. The collectors were made of 20-L, open-bottom carboys (0.275 m diameter) with flotation collars at the top of the carboys (Fig. 1) and tethered to the lagoon bottom to collect the mass-flow gases (bubbles) before they reached the water–air interface. All air was removed from the collectors at placement. Water in the collectors was displaced by the ebullition gases over time, visually measured on a graduated scale on the collector periodically to determine gas mass-flux. Gases were transferred from the collectors using sample lines flushed with the gases from the collectors and then subsequently attached to evacuated six-L SUMMA canisters. The SUMMA canister samples were then transported to a laboratory where gas samples were analyzed by gas chromatography (Harper et al. 2004b; Weaver et al. Weaver et al. 2012). No N_2O was found in the collectors via GC. In other studies no N_2O emissions were found from anaerobic lagoons using atmospheric transport techniques and tunable diode laser spectroscopy (Harper et al. 2000, 2004a, b). Samples of helium (He) injected into the collectors showed a sampling procedure error of about 1 % due to atmospheric N_2 contamination (see Harper et al. 2004b). Further, modeling studies showed the theoretical maximum contamination from the atmosphere would be <5–10 % (De Visscher and Harper 2005, unpublished data). Gas fluxes were determined by measuring the amount of gases collected divided by the time between measuring intervals (collection volumes were measured as ebullition necessitated, normally from two to three times per week in summer and weekly or bimonthly in winter) and then multiplying the emissions by the measured concentrations of each gas. This sampling protocol has been used extensively and further description of the measurement technique may be found in Harper et al. (2000, 2004b) and Weaver et al. (2012).

A summary of all farms in this study is included in Table 1. Fifteen farms of four different types in the CGB were sampled during 2002–2006: two sets (2002–2003 and 2004–2006) of three each F farms; another set of three F farms with organic matter removed for biogas production (2004–2006); one set of three each of nursery (N) farms (2002–2003) and sow (S) farms (2002–2003). Data from 2004 to 2006 are from an earlier published study (*after* Weaver et al. 2012). Six farms were sampled during 1999–2001 for N and C emissions in NC including three farrow-to-wean (FW), two finisher (F), and one farrow-to-finish (FF) farms. Data from an F farm in GA during the period of 1994–1998 were included (*after* Harper et al. 2000). Farm animal numbers ranged from 1,400 to 12,000.

Farms were selected in three geographical areas: fifteen in the CGB, six in three NC counties, and one in GA, to evaluate the effect of management on biogas emission rates (subject to host availability). The farm types included F, FW, and FF farms with input feed protein ranging from 13 to 17 % (feed N from 2.1 to 2.7 %). Three sow farms in the CGB were selected for comparison to production farms. Feed input, feed analysis, animal numbers and weights, number of animals sold, and other management information were supplied by the host owners/managers where available. Lagoon temperature was measured 2.5 cm below the water surface and within the sludge layer with micro temperature-loggers [Onset Computer Corp, Bourne, ME (Note: commercial names are included for the benefit of the reader and do not imply endorsement by the authors or their host institutions)]. The lagoons typically never formed crusts on the surface and were well mixed as demonstrated by near uniform temperatures from the top to the top of the sludge layer in lagoons of the CGB study. Since it is not appropriate to calculate NH_3 emissions from chamber systems (Harper 2005), lagoon NH_3 emissions were calculated from pH, NH_4^+ measurements of effluent samples (collected in bottles at the surface of each lagoon), surface lagoon temperatures, and wind speeds measured at 1.5 m height (from a metereological station on site), and a lagoon NH_3 emissions model by De Visscher et al. (2002). Housing NH_3 emissions were estimated from a model developed by Harper et al. (2004a) for North Carolina swine farms.

Effluent and sludge layer samples collected were frozen immediately and shipped to a laboratory for analysis of NH_4^+, nitrate (NO_3^-), nitrite (NO_2^-), and pH (for a description of analysis procedures see Harper et al. 2000, 2006). All lagoons were sampled similarly on a monthly basis.

The precision of biogas emission measurement was evaluated using the absolute value of the coefficient of variation, or relative standard deviation (RSD), obtained by dividing the standard deviation by the mean. To evaluate precision of the individual carboy measurements, the daily carboy emissions of the six lagoon carboys were used to calculate the daily average for the lagoon along with its RSD. The daily RSDs of the lagoons were averaged to calculate the average daily RSD and standard deviation of the daily RSD. To evaluate the precision of the farm lagoon emissions, a similar procedure was followed. Individual farm lagoon emissions are the average of the six carboy measurements. As lagoon emissions from three identical farms were measured for each farm type, the average individual farm emissions per farm type could be determined as well as the standard deviation of the individual farm emissions to calculate daily, monthly and yearly RSDs for each farm type. The RSDs for each farm type were averaged and a standard deviation was subsequently determined for daily, monthly and yearly RSD of individual farm emissions.

Results and discussion

Precision of biogas emission measurements

Average annual gas emissions (total component and percent of total) increased as the amount of farm input-feed per size-of-lagoon increased (i.e. increased manure C with respect to lagoon processing size). Biogas production varied substantially among the six collectors on each lagoon site. The RSD between collectors on a single lagoon, on a daily basis, was 48 ± 13 %. While there was considerable variability between individual collector's measurements, the

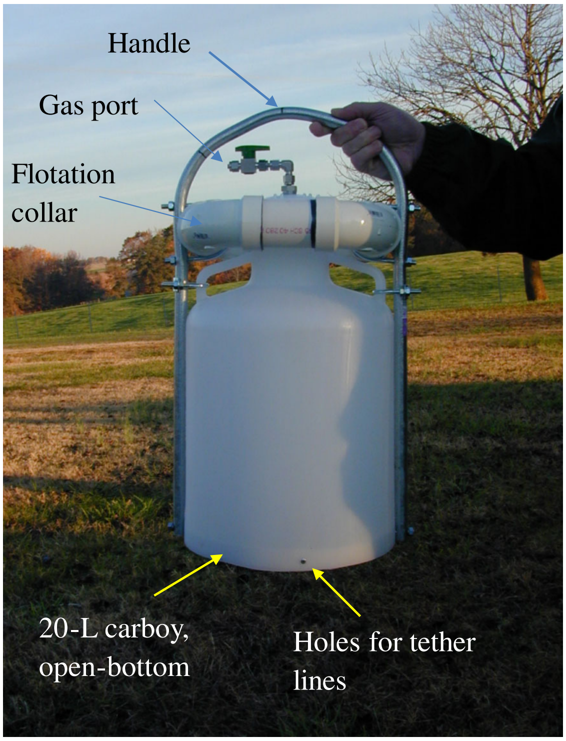

Fig. 1 Gas collectors constructed from open-bottom 20-L carboys. Graduations for evaluation of gas volumes located on the side of the carboy

variability of biogas emissions measurements was much less between lagoons when the six collectors were averaged. For example, the average RSDs of lagoon daily biogas emissions (average of six collectors) from lagoons of identical farms in the CGB were 23 ± 2 %. The variability of measurements between identical farms decreased even further when compared on a monthly (average RSD = 14 ± 6 %) or yearly basis (8.8 ± 6.0 %). We interpret this to mean that the 6 collectors are adequate to determine representative emission measurements on a yearly basis. Individual gas emissions showed regression relationships vs. feed input (R^2) greater than 0.67 for total component emissions (Fig. 2a) and greater than 0.86 for percent of all component gas emissions versus feed input (Fig. 2b).

Climate/temperature effects

When comparing biogas production between farms, temperature effects in the lagoon sludge must be considered. Farms from the CGB were included to test the robustness of the trends in biogas production and their relationship to feed input and temperature. Each system monitored in the CGB was comprised of three identical farms allowing for quantification of the variance in the data. Average monthly CH_4 production was directly related to sludge (where most of the processing occurs) temperature (Fig. 3a). On an annual basis, measured sludge temperatures were found to be within one degree (0.8 °C higher) of the average annual air temperature at 1.5 m height (Harper and Weaver, unpublished data), and we suggest that air temperature can be used as a surrogate temperature for the sludge. When CH_4 production was plotted versus average monthly air temperature (Fig. 3b), the gas production dependence upon monthly air temperature was almost as good as sludge temperature (R^2 values similar). Additionally, the dry climate of the CGB causes much higher evaporation rates and results in different management of swine lagoons.

Feed input effects

Data from the NC farms were used to test for the effects of feed input on biogas production. The NC data demonstrated that total biogas emissions (kg gas ha^{-1} d^{-1}) increased linearly (Fig. 2a) with daily feed input per lagoon size (kg feed d^{-1} ha^{-1}) ($R^2 = 0.67$). Component gas emissions all increased linearly with feed input but CH_4 had the largest increase with feed input per lagoon size ($R^2 = 0.78$). Carbon dioxide and N_2 gas emissions also increased linearly but at smaller rates than CH_4 (with correlations of $R^2 = 0.76$ and 0.32, respectively). Lower correlations for N_2 gas can be partially explained by a change in composition of biogas with feed input (Fig. 2b) where CH_4 and CO_2 emissions, as the percentage of total gas production, increased and N_2 emissions decreased with respect to increased daily feed input rates (kg feed $d^{-1}ha^{-1}$). The N_2 gas produced from the conversion of NH_4^+ to N_2, was not positively correlated with feed input (as was CH_4 and CO_2) since N_2 is produced via a different mechanism than methanogenesis (Weaver et al. 2012).

Feed input values from the CGB could not be used to predict emissions (using the linear relationships determined in Fig. 2a) in other areas due to large differences in lagoon temperatures and to very different animal and manure management. In the CGB lagoons, no effluent was discharged from the lagoon system to maintain water levels (evaporation was sufficient); thus, organic matter was diminished only by anaerobic decomposition and all lagoon N was removed either via NH_3 volatilization and/or conversion of NH_4^+ to N_2 gas (Harper et al. 2000, 2004b; Weaver et al. 2012). Harper et al. (2000) found no N_2O emissions from swine anaerobic processing lagoons (indeed, there was absorption of N_2O from the atmosphere by the lagoon). Additionally, because the feed input (kg feed $ha^{-1}d^{-1}$) was similar between lagoons in CGB (Table 1), the relationship between feed input and emissions could not be tested in the CGB.

The relationship between NH_4^+ concentration and gas emissions was evaluated in the NC lagoons. Similar to lagoon biogas emissions in a GA study (Harper et al. 2000), as NH_4^+ concentration increased across the six NC lagoons, total and individual gas emissions increased. However, the increased emissions effect was due to an increase in manure availability resulting in more biological decomposition from more feed input (Fig. 2a). Additionally, NH_4^+ concentrations also increased with more biological decomposition. Consequently, higher NH_4^+ concentrations and gas emissions are both correlated to feed input and not necessarily to each other.

Mechanisms for N_2 production

When Harper et al. (2000) could not balance the feed N input and all forms of N output (including meat, lagoon NH_3 volatilization, field application NH_3 losses, field denitrification losses of N_2 and N_2O emissions, lagoon N_2O emissions, etc.), they suggested the possibility that some of the NH_4^+ may have been converted to N_2 during manure-processing and that different reactions were involved, depending on the N form and concentration. With higher NH_4^+ concentration and biological activity (i.e. CH_4 production) their studies suggested that the N_2 production may have occurred via 'chemical denitrification' (Van Cleemput 1997). Thermodynamics and the Gibbs free energy of reaction for chemical denitrification (Van Cleemput 1972) suggest that spontaneous conversion of NH_4^+ to N_2 may occur in animal manure lagoons (Harper et al. 2004b, Table 7). It is possible that there is some biological denitrification in the lagoons, but we think it is small since we measured little NO_3^- (<0.1 mg NO_3^--N L^{-1}). Furthermore, dissolved

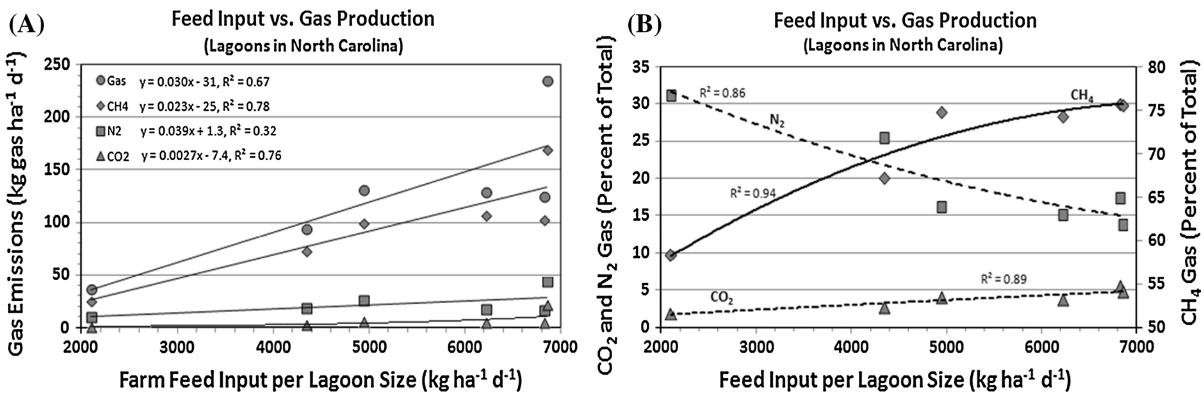

Fig. 2 Average annual lagoon methane, dinitrogen, and carbon dioxide emissions as emissions per unit area of lagoon surface (**a**) and percent of total gas emissions (**b**) with respect to feed input per lagoon size in North Carolina

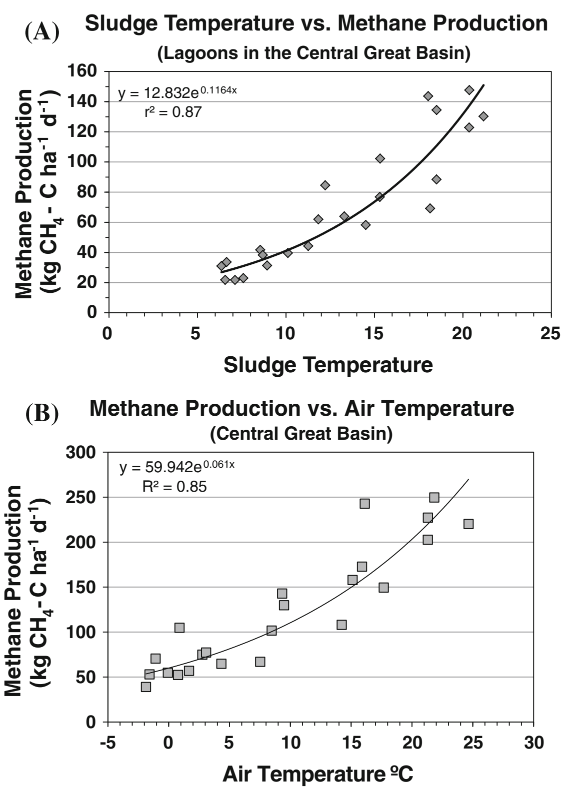

Fig. 3 **a** Average monthly methane production (of three farms) in relation to the sludge temperature at the bottom of the lagoons (where most of the decomposition occurs) over 2 years in the Central Great Basin (CGB). **b** Average monthly methane production (of three farms) in relation to the air temperature over 2 years in the CGB

oxygen (O_2) concentrations (mean of about 0.1 % dissolved O_2 across all the primary lagoons) can barely support autotrophic nitrification even under otherwise optimal conditions. We did not find NO_2^-, an intermediate step in biological nitrification/denitrification, in any of the primary lagoons. Zhang (2003) in studies of an anaerobic sludge reactor also found almost all nitrite removed (97–100 %) with gas contents of 89, 8, and 3 % of N_2, CH_4, and CO_2, respectively. These and other anaerobic laboratory studies (Harper et al. 2001, unpublished data) showed similar conversion of solution NH_4^+ to N_2 gas. Studies of swine lagoons by Hunt et al. (2010) found similar conclusions to Harper et al. (2000, 2004) finding little N_2O (produced from incomplete denitrification) being part of the system N balance. They also found there was a lack of sufficient denitrification enzyme activity (DEA) within the wastewater to support large N_2 losses via classical nitrification and denitrification.

There are other possible microbial processes to explain the N_2 production (Thamdrump 2012). Like classical denitrification and the anaerobic ammonia oxidation bacterial process (ANAMMOX), the full extent of conversion of NH_4^+ to N_2 remains unclear (Ettwig et al. 2009). Kartal et al. (2011) has recently presented strong evidence to explain the ANAMMOX mechanism for conversion of NH_4^+ to N_2 production; meanwhile, in this paper we demonstrate that the simple conversion of NH_4^+ to N_2 is thermodynamically favorable later in the manuscript.

Harper et al. (2000) showed that as lagoon NH_4^+ increased, NO_3^- and dissolved O_2 decreased, while N_2 and CH_4 emissions increased. Other studies have shown that when organic C is removed for biogas production, methanogenesis is reduced and the lagoon NH_4^+ content is increased (Amon et al. 2005) and measured whole-farm NH_3 emissions are increased (Harper et al. 2010). The above studies had treatments which reduce methanogenesis or lagoon NH_4^+ concentration but the studies in this research compare emissions from normal animal management and manure processing systems. The three lagoons in which organic matter was removed for biogas production were included to provide an additional comparison for the effect of reducing decomposition and methanogenesis.

Thermodynamic relationships

The net effect of all these studies suggests that as methanogenesis is decreased, conversion of NH_4^+ to N_2 is decreased. We think the causal relationship between methanogenesis and NH_4^+ to N_2 conversion is thermodynamically favored, while competing with other NH_4^+ oxidizing reactions. The following reactions are considered:

$$NH_4^+(aq) + 0.75\ O_2(g) \rightarrow 0.5\ N_2(g) + H^+(aq) + 1.5\ H_2O\,(l) \quad (1)$$

$$NH_4^+(aq) + 2\ O_2(g) \rightarrow NO_3^-(aq) + 2\ H^+(aq) + H_2O\,(l) \quad (2)$$

$$NH_4^+(aq) + 1.5\ O_2(g) \rightarrow NO_2^-(aq) + 2H^+(aq) + H_2O\,(l) \quad (3)$$

Reaction (1) could represent either a chemical denitrification step, or a microbial process. Without more direct evidence no distinction can be made between a chemical and a microbial process. Hence, we simply refer to reaction (1) as a "conversion" without specifying its nature. Reaction (2), or nitrification, is discussed below. Reaction (3) is significant as no appreciable concentrations of NO_2^- were determined in any of the lagoons. The nitrite ion is key for the anaerobic oxidation of NH_3 (ANAMMOX) as NO_2^- must be present [Eq. (4)]:

$$NH_4^+(aq) + NO_2^-(aq) \rightarrow N_2(g) + 2\ H_2O\,(l) \quad (4)$$

The Gibbs free reaction energy Δ_rG of the three reactions was calculated under the following conditions: NH_4^+ concentration 1500 mg L^{-1}, NO_3^--N concentration 0.1 mg l^{-1}, NO_2^--N concentration 0.1 mg L^{-1}, pH 8, N_2 partial pressure 81 kPa, O_2 partial pressure 0.1–10^{-15} bar. The calculation is similar to that of Harper et al. (2004b) except that the speciation between NH_3 and NH_4^+ was not considered (NH_4^+ is the dominant species and its concentration does not influence the relative Δ_rG between the three reactions).

This relationship is illustrated in Fig. 4. A negative value of Δ_rG indicates that the reaction is thermodynamically favorable. It is clear that the formation of NO_3^- from NH_4^+ is thermodynamically more favorable than N_2 or NO_2^- formation at O_2 partial pressures above 10^{-8} bar when other concentrations remain the same. At lower O_2 partial pressures N_2 formation is thermodynamically more favorable than the formation of NO_3^- and NO_2^- from NH_4^+. This might explain why N_2 production and CH_4 production are correlated. Methanogenesis is only possible at extremely low O_2 concentrations, and under these conditions N_2 production is thermodynamically more favorable than NO_3^- production. This should not be interpreted as conclusive evidence, as both reactions are thermodynamically favorable in all conditions considered; and, other factors like kinetics play a role as well. The presence of an electron donor (organic material) removes oxygen to the point where NO_3^- production becomes thermodynamically less favorable than N_2 production. Kinetically, nitrification has an estimated saturation constant of 0.5 mg L^{-1} according to the standard activated sludge model, ASM3 (Gujer et al. 1999). The ASM3 model predicts that nitrifiers cannot maintain their activity at oxygen concentrations below 0.026 mg L^{-1} (6.3×10^{-4} bar) under otherwise optimal conditions (i.e., in the absence of any other limiting factor).

The sensitivity of the thermodynamics of reactions (1) (2), and (3) to the variables that were kept constant in the above analysis was investigated. The sensitivity of Δ_rG to any of the reactants or products was determined to be less than 11.42 kJ mol^{-1} for any 100-fold change in concentration (or 2 pH units). It is concluded that the thermodynamics of NH_4^+ oxidation is only slightly sensitive to pH and concentrations of NO_3^-, NO_2^-, N_2, and NH_4^+, so a possible uncertainty of any of these variables will not invalidate the analysis.

Comparison of system N emissions

The relative N emissions (ratio of N emitted to feed N input) from the farms in a geographical area (in NC) are shown in Fig. 5 (volatile NH_3-N from housing and lagoons, NH_4^+-N conversion to N_2, protein-N, and unknown-N). Measured N_2 emissions were not consistent within farm types or across all farm locations. The smallest N_2 flux occurred in a farm (FW #3) which also had the highest estimated housing NH_3 emissions. Inversely, the largest N_2 flux was in a farm (FF) with the smallest housing NH_3 emission losses [housing NH_3 emissions were only slightly linearly correlated with N_2 emissions across all farms, R = 0.63 ($R^2 = 0.40$, n = 6)]. Although not conclusive, the inverse relationship suggests that increased N loss as NH_3 will reduce N_2 emissions.

Statistical models for gas emissions

The correlation of methanogenesis and N_2 emissions ($R^2 = 0.78$) was quite good across the lagoons studied in NC leading us to consider if the relationship ($y = 0.23x$) would be comparable across wide geographical regions of the U.S., as well as with management practices. Methane and N_2 emissions were combined (Fig. 6) with the studies in the CGB and from a previous study in GA (Harper et al. 2000). The relationship between CH_4 and N_2 emissions were surprisingly similar changing the overall correlation only slightly, $R^2 = 0.71$, and a linear relationship of $y = 0.20x$, suggesting a near-universal relationship between methanogenesis and conversion of NH_4 to N_2 in highly anaerobic conditions (comparing NC results to all results). The correlation of fluxes was significant at the 2 % level ($t = 3.76$). A linear relationship can be inferred from the data:

$$F_{N_2} = BF_{CH_4} \tag{5}$$

with F_i the flux of compounds i in kg ha^{-1} d^{-1} and B an empirical coefficient. Based on simple linear regression, the value of $B = 0.20$ is found because of the similar compositions of gas from individual systems.

The S farms were not included in the relationship (see X data point) since the animal size and management, feed input, and manure and urine management were very different.

Gas emissions will vary with respect to farm management (feed input, animal weight, etc.) and climatic conditions. As such, it is difficult to directly compare emissions from different locations. Farm management factors most correlated (and data most likely available) are feed input and size of animal. The climatic

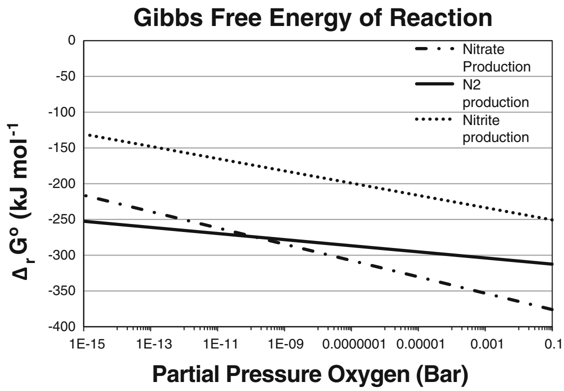

Fig. 4 Gibbs free energy of reaction for N_2 production and NO_3^- production from NH_4^+ versus O_2 partial pressure (NH_4^+ concentration 1,500 mg L^{-1}, NO_3^- concentration 0.1 mg L^{-1}, pH 8, N_2 partial pressure 81 kPa)

factor which most affects the biological decomposition of sludge is the temperature of the biological material in the lagoon anaerobic layer (i.e., sludge temperature, see Fig. 3a). Measurements were used from all the farm systems in the CGB to correct for temperature effects by correlating monthly air temperature with monthly gas emissions as discussed previously. The dependence upon feed input per surface area was estimated from NC data where there was no significant temperature difference between farms. Annual CH_4, N_2, and CO_2 emissions (kg gas component ha^{-1} d^{-1}) were estimated from lagoons by the following relationships:

$$CH_4 = (0.023 \times \text{FIS} - 25) \times (0.039 \times T_a + 0.26) \tag{6}$$

$$N_2 = (0.0039 \times \text{FIS} + 1.3) \times (0.033 \times T_a + 0.41) \tag{7}$$

$$CO_2 = (0.0027 \times \text{FIS} - 7.4) \times (0.040 \times T_a + 0.24) \tag{8}$$

where FIS is the annual average daily feed input per lagoon surface area (kg feed d^{-1} ha^{-1}) and T_a is the average annual air temperature (°C) at the site. Temperature corrections were standardized to the average annual air temperature in the NC studies (18.85 °C). When these relationships were used to estimate CGB gas emissions, estimated CH_4 emissions were 74 ± 24 % high, CO_2 emissions were 58 ± 13 % low, and N_2 emissions were 49 ± 42 % high compared to measured emissions.

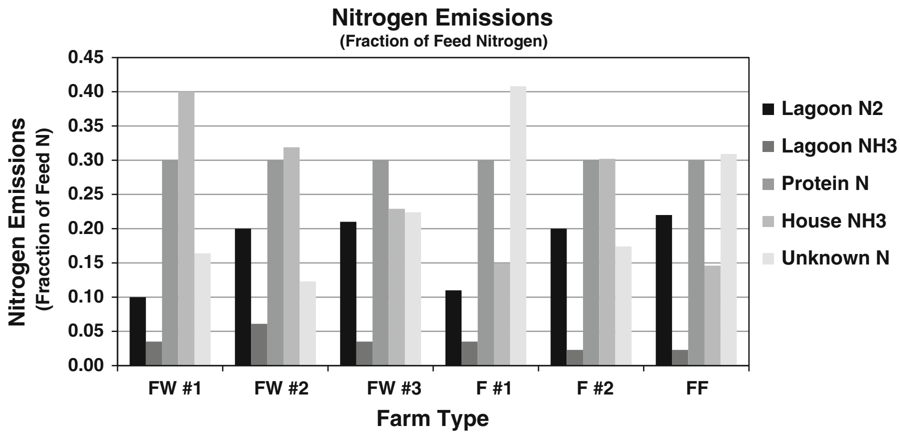

Fig. 5 Comparison of N emissions from farms due to housing NH_3 losses, lagoon NH_3 and N_2 losses, and protein N removal from the farms (*F* finisher, *FF* farrow to finisher, and *FW* farrow to wean)

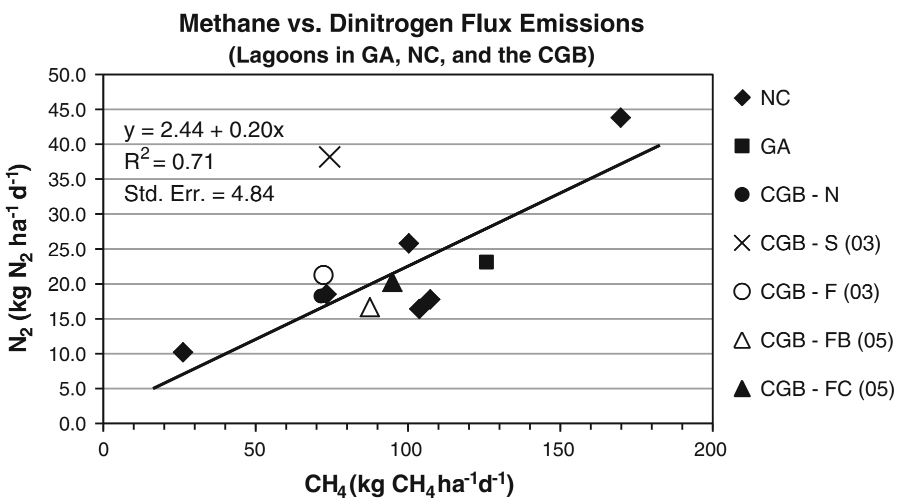

Fig. 6 Average annual dinitrogen production due to anaerobic decomposition in relation to methane production at six farms in North Carolina, 15 in the Central Great Basin (CGB, all data points from the CGB are the average of three identical farms), and one in Georgia (from Harper et al. 2000). The two data points from CGB –F(05) are from Weaver et al. 2012. The Sow farm in the CGB was not used in the relationship since the animal and waste management systems were very different (see X data point)

Using information on the variables measured, we analyzed the data to determine the variables most related (and possibly causal), not already mentioned, to the conversion of NH_4^+ to N_2 for the studies in NC. The amount of feed per average animal weight (and C input) had the highest correlation with N_2 emissions ($R^2 = 0.87$). This is not surprising as feed per animal correlates highly with C and N lagoon input (and consequent increased methanogenesis), along with NH_4 conversion to N_2, across studies over three states (Fig. 6).

Conclusions

In summary, gas emissions were measured in six anaerobic, manure-processing swine lagoons across NC, 15 in the CGB, and one in GA. Conversion of

NH_4^+ to N_2 was observed in all lagoons and a correlation was found between methanogenesis (CH_4 emissions) and conversion of ammoniacal N to benign N_2 gas. Anaerobic digestion not only decomposes organic C to CH_4, but also organic N to NH_4 conceptually leading to an increase in NH_4 concentration and, as a consequence, a potential increase in NH_3 emissions. However, we find in these studies that a reduction of C causes an *increase* in NH_3 emissions, rather than a decrease, since NH_4 is not converted to N_2. Dinitrogen emissions were seen to linearly increase with methanogenesis (CH_4 production), further explaining why removal of organic material from lagoons for biogas production would increase NH_3 emissions from lagoons, a phenomenon which has been seen in other studies (Harper et al. 2010; Weaver et al. 2012). A causal effect for the relationship between methanogenesis and the potential conversion of NH_4^+ to N_2 is explained based on thermodynamics. Dinitrogen emissions can be estimated across all regions utilizing CH_4 emissions (if available). The highest correlation between normally-obtained management variables and N_2 emissions was input-feed per animal-weight which provides the organic C for methanogenesis. Simple statistical regression models including average annual feed input and annual average air temperature were developed which explained most of the N_2 emissions variability and had an acceptable error when tested against other lagoons. These studies provide the capability to estimate farm lagoon CH_4, CO_2 and N_2 emissions from normally-available farm input and local climate data. Further investigations into the mechanisms of NH_4^+ to N_2 conversion and into the variability of CH_4 emissions are needed.

Acknowledgments The authors wish to express their appreciation to the project technical assistants, M.F. Thornton, J. Scarbrough, C. Butler, P. Caddis, L. Mathis, and J. Merritt for their efforts in these studies and to the numerous undergraduate students from SUU for their assistance. Gratitude is expressed to R.R. Sharpe (USDA, *ret*.) for his support in these studies and to P. Rochette and T. Clough for manuscript reviews. A special thanks is extended to the Global Climate Change Program, USDA-ARS; the North Carolina Pork Council; the Utah Pork Council; Smithfield Co.; and to the host swine producers who helped make these studies possible.

Methane (CH_4) and ammonia (NH_3) are emitted to the atmosphere during anaerobic processing of organic matter, and both gases have detrimental environmental effects. Methane conversion to biofuel production has been suggested to reduce CH_4 emissions from animal manure processing systems. The purpose of this research is to evaluate the change in CH_4 and NH_3 emissions in an animal feeding operation due to biofuel production from the animal manure. Gas emissions were measured from swine farms differing only in their manure-management treatment systems (conventional vs. biofuel). By removing organic matter (i.e., carbon) from the biofuel farms' manure-processing lagoons, average annual CH_4 emissions were decreased by 47% compared with the conventional farm. This represents a net 44% decrease in global warming potential (CO_2 equivalent) by gases emitted from the biofuel farms compared with conventional farms. However, because of the reduction of methanogenesis and its reduced effect on the chemical conversion of ammonium (NH_4^+) to dinitrogen (N_2) gas, NH_3 emissions in the biofuel farms *increased* by 46% over the conventional farms. These studies show that what is considered an environmentally friendly technology had mixed results and that all components of a system should be studied when making changes to existing systems.

Mitigation of trace gas emissions has become an important consideration in the design and management of animal feeding operations (AFOs). Although the trend toward increased size of AFOs may increase unit animal production efficiency, both in terms of energy consumption and emissions due to urine and manure management, the consolidation of large numbers of animals can result in a large, localized source of greenhouse and air-quality gases, including methane (CH_4), ammonia (NH_3), and odors. The conversion of animal manure to biofuels (e.g., methanol) is often promoted as an environmentally beneficial management system, with the potential to reduce greenhouse gas emissions (e.g., Wulf et al., 2006; Ghafoori et al., 2006; Brown et al., 2007). Biofuel production systems are designed to remove organic matter (carbon [C]) from the manure stream to produce hydrocarbon fuels. In traditional manure management, this C would ultimately be emitted to the atmosphere as carbon dioxide (CO_2) and CH_4 during decomposition. In theory, biofuel management leads to a direct reduction in greenhouse C gas emissions by diverting the products of manure decomposition, that is, CH_4 with a global warming potential (GWP) equivalent of approximately 25 times CO_2, to a fuel source that is consumed for its energy with its byproduct C emitted as CO_2 (with a GWP of 1).

During urine and manure management processing, however, complex decomposition interactions occur between C and nitrogen (N) compounds. Much of the N that enters into manure processing lagoons is converted to environmentally benign dinitrogen (N_2) gas (Harper and Sharpe, 1998; Harper et al., 2000, 2001, 2004) by microbial and/or chemical denitrification, which reduces the potential for NH_3 emissions. Harper et al. (2000, Table 2) found interesting correlations between emissions of NH_3, CH_4, nitrous oxide (N_2O), and CO_2 from the urine and manure-processing lagoons, suggesting that manipulation of the management system to reduce emissions of one constituent may affect the emissions of another. This study showed that in urine and manure lagoons with a high rate of methanogenesis, there was a significant

amount of chemical conversion of ammonium (NH_4^+) to N_2; however, when CH_4 production (methanogenesis) decreased, smaller N_2 emission rates coincided with higher rates of N_2O production instead of N_2 production. Methanogenesis is only possible at extremely low O_2 concentrations, and under these conditions N_2 production is thermodynamically more favorable than nitrate (NO_3^-) production.

In a series of six geographically widely spaced swine operations in North Carolina, Harper and De Visscher (unpublished data) showed a relationship between CH_4 production and conversion of NH_4^+ to N_2. They found that as CH_4 emissions increased, N_2 emissions increased by a 4:1 CH_4/N_2 ratio (i.e., for a four CH_4 emissions unit increase, N_2 emissions increased by one unit). Amon et al. (2005) and Clemens et al. (2006) found higher NH_3 emissions from biogas-effluent manure slurry than from untreated manure, which they explained by higher NH_4–N content and pH of the effluent. These studies are consistent with the work of Strik et al. (2006), who found an increase in NH_4–N content of manure with time spent in a biogas reactor, and that of Loria et al. (2007), which suggested biogas production increases the NH_4–N content of manure slurry. These latter two studies did not evaluate N_2 production. Because of these relatively new insights, there was concern that removal of the organic matter (and decreasing lagoon methanogenesis) from lagoon urine and manure processing systems may reduce the NH_4^+-to-N_2 conversion and increase the amount of NH_3 emissions from the farms associated with biofuel production. Could the implementation of a biofuel system as a component of the urine and manure processing strategy for AFOs also have negative consequences? Accordingly, the purpose of this study is to evaluate CH_4 and NH_3 gas emissions from farms that are nominally identical, except in regard to manure management, and to determine if the reduction of CH_4 by a biofuel production system affects the total nutrient cycling in the animal production system.

Materials and Methods

Biofuel Facility

The focus of this study was a biofuels facility constructed to capture biogas from digested pig manure and for conversion of the biogas into biomethanol and biodiesel, a process whereby C in the animal manure is converted to a usable and less-polluting fuel for internal combustion engines. As a result, the manure C, which is aerobically or anaerobically decomposed in normal manure-management systems and generally lost to the atmosphere as CO_2 and CH_4, is converted to a usable product.

This biofuel facility is part of a multifarm swine complex in the semiarid Central Great Basin of the United States. Farms are spread over several kilometers along a broad valley (elevation 1500 m), separated from each other by several hundred meters. Liquid manure is collected from 12 12,000-animal finishing farms (144,000 animal total, Fig. 1A) and conveyed to a central treatment plant. The manure is first concentrated, by means of gravity thickeners, and then conveyed to two covered earthen digester tanks, where it is heated to 35°C for undergoing bacterial processing ("digestion"), resulting in the biogas production. The digester effluent, digester sludge, and gravity thickener supernatant are conveyed back to the farm manure

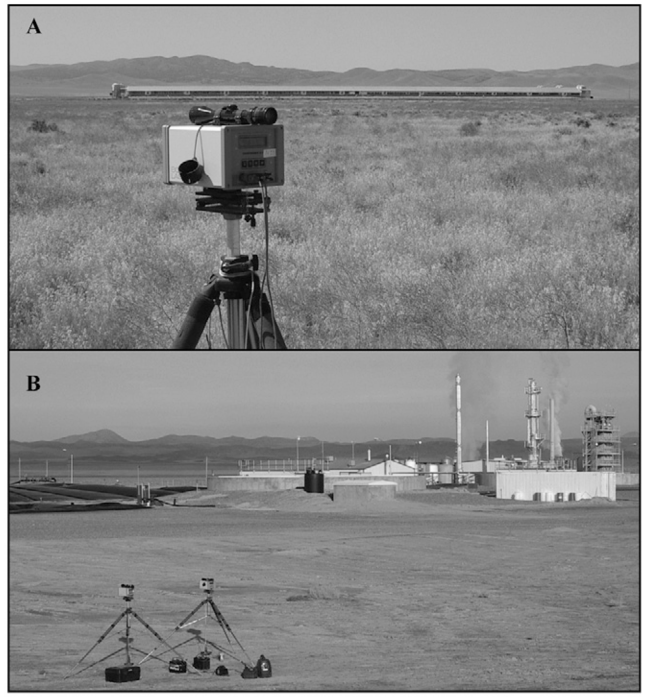

Fig. 1. (A) Open path laser unit located downwind of a farm. (B) Two laser units located at the biofuel facility (B). The laser reflectors are not visible in these pictures.

lagoons where the lagoons operate at the same hydraulic loading rate as they would without the biofuels plant, but with a much-decreased solids loading rate due to the extraction of manure C for methanol production. The biogas is collected and conveyed to a biomethanol conversion plant on the site (Fig. 1B). Biomethanol produced at the facility is trucked from the site as a liquid for conversion to biodiesel at a location remote from the swine production facility.

The Swine Farms

Methane and NH_3 gas emissions were measured from three farms at the production complex. These farms were nominally identical 12,000 animal "finisher" farms. Each consisted of three closely spaced and joined barns with adjacent primary and secondary open-air manure lagoons. The "conventional" farm (Control) uses traditional manure treatment: liquid manure is transferred from the barns into lagoons, where evaporation and decomposition maintain long-term manure equilibrium at the farm such that no manure removal (other than that occurring naturally, i.e., unimpeded venting of C and N compounds to the atmosphere) is performed. Water temperature data were collected using HOBO Water Temp Pro data loggers (Onset Computer Corporation, Bourne, MA). Lagoon pH was measured with pH probes on-site and on samples of the effluent collected twice a month, and frozen, for subsequent pH and NH_3/NH_4^+ analysis. The two "biofuel" study farms (BF1 and BF2) were converted from the traditional manure-management system to the biofuel system as described above.

Emissions measurements were also made at the biofuel plant site. Because the gravity thickeners expose manure to the air, there will be gas emissions from these locations. The rest of the biofuel site is enclosed (i.e., sealed off from the atmosphere), the intent being to eliminate all other emission points.

Emission measurements were conducted from 30 January to 23 February and 27 June to 14 July 2005.

Inverse-Dispersion Technique

The inverse-dispersion technique uses an atmospheric dispersion model to infer the emission rate that best explains the observed downwind gas concentration under existing meteorological conditions, namely, wind direction and speed, temperature stratification, and (consequent) degree of turbulent mixing (Flesch et al., 2004). Consider an area source emitting tracer gas at a uniform but unknown rate Q (g m^{-2} s^{-1}) and assume an average tracer concentration C (g m^{-3}) measured in the plume of dispersing gas. The dispersion model predicts the ratio of the concentration at the measurement location (or more specifically, the increase in atmospheric concentration above background levels attributable to the source) to the emission rate, $(C/Q)_{\mathrm{sim}}$. The emission rate may be computed as

$$Q = \frac{(C - C_{\mathrm{b}})}{(C/Q)_{\mathrm{sim}}} \qquad [1]$$

where C_{b} is the background tracer concentration. This technique is well suited for "ideal surface layer problems" (see Flesch et al., 2004), that is, horizontally uniform terrain where the wind and turbulence can be described by well-known functions of height. In these cases, the wind statistics needed to predict $(C/Q)_{\mathrm{sim}}$ can be inferred from the friction velocity, u_*, the Monin–Obukhov stability length, L, the surface roughness length, z_0, and the average wind direction, β. These primary meteorological properties can be measured with a three-dimensional sonic anemometer. The averaging interval for this type of measurement is ideally in the range of 10 to 60 min.

The terrain around the farm complex is ideal for application of idealized dispersion models: flat and uniform with a sparse coverage of low sagebrush and grass extending in all directions (Fig. 1A). But the farms can complicate an idealized dispersion calculation because farm structures can create wind complexity and the exact spatial distribution of emissions from the barns and lagoons are unknown. (For a compound emission source, e.g., a farm with barns and urine and manure lagoons, one must make assumptions about the relative distribution of the component emissions.) However, Flesch et al. (2005b), McGinn et al. (2006), and Gao et al. (2010) suggested that if the concentration and wind measurements are made far enough downwind of the farm, the emission calculations will be insensitive to these complications. With regard to estimating how far downwind to measure concentrations, Flesch et al. (2005b) suggested that the crucial distance scales are the height of the largest wind obstacle, h, and the maximum distance between the source components, x_{s} (e.g., the distance between the centers of the barn and lagoon). They recommended concentration observations be made more than $10h$ downwind of a farm and more than $2x_{\mathrm{s}}$. This technique has been used in a number of animal feeding operations (e.g., Flesch et al., 2005b; McGinn et al., 2006; Harper et al., 2009, 2010).

Concentration and Wind Observations

Methane and NH_3 concentrations were measured with open-path lasers (GasFinders, Boreal Laser Inc., Edmonton, Canada). The path-average gas concentration was measured between the laser and a distant retroreflector and processed to give 15-min averages (C). Lasers were calibrated on-site using calibration tubes flooded with gas standards. Three NH_3 lasers and a single CH_4 laser were used. Background concentrations of CH_4 and NH_3 were taken as C_{b} = 1.75 and 0 μL L^{-1}, respectively (corroborated when the wind brought air with no farm-gas sources upwind over the laser paths).

The lasers were placed so their paths would be downwind of the emission sites for the prevailing southwest winds. Figure 2 shows the configuration of the sites and laser locations for summer measurements. Configurations for winter measurements were slightly different due to a shift in predominant wind direction between seasons. At the three farms the lasers paths were approximately 200 m downwind of the barns and/or lagoons at the nearest point (Fig. 1A). This was more than $25h$ from the barns and, depending on the farm, was $1.3x_{\mathrm{s}}$ to $6x_{\mathrm{s}}$ downwind (where x_{s} is the distance separating barns from lagoons). Ammonia emissions were measured from the three farms concurrently using the three NH_3 lasers. With only one CH_4 laser during summer, we first measured CH_4 emissions from the control farm and then moved to one of the treatment farms. During winter, lasers were available to measure downwind concentrations for both farms simultaneously. All lasers were used at the biofuel site (Fig. 1B). The NH_3 lasers were positioned so their paths made up three sides of a square

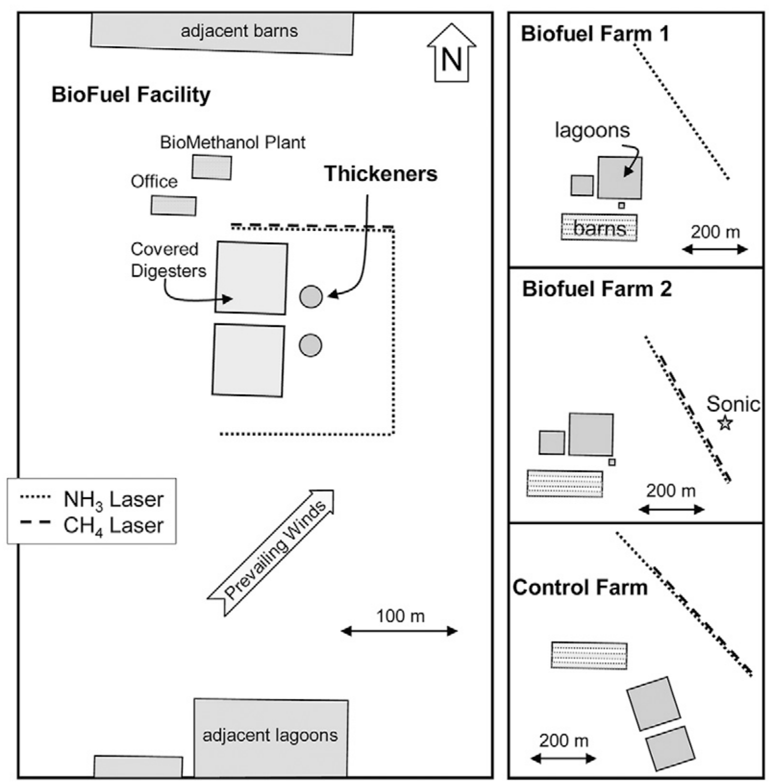

Fig. 2. Summer measurement locations at the four emission sites.

around the two open-air thickeners. In theory, this allowed us to make emission measurements for a wide range of wind directions. The single CH_4 laser during summer was placed northeast of the thickeners. At the closest location, the laser paths were 60 m from the thickeners.

A three-dimension sonic anemometer (CSAT-3, Campbell Scientific, Logan, UT) provided the wind information for the dispersion calculations. The anemometer was placed at height of 2 m. Wind velocity and temperature signals were sampled at a frequency of 16 Hz. The necessary wind statistics (u_*, L, z_0, β) were calculated for 15-min intervals to match the C observations, as described in Flesch et al. (2004). The sonic observations also provided velocity standard deviations (in each of three-dimensions) that were used in the dispersion model.

The sonic anemometer was placed to measure the ambient winds (unaffected by farm structures) at a location central to the study sites: approximately 400 m from the first treatment farm, 1.5 km from the second treatment farm, and 8 km from the control farm. Given the homogeneous character of the landscape (Fig. 1A, flat terrain, low shrub desert flora, no obstacles), we assumed the winds measured at the sonic location were representative of the conditions at the four sites. It should be noted that because of the distance between the farms (and the anemometer), the measured wind statistics for any one 15-min analysis period may not be applicable (concurrently) at all the sites. This adds uncertainty to our individual 15-min emission values. However, over many observations we assume the wind regime between the sites is nearly identical, and our average emission calculations are more accurate.

Backward Lagrangian stochastic Application Details

Following Flesch et al. (2005a), we used a backward Lagrangian stochastic (bLS) dispersion model to calculate $(C/Q)_{\mathrm{sim}}$ (WindTrax, Thunder Beach Scientific, Nanaimo, Canada). Thousands of trajectories are calculated upwind of the laser path for each 15-min observation period (e.g., 250,000). The important information is contained in the trajectory intersections with ground ("touchdowns"), and we compute

$$(C/Q)_{\mathrm{sim}} = \frac{1}{N}\sum\left|\frac{2}{w_0}\right| \qquad [2]$$

where N is the number of computed trajectories, w_0 is the vertical velocity at touchdown, and the summation covers only touchdowns within the source. (The units of Q are g m^{-2} s^{-1} in this equation. Hereafter, we multiply the areal emission rate by the source area and report Q as an area-integrated emission rate with units of kg h^{-1}.) The touchdowns map the concentration "footprint", that is, the ground area where emissions influence concentration.

Each farm is represented as three surface area sources: the two lagoons and the area outlined by the barns (Fig. 2). Each area is assumed to have the same areal emission rate so that touchdowns in any of these areas are counted equally in Eq. [2]. Equating the areal emissions rates in this manner represents an approximation. The two lagoons may have somewhat different emission rates, while the barn is not, in fact, an area source (emissions occur from vents on the walls) and, even if treated as such, may have an effective area source strength differing from that of the lagoons. However, following the arguments of Flesch et al. (2005a), we assume that with C measured sufficiently far downwind, the inferred mean emission rate from the complex is insensitive to the correctness of the approximation. Emissions at the biofuel site were assumed to originate exclusively from the two thickeners, which, having identical manure input rates, were assumed to have equal areal emission rates.

The bLS technique to estimate emission rate depends on a good description of atmospheric transport, which is known to be difficult in extreme conditions. Following Flesch et al. (2005a), we eliminated measurements during periods (i) where $u_* \leq 0.15$ m s^{-1} (low wind conditions), (ii) where $|L| \leq 10$ m (strongly stable/unstable atmosphere), and (iii) where $z_0 \geq 1$ m (associated with uncertainty regarding the proper wind profile). For some wind directions, the farm plumes only "glanced" the path of the lasers, giving more uncertain Q estimates. To avoid these problems we removed periods (iv) where the laser touchdowns do not cover some portion of all the source areas (e.g., at least 50% of the barn and lagoons, or both thickeners).

The bLS technique for calculating emissions has been tested in a number of tracer release studies, conducted in a variety of terrain settings and source configurations. Some of these verification studies are listed in the Appendix. One concludes that with careful use of the technique (e.g., proper equipment siting, data filtering, data averaging), the expected accuracy of the emission calculations should be approximately ±10%.

A problem in this study was a lack of nighttime data suitable for emission calculations, either because of laser alignment problems, unsuitable wind directions, or wind statistics that did not meet the analysis criteria (e.g., low winds). The summer control farm, in particular, had little data that conformed to the selection criteria during the periods from 2300 to 0800 h. To obtain sufficient data to create daily emission curves we relaxed the nighttime data criteria, for the summer control farm only, to include data with an atmospheric stability of $|L|$ from 5 to 10 m for nighttime periods (see Fig. 3C, open circles, for the relaxed data criteria periods). As explained in Flesch et al. (2005b), we thus anticipate greater errors than ±10% (Appendix) for these periods.

Results and Discussion

Biofuel Production Site

Manure slurry from the swine farms is transported and injected into sealed digesters at the biofuel production site. Before injection into the digesters, there was a potential for CH_4 and NH_3 emissions from the gravity thickeners (Fig. 1B and 2), which had an open surface.

Methane emissions should be small at the biofuel site. However, we found some periodic evidence of fugitive CH_4 emissions around the digester pits (either from leaking pipes, digester covers, or leakage from the soil around the pits). We omitted these emission periods on the principle that they are not representative of a well-designed and maintained system. Thus, in our study, we assume CH_4 emissions from the biofuel site are negligible (compared with the farm sites) and can be ignored.

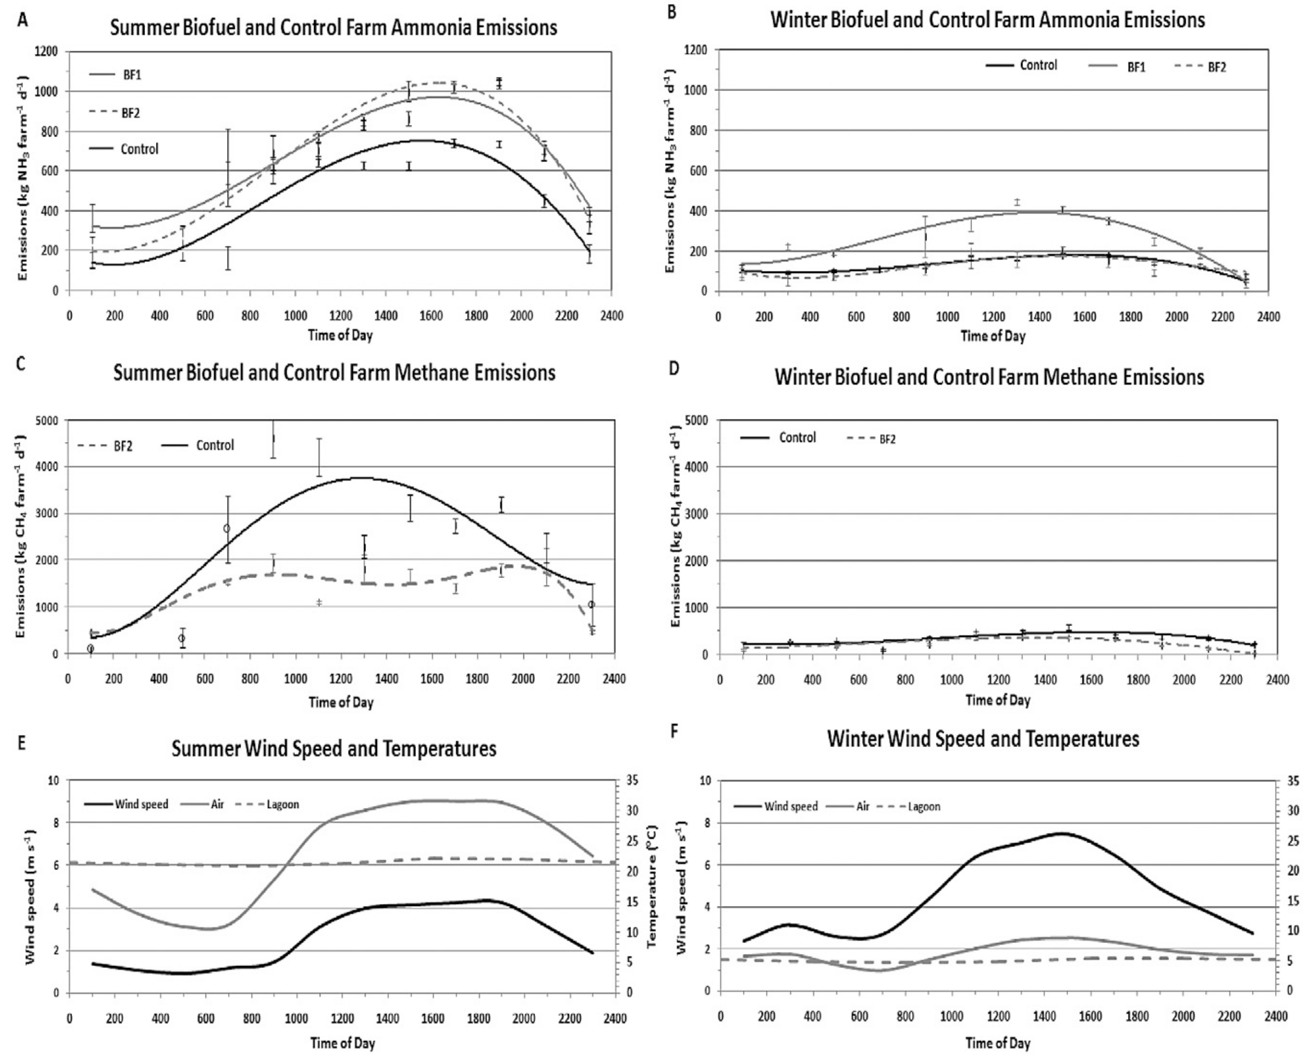

Fig. 3. (A, B) Average summer and winter NH_3 emissions, plotted versus time of day, for biofuel (BF1, BF2) and control farms in the Central Great Basin (error bars are one standard error for each 2-h period). (C, D) Average summer and winter CH_4 emissions for biofuel and control farms. (E, F) Average summer and winter wind speed plus air temperature (height = 2 m) and lagoon temperature (depth = –0.05 m) at the farm site.

On-site NH_3 measurements showed average summertime emissions were 2.6 kg NH_3 h^{-1}, equivalent to 0.4 kg NH_3 h^{-1} for each of the six farms providing organic matter to the site. This was only 2% of the farm emissions during this period. Thus, like methane emissions, these additional NH_3 emission rates were ignored when calculating representative emissions from the biofuel system.

Farm Sites

Figure 3 gives the average diurnal emissions relationship for NH_3 and CH_4 during summer and winter for two biofuel farms and one control farm, along with average wind speed plus air and lagoon temperatures. These emissions were calculated by grouping the available data (15-min observations) according to the time of day, and averaging the data in 2-h blocks throughout the 24-h day. The objective was to create a properly weighted daily average emission rate (i.e., our 15-min observations were not evenly distributed over the day). The curves in Fig. 3 were obtained from these 2-h block averages, with the error bars showing the standard error of the 15-min observations within each block.

The annual emissions were estimated by averaging the daily emission rates from the summer and winter periods. Previous studies (Harper et al., 2004, 2009; Zhu et al., 2010) showed that an annual estimate obtained from the winter and summer averages adequately estimates the annual average, and the addition of a transitional season (three total seasons) did not significantly change the average annual emissions.

Methane and Ammonia Emissions

Comparison between Biofuel Farms

We anticipated that the two biofuel farms, which are nominally identical in management, would have similar emission rates. This was observed to be the case for NH_3 during summer (Fig. 3A) as the two biofuel treatment farms showed no significant difference in NH_3 emissions ($p > 0.05$). However, there was a small difference during winter (Fig. 3B, $p < 0.01$). The difference between the two biofuel farms' emissions during winter was perhaps due to differences in lagoon solution temperature (average wintertime temperatures for the BF1 and BF2 farms were 6.4 and 5.4°C, respectively.). We believe the lagoon temperature for BF1 farm was higher since it is about 1 km closer to the biofuel production site (effluent thermal absorbtion by the soil during return transmission). Ammonia emissions showed diurnal variability during both measurement seasons, but, as anticipated, the winter emissions were a fraction of the summer emissions. Comparison of annual emissions showed no difference between the biofuel farms ($p > 0.05$).

Comparison between Biofuel and Control Farms

Comparisons between the average of the two biofuel farms and the control farm NH_3 emissions (Table 1) showed significantly higher emissions from the biofuel farms during summer (188 kg NH_3 farm^{-1} d^{-1}, +38%, $p < 0.02$) and winter (62 kg NH_3 farm^{-1} d^{-1},+48%, $p < 0.01$). Although there was no significant difference (Table 1) in annual lagoon NH_4^+ concentrations between the biofuel and control farms ($p > 0.05$), the annual lagoon pH was significantly higher in the biofuel farms ($p < 0.05$). This higher pH allows for a greater dissociation of NH_4^+ to NH_3 and therefore the potential for larger NH_3 emissions (Harper, 2005; Koelliker and Kissel, 1988). Comparison of CH_4 emissions between the biofuel and control farms showed significantly smaller CH_4 emissions from the biofuel farm during both summer (1552 kg CH_4 farm^{-1} d^{-1}, –49%, $p < 0.05$) and winter (108 kg CH_4 farm^{-1} d^{-1}, –32%, $p < 0.05$). Both winter NH_3 and CH_4 emissions were only a fraction of summer emissions. When we take the average of winter and summer emission rates to estimate annual emissions, we find that the biofuel farm had annual emissions of CH_4 that were 47% lower but NH_3 emissions that were 46% higher, with the differences being mostly due to the differences in summer emissions. This study showed that on an annual basis, the biofuel farms had CH_4 and NH_3 emissions differences (Table 1) greater than the 10% level of uncertainty we believe exists in the bLS technique (Appendix).

We found the expected result that CH_4 and NH_3 emissions were correlated with wind speed and air temperature (Fig. 4A–D). Studies (Harper et al., 2000, 2004) have shown that increasing wind speeds lead to increasing emissions, on a short-term or diurnal basis, from ponds and naturally ventilated sources. For example, at the control farm (Fig. 4A and 4C), emissions were weakly correlated with wind speed within seasons (r^2 ranging from 0.01 to 0.46). When comparing winter and summer emissions with air temperature, however, we see that long-term emissions are better related to air temperature ($r^2 \geq 0.80$ for both gases). Over long periods of time, the air temperature will be a surrogate of the solution temperature (Fig. 3E and 3F) in both the lagoons and barns. Studies have shown for NH_3 (Harper et al., 2000, 2004) that solution temperature affects the dissociation between NH_4^+ and NH_3 in solution and the diffusion of NH_3 in solution, both of which will alter the emission rate. (NH_3 is a diffusive gas influenced by the physical and chemical factors of solution concentration [NH_4^+], solution hydrogen ion concentration [pH], turbulence [wind speed], and solution temperature. For a discussion of the relationship of physical and chemical factors to NH_3 emissions, see De Visscher et al., 2002; Harper, 2005.) Temperature has a similar effect on emissions from the barns because of the amount of barn air exchanged to maintain comfort of the animals. The effect of temperature on CH_4 emissions has a greater effect on biological activity than on the physical chemistry of gas in solution and transport since CH_4 has five orders of magnitude less solubility in water than NH_3.

GWP Comparison between the Biofuel and Control Farms

There was a 47% decrease in average annual CH_4 emissions at the biofuel farm compared with the control farm; however, average annual NH_3 emissions increased by 46% compared with control farm emissions. These changes in emissions can be used to look at the effect of biofuel production on the GWP of a farm system.

The annual GWP decrease, when considering that methanol (from methane, GWP of 25, 100-yr time horizon) is consumed as biodiesel and emitted as CO_2 (GWP of 1), was 45% compared with control farm emissions. However, NH_3 emissions were increased on the biofuel farms, which is a precursor of indirect nitrous oxide (N_2O, GWP = 298, 100-yr time horizon) emissions. Because a fraction of the NH_3 will, on redeposition on the soil environment elsewhere, be transformed into N_2O (assuming an emissions factor of 1% of deposited NH_3/NH_4^+, Intergovernmental Panel on Climate Change default), an annual NH_3 increase of 144 kg NH_3 d^{-1} would result in a combined net reduction in GWP of 44% for this biofuel management system. By removing the C, and reducing methanogenesis and global-change gas emissions (Harper et al., 2000, 2004; Harper and De Visscher, unpublished data) from the manure-processing system of swine production, the

Table 1. NH_3 and CH_4 emissions from biofuel production and control farms.

Farm type	Season	Lagoon surface concentration	Lagoon surface pH	NH_3 emissions	CH_4 emissions
		mg NH_4^+-N L^{-1}	$[H^+] = 1 \times 10^{-pH}$	kg NH_3 farm^{-1} d^{-1}	kg CH_4 farm^{-1} d^{-1}

% difference	Annual	–	–	+46%	–47%

† Standard error.

processing of manure NH_3/NH_4^+ to N_2 gas was detrimentally causing an *increase* in NH_3 emissions (air-quality gas) by 46%. This increase in NH_3 emissions creates a potential for additional NH_4^+ particulates and haze production compared with conventional production practices. What had been intended to function as an environmentally friendly technology had (according to our observations) mixed results.

Conclusions

We have seen encouragement to develop "manure-to-fuel" technologies for farming systems, including removal of organic C from animal manure processing systems (e.g., lagoons) for fuel production. As we document in this study, manure-to-fuel production has the benefit of reducing greenhouse gas emissions from animal production systems. It appears, however, that it can also have unforeseen consequences. With the manure removed from the processing system (reduction of methanogenesis), NH_3 emissions were increased. Other studies also have shown that as methanogenesis decreases, the rate of conversion of NH_4^+ to (harmless) N_2 undergoes a parallel decrease. These studies show that we should be aware of the potential for countervailing interactions (in terms of release rates to the atmosphere of diverse species) when modifying animal manure management systems.

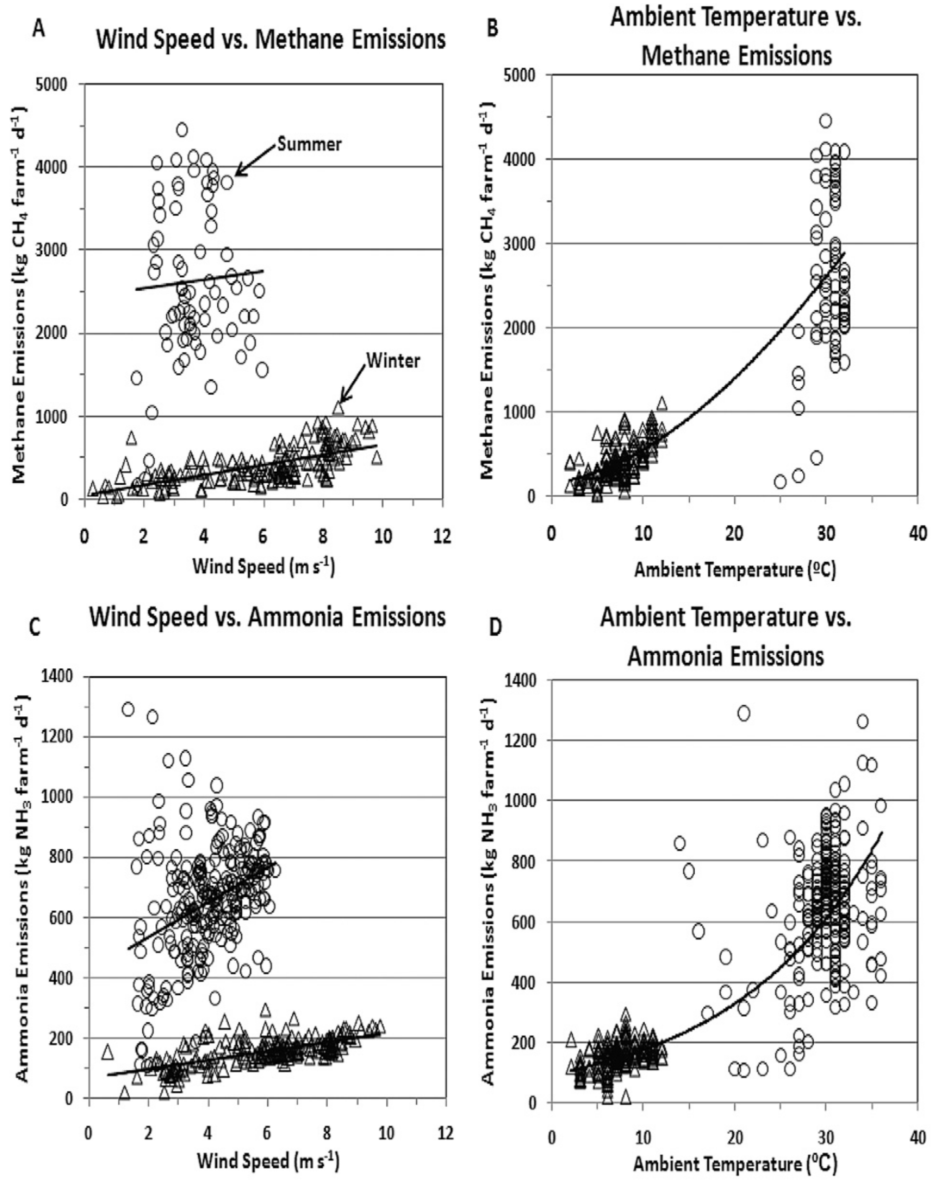

Fig. 4. Emission rates of CH_4 and NH_3 plotted versus ambient wind speed and air temperature (height = 2 m) from the control farm.

Appendix

Table A1 summarizes several tracer studies on the accuracy of the bLS analysis technique for calculating emissions (Q). Accuracy is indicated by the gas recovery, which is the percentage ratio of the bLS calculated emissions to actual emissions (i.e., $Q_{bLS}/Q_{release} \times 100$). These studies had an average recovery of 98% with a standard deviation of 5%. We conclude that for a good site with appropriate instrument placement and data filtering (as discussed in detail in these studies), one can expect a nominal bLS accuracy of 100 ± 10% (± two standard deviations—a span that includes 95% of a Gaussian distributed population). This would be the accuracy of an average of multiple measurement periods. For a single observation (e.g., one 15-min value), these results suggest a higher ±42% uncertainty (twice the average of the within-study standard deviation). This period-to-period uncertainty is due to uncertainties in the bLS model, uncertainty in the idealized representation of the wind, noisy C observations, and so on, uncertainties that are reduced by appropriate averaging.

Table A2 compares nine studies where trace-gas emissions were determined using the bLS analysis procedure and alternative techniques (true emissions were unknown). The alternative techniques include the integrated horizontal flux and flux-gradient micrometeorological techniques and a SF_6 ruminant tracer technique (SF_6).

Acknowledgments

This work was supported by research grants from the Utah Pork Council, Smithfield Corporation, USDA–ARS Global Change National Program, Natural Sciences and Engineering Research Council of Canada, Southern Utah University, and the Canadian Foundation for Climate and Atmospheric Sciences. Thanks are extended for the support provided by R. Sharpe, USDA–ARS, Watkinsville, GA (retired), and the host producers. The authors would also like to acknowledge the technical support of M. Thornton and J. Scarbrough.

Table A1. Tracer studies using the backward Lagrangian Stochastic (bLS) analysis procedure. These studies evaluated emissions in both ideal wind conditions (homogeneous terrain) and in winds disturbed by obstacles, from either single or multiple sources, and with either point or line-average concentration (*C*) measurements. Each study was based on many measurement periods (typically 15 min each), and the average gas recovery and standard deviation of the recovery are presented. Well-described data-filtering criteria were used in each study to reduce bLS errors. For studies with wind obstacles, the downwind distance (*M*) between the *C* measurement and the upwind obstacle is given in terms of the obstacle height (*h*).

† Results for trial C1 are given here—simplest of the multisource layouts studied. Recovery is calculated based on the summation of all emission sources.

‡ Results for trial C2 are given here—simplest of the layouts studied, but with obstacles placed around the sources. Another trial in this study used higher obstacles ($M \sim 5h$), and the recovery was reduced to 0.75. Recovery is calculated based on the summation of all emission sources.

§ Reported recovery in this study was 109 ± 45. The high standard deviation (45%) was due to the experimental design (4 laser lines, solving for C_b [background tracer concentration] and *Q* [uniform gas emission rate]) which led to ill-conditioned solutions. We report the recovery calculated when periods with very large uncertainties are removed (as discussed in Gao et al., 2009b).

CONSERVATION PRACTICE STANDARD

ANAEROBIC DIGESTER

Code 366

(No.)

DEFINITION

A component of a waste management system in which biological treatment breaks down animal manure and other organic materials in the absence of oxygen.

PURPOSE

This practice is applicable for one or more of the following purposes:

- manage odors
- reduce the net effect of greenhouse gas emissions
- reduce pathogens
- captures biogas to facilitate energy production

CONDITIONS WHERE PRACTICE APPLIES

This practice applies where:

- Biogas production and capture are components of a waste management system plan and Comprehensive Nutrient Management Plan (CNMP)
- Sufficient and suitable organic feedstocks are readily available.

CRITERIA

General Criteria Applicable to All Purposes

Laws and Regulations. Plan, design, and construct the anaerobic digester to meet all federal, state, local and tribal laws and regulations.

Location. Locate the anaerobic digester outside the 100-year floodplain unless site restrictions require locating it within the floodplain. If located in the floodplain, protect the facility from inundation or damage from a 25-year flood event. Additionally, follow the policy found in the NRCS General Manual (GM) 190, Part 410.25, Floodplain Management, which may require providing additional protection for structures located within the floodplain.

Feedstock Characteristics. Digester design must take into account the varying feedstock properties. Depending on the system design, extraneous material such as soil, sand, stones or fibrous bedding material (including clumps of straw), may need to be ground, removed, reduced, or otherwise handled. Ensure that the total solids of feedstock influent match the digester type and process design. Exclude excess water and foreign material from the digester. Food waste, wastewater from food processing operations, and other allowable organic substrates may be added as supplemental feedstock to a digester when the digester is designed to treat such wastes, as described in the operation and maintenance plan.

Connections. Ensure that all connections and fittings are properly sized and installed for design flows and vibrations.

Agricultural Waste Management System. Do not consider the volume of the digester in determining the storage requirement of the waste storage facility.

Safety. If the digester has the potential to create a safety hazard, install fence and post warning signs to prevent using it for purposes other than intended. Include appropriate safety features to minimize the hazards of the facility (refer to American Society of Agricultural and Biological Engineers (ASABE) Standard EP470, Manure Storage Safety for guidance, as needed).

Biogas is flammable, highly toxic, and potentially explosive. For the design of the digester and gas components, including the gas collection, control, and utilization system and understand the hazards associated with normal operation and maintenance, provide adequate safety measures including appropriate earthquake loads (as required)**,** and install components in accordance with standard engineering practice for handling a flammable gas and to prevent undue safety hazards. As a minimum:

- Post “Warning Flammable Gas” and “No Smoking” signs.
- Provide appropriate fire protection equipment and biogas leak detection sensors, especially in confined areas.
- Install a flare for the anaerobic digestion system unless another option is provided by the manufacturer which adequately addresses conditions to prevent biogas release into the atmosphere.
- Locate flares the appropriate distance from the digester and other buildings according to manufacturer’s specifications, and electrical code. Install flares a minimum of 10 feet above the ground. Locate open flares a minimum distance of 50 feet from the biogas source. Properly ground flares or protect to minimize potential damage caused by lightning strikes.
- Provide a flame trap device in the biogas line between the digester and sources of ignition to prevent flame migration from the flare to the gas source or as otherwise recommended by the flame arrester manufacturer.
- Use explosion-proof motors, switches and other spark producing devices on all biogas blowers or other equipment installed where biogas is present.
- Provide and maintain above ground permanent markers to indicate the location of underground gas lines to prevent accidental disturbance or rupture. Mark exposed pipe to indicate type of pipe whether gas or other.

Criteria for Plug Flow Digester

- Recommended total solids content of influent is 11 to 14 percent.
- Minimum digester retention time is 20 days.
- Operational temperature is mesophilic (ranging from 95 to 104 ºF).
- Minimum length to width ratio of digester flow path is 3.5:1
- Maximum ratio of flow path width to fluid depth is 2.5:1.
- Design the floor and wall shapes to facilitate the movement of all material through the digester to minimize short-circuiting flow.

Criteria for Complete Mix Digester

- Recommended total solids content of manure influent is less than 11 percent.
- Minimum digester retention time is 17 days.
- Operational temperature is mesophilic (ranging from 95 to 104 ºF).
- Provide appropriate devices, as necessary, to assure a continuous flowing and mixing process.

Criteria for Covered Lagoon

Meet the “General Criteria for All Lagoons” given in Practice Standard 359, Waste Treatment Lagoon, as appropriate. Additional requirements include:

- Minimum Design Operating Volume. Base the design operating volume either on the daily volatile solids (VS) loading rate per 1,000 ft^3 or the minimum hydraulic retention time (HRT) adequate for methane production, whichever volume is greater. Select and apply the maximum daily VS loading rate from the values listed on the map in Figure 1. Select and apply the minimum HRT from values indicated on the map in Figure 2.
- Required Total Volume. The required total volume of the digester is equal to the minimum design operating volume except where waste storage is also included in the design. For this exception, meet the additional criteria pertinent to volume requirements found in the Design Storage Volume in Practice Standard 359, Waste Treatment Lagoon, as appropriate.
- Provide a minimum of 2 feet of freeboard above the digester design water surface; if rainfall is included in determining the operating volume, only 1 foot of freeboard is required. The digester storage volume does not need to account for rainfall for completely covered digesters.
- Operating Depth. The minimum operating depth of the digester is 8 feet.
- Inlet and Outlet. Locate the inlet and outlet devices as far apart as practical to minimize “short circuiting.” Locate the inlet discharge a minimum of 12 inches below the digester liquid surface. Equip the digester with an outflow device that maintains the digester liquid surface at its design operating level.
- Digester Cover. Design the digester cover, materials, anchorage, and all appurtenances, such as weights and floats, to capture and convey biogas to the gas collection system. The digester cover and associated materials must meet the requirements of Practice Standard 367, Roofs and Covers.

Criteria for Alternative Type Digester

For digester types not meeting the above criteria or for digester types other than listed in this standard (such as fixed film, induced blanket, high solids (dry digesters) or thermophilic reactors) follow the documented design and performance requirements of the proposed anaerobic digester.

Alternative Type Digester Containment Characteristics. For the various alternative digester types, ensure that the following applicable criteria are applied:

- For earthen structures meet the “General Criteria for All Lagoons” given in Practice Standard 359, Waste Treatment Lagoon, as appropriate.
- Design tanks and internal components, including heat pipes to facilitate periodic removal of accumulated solids and for corrosion protection.
- For tanks meet the structural criteria for “Fabricated Structures” in Practice Standard 313, Waste Storage Facility, and the requirements of state and local seismic codes as applicable.
- The following additional criteria apply:
  - Design Operating Volume. Size the digester to retain the design requirements to meet the hydraulic and solids retention times (days).
  - Inlet and Outlet. Locate the inlet and outlet devices to facilitate process flow. Design inlets and outlets of any permanent material to resist corrosion, plugging, freeze damage, and prevent gas loss. To maintain the operating level, maintain a gas seal under the cover, prevent gas loss, and release effluent directly to separation, storage, or other treatment facility. Equip the digester with an outflow device, such as an underflow weir.
  - Cover. For covers meet the requirements of Practice Standard 367, Roofs and Covers. Equip tanks with suitable covers designed for accumulation and collection of biogas.

- o Heating System (if required). Design and install the heating system to maintain proper digester temperature and to minimize corrosive attack and scalding build-up on the heated surfaces.

Gas Collection, Transfer, and Control System. Design the biogas collection, transfer, and control system to convey captured gas from within the digester to gas utilization equipment or devices (flare, boiler, engine, etc.).

- Gas collection and transfer – Meet the following for pipe and/or appurtenances:
  - o Design the gas collection system within the digester to minimize plugging or install cleanout ports as needed.
  - o Securely anchor pipe and components within the digester to prevent displacement/damage from normal forces including loads associated with scum accumulated.
  - o Design the collection and transfer pipe for wet biogas. In colder climates, protect the pipe as necessary to prevent frost buildup. Use pipe sizes no smaller than 3-inch diameter, unless a detailed design is performed to account for frost buildup and pressure drop in a low-pressure system. Design pressurized systems as an Alternative Type Digester.
  - o For pipes used to transfer biogas include provisions for drainage of condensate, pressure and vacuum relief, and flame traps.
  - o For steel pipe meet the requirements of AWWA Specification C-200 or ASTM A53/A211 for stainless steel.
  - o For plastic pipe meet the requirements of AWWA Specification C-906 or ASTM D-3350 for HDPE.
  - o Install pipes to ensure all sections can be safely isolated and cleaned as part of routine maintenance.
- 2. Gas Control
  - Locate and shelter all equipment and components from the elements.
  - The minimum service life for all equipment and components is 2 years or more. Provide easy access for replacement or repair of components.
  - Base the size of equipment and connecting pipe on head loss, cost of energy, cost of components, and manufacturers' recommendations.
  - Where electrical service is required at the control facility, follow the National Electrical Code and local and state requirements for the installation and all electrical wire, fixtures, and equipment.

Gas Utilization. Design and install gas utilization equipment in accordance with standard engineering practice and the manufacturer's specifications.

- Equip flares with automatic ignition and powered by battery/solar or direct connection to electrical service. Ensure that the flare capacity is equal to or greater than the anticipated maximum biogas production. Install a windshield or other device to protect an open flare against wind.
- As needed, design appropriate facilities to store excess gas.
- Design gas-fired boilers, fuel cells, turbines, and internal combustion engines to burn biogas directly, in a mix with other fuel, or include equipment for removing hydrogen sulfide and other contaminants from the biogas.
- Install and maintain a gas meter, suitable for measuring biogas.

Monitoring for mesophilic and thermophilic digesters. Install equipment needed to properly monitor the digester and gas production as part of the system. As a minimum the following equipment is required:

- Temperature sensors and readout device to measure internal temperature of digester

- Temperature sensors and readout device to measure inflow and outflow temperature of digester heat exchanger

CONSIDERATIONS

Location. Locate the digester as near the source of manure and as far from neighboring dwellings or public areas as practicable. Consider slope, distance of manure transmission, vehicle access, prevailing wind direction, proximity to hydrologically sensitive areas, and visibility for proper location. Locate the digester near a suitable site for energy utilization equipment. Minimize distances for the transmission of biogas through buried pipe. Locate the waste storage facility, considering elevation and distance from the digester, to take advantage of gravity flow.

Manure Characteristics. Consider using only fresh manure which has the highest energy content. The biogas yield from aged manure (generally less than 6 months old) is dependent on the biodegradation that has taken place during the storage period. Little biodegradation occurs when frozen. Manure stored in a warm, moist state could be significantly degraded resulting in reduced biogas production.

Chemicals and Amendments. Consider potential inhibitory effects on gas production of any antimicrobial agents in the manure or waste stream.

Waste Separation. Consider waste separation to prepare the waste stream for introduction to the anaerobic digester or for post-digestion treatment.

Collection/Mix Tank. Consider using a collection/mix tank to accumulate manure, settle and separate foreign material, pre-heat, and/or pre-treat influent waste to the appropriate total solids concentration. A volume of 1 to 3 days of manure collection, depending on the planned system management, is often used.

Overflow Protection. In case of digester equipment failure, consider designing the transfer system with the capability to bypass the digester, going directly to storage or land application equipment.

Digester Type. The type of digester selected may be affected by geographical location (Figure 3), energy considerations, wastewater properties, and other design considerations (Figure 4).

Digester Design. A digester operating fluid depth of 8 feet or greater is usually more economical for tank design. Tank dividers or flow separators may be utilized to increase efficiency and prevent short-circuiting. Install interior slopes as steep as permitted by soil properties and construction techniques.

Grounding and Cathodic Protection. Stray voltage, electrolysis and galvanic corrosion can damage pipes inside digesters. Consider the design requirements for electrodes and anodes.

Electrical Component Protection. Very small concentrations of biogas can corrode electrical hardware. Consider locating electrical controls in a separate room or building away from the digester and generator.

Temperature Maintenance: For the design include a means of maintaining the digester within acceptable operating temperature limits, use insulation where appropriate.

Gas Transfer Pipe. Exposed pipe conveying flammable gas is generally painted yellow, per IAW ASME A13.1-2015.

Gas Collection Cover. In areas of extreme wind or excessive snow, consider installing structures to protect inflatable and floating digester covers from damage.

Air Quality. Recovering energy from the biogas may be a preferable alternative to flaring. This could reduce fossil fuel combustion and associated emissions, thereby reducing the net effect of greenhouse gases and improving air quality. Some energy recovery options, such as the use of internal combustion engines to convert biogas to energy, may also result in additional emissions of some air pollutants.

Gas Utilization. Investigate and select the most beneficial and economical use of the biogas energy. Sales of carbon credits may affect the manner of utilization. Depending on the design and climate, digesters may require more than 50 percent of the biogas heat value to maintain the design temperature in the winter. Digesters can be heated by hot water from boilers burning biogas or by heat recovery from internal combustion engines and micro turbines burning biogas for power generation.

Effluent Tank. Due to the potential use of digested separated solids for bedding or soil amendment consider utilizing an effluent tank to hold digester effluent for subsequent mechanical solid-liquid separation.

Siting and Vegetation. Analyze the visual impact of the digester within the overall landscape context and effects on aesthetics. Consider screening with vegetative plantings, landscaping, or other measures to alleviate a negative impact or enhance the view. In addition, vegetate disturbed areas as soon as possible.

Soil Properties. Consider soil properties such as texture, saturated hydraulic conductivity, flooding, slope, water table and depth, as well as limitations related to seepage, corrosivity, or compactability of soil material when designing and installing an anaerobic digester. Refer to local soil survey information and on-site soil investigations during planning.

Nutrient Availability. Consider the effects of digestion upon nutrient availability. Land application of digester effluent, compared with fresh manure, may have a higher risk for both ground and surface water quality problems. Compounds such as nitrogen, phosphorus and other elements become more soluble due to anaerobic digestion and therefore have higher potential to move with water.

PLANS AND SPECIFICATIONS

Prepare plans and specifications that describe the requirements for applying the practice according to this standard. As a minimum, include—

- Plan view of the system layout and location of livestock facilities, waste collection points, waste transfer pipe, digester, biogas utilization facilities, and digester effluent storage. Include utilities and structures on the site.
- Grading plan showing excavation, fill, and drainage, as appropriate.
- Materials and structural details of the digester, including all premixing tanks, inlets, outlets, pipes, concrete, pumps, valves, and appurtenances as appropriate for the complete system.
- Foundational requirements including preparation and treatment.
- Details of biogas collection, control, and utilization system including type of materials for pipe, valves, regulators, pressure gages, electrical power and interface as appropriate, flow meters, flare, utilization equipment, and associated appurtenances.
- Specify insulation, heat exchanger capacity, and energy requirements as appropriate for maintaining the digester operating temperature within acceptable limits.
- Provide a process flow diagram with the following design information:
    - Flow rates of influent, effluent, and biogas.
    - Design total and volatile solids content of influent and effluent.
    - Digester volume.
    - Hydraulic and solids retention times.
    - When applicable, heating system type and capacity, control, and monitoring.
    - Biogas production, including methane yield.
    - 12-month energy budget when applicable.
    - Safety features

OPERATION AND MAINTENANCE

Prepare an operation and maintenance plan for the operator.

As a minimum, include the following items in the operation and maintenance plan:

- Proper loading rates of the digester and total solids content of the influent.
- Accounting for the nutrient impact of all feedstock in the farm's nutrient management plan.
- Proper operating procedures for the digester.
- Estimates of biogas production, methane content, and potential energy recovery.
- Description of the planned startup procedures, normal operation, safety issues, and normal maintenance items.
- Alternative operation procedures in the event of equipment failure.
- Instructions for safe use and flaring of biogas.
- Digester and other component maintenance.
- Troubleshooting guide.
- Monitoring plan with frequency of measuring and recording digester inflow, operating temperatures,

biogas yield, and/or other information as appropriate.
- Maintain the internal temperatures for controlled temperature digesters as appropriate to the digester type and design. For mesophilic digesters maintain the temperature between 95 ºF and 104 ºF with an optimum of 100 ºF and daily fluctuation of digester temperature limited to less than 1 ºF.
- Design the digester with appropriate freeboard and overflow or automatic shutdown devices to prevent accidental spillage of effluent or discharge into the gas collection system.
- Establish and maintain emergency contact information for consultation with qualified experts.

Summary of Expert Opinions
Dr. Shane W. Rogers
September 10, 2021

1. **The lagoon and spray swine waste manure management system used at swine concentrated animal feeding operations (CAFOs) in North Carolina leads to negative environmental and public health consequences.**[1]

   A. The U.S. Environmental Protection Agency defines an Animal Feeding Operation (AFO) as one in which animals have been, are, or will be stabled or confined and fed or maintained for a total of 45 days or more in any 12-month period, and crops, vegetation, forage growth, or post-harvest residues are not sustained in the normal growing season over any portion of the lot or facility."[2] Concentrated Animal Feeding Operations (CAFOs) are generally identified as the largest of the AFO operations owing their potential for significant pollution. Large swine CAFOs are those operations that confine at least 2,500 swine weighing over 55 pounds, or that confine more than 10,000 swine weighing less than 55 pounds.[3]

   B. It takes about 24 to 29 weeks for a hog to reach an average market weight of 283 pounds from birth, including about 3 weeks to wean, 6 weeks in a nursery stage, and then 16 to 20 weeks for the finishing stage.[4] A typical finishing operation for Smithfield may have 2.5 sellouts (rotation of hogs) per year. To get from birth to 283 pounds in 200 days means that the hogs must gain weight rapidly; industry reports reflect average daily weight gains of as much as 1.95 pounds as of the year 2001.[5] This requires significant food and water intake, and with that comes significant manure production. Based on reported manure production characteristics, hogs produce multiple times more waste than humans. As shown in Table 1, a 283-pound finishing hog can be expected to produce on average about 1.67 gallons (13.8 pounds) of manure each day.[6]

   C. Most swine CAFOs in North Carolina, including (at present) the subject swine CAFOs, use a lagoon and spray system of manure waste management. There are three primary

---

[1] Swine CAFOs may also be referred to as industrial hog operations in some scientific literature.
[2] See https://www.epa.gov/npdes/animal-feeding-operations-afos
[3] According to the U.S. EPA regulatory definitions of Large CAFOs, Medium CAFOs, and Small CAFOs, swine AFOs that are smaller than this size threshold may also be designated a CAFO owing a manmade ditch or pipe discharge of manure or wastewater to surface water, if there is direct contact of animals with surface water that passes through the confinement area, or if the permitting authority finds an operation to be a significant contributor of pollutants. See https://www.epa.gov/npdes/npdes-afos-policy-documents-0 for more details.

sources of concern regarding pollution in this system that include the swine housing facilities, anaerobic lagoons, and spray application of swine wastes.

Table 1. Manure production characteristics of swine[7]

Life Stage	Animal size	Daily Manure Production		
	Pounds	Pounds	Gallons	Liters
Nursery	25	1.9	0.23	0.87
	40	3.0	0.37	1.40
Finishing	150	7.4	0.89	3.37
	180	8.9	1.07	4.05
	220	10.9	1.31	4.96
	260	12.8	1.55	5.87
	300	14.8	1.79	6.78
Gestating	300	6.8	0.82	3.10
	400	9.1	1.10	4.16
	500	11.4	1.37	5.19
Lactating	375	17.5	2.08	7.87
	500	23.4	2.78	10.5
	600	28.1	3.33	12.6

Animals housed in swine CAFOs continually defecate. As swine manure waste is produced in the swine houses, it falls, or is pushed through (by the animals), slots in the concrete floor into pits or flush lanes under the floor. Removal of manure waste from underfloor of the swine houses occurs 4-8 times per day (typical). This is accomplished by flushing the manure that accumulates under the slotted portion of the floors out to the lagoon using wastewater drawn from near the top of the anaerobic lagoon.

D. An anaerobic lagoon is an in-ground manure holding structure, commonly left uncovered and open to the air. The subject swine CAFO sites have historically relied on open lagoons to store manure. Aside from rain that may fall over the anaerobic lagoons, no additional water aside from that contained in swine manure is typically added to the lagoon - by design. The high waste load rapidly depletes oxygen, and thus decomposition of the waste occurs under anaerobic conditions. Anaerobic bacteria in well-functioning anaerobic lagoons break down and stabilize the organic fraction of materials. When this process is upset due to a number of potential factors such as overloading with wastes, solids accumulation and reduction of treatment volume, pH changes or other upsets, the stabilization process is greatly reduced or eliminated.

E. Anaerobic decomposition in anaerobic lagoons generates significant quantities of methane gas, carbon dioxide, ammonia, nitrous oxide, and other noxious gases that are emitted to the atmosphere along with other pollutants. Methane, a greenhouse gas, is a

[7] Source: Midwest Plan Service, 2004 Manure Characteristics, MWPS-18 Section 1, Second Edition, Jeff Lorimor, Wendy Powers, and Al Sutton (eds.). Manure Management Systems Series, Iowa State university, Ames, IA.

significant component of the biogas produced during anaerobic decomposition.[8] The quantity of ammonia nitrogen emitted is also large and of concern.[9] Its uncontrolled emission reduces the nitrogen content of the waste and poses a risk to the environment and public health. It has been estimated that 80-90% of the total ammonia emitted from livestock operations is redeposited uncontrolled within 10 km of the source, while the remainder is dispersed into the atmosphere contributing to the haze, acid rain, acidification of terrestrial and aquatic ecosystems, and eutrophication of surface water bodies.[10]

F. Swine manure wastes are held, exposed to the atmosphere, in anaerobic lagoons until such time they can be applied to land. Land application of manures is permitted in North Carolina so long as it is done in accordance with a certified animal waste management plan (CAWMP). The purpose of the CAWMP is to assure that manure is applied at a rate to meet, but not exceed, the nutrient requirements of the crop to receive the manure as a nutrient source. In general, CAWMPs consider application history and nutrients contents of the soil, nutrient content of manure, infiltration rates and application equipment used (effect on nutrient delivery to the plants), and land area over which the crop(s) will be grown. Like for most swine CAFOs in North Carolina, the subject swine CAFO sites are permitted to apply their manure waste at an agronomic rate for nitrogen. This does not assure that overapplication of phosphorus, an important nutrient that affects water quality, does not occur. It also does not assure that nitrogen and other pollutants in swine manure do not affect nearby water quality.

Available at http://www.hsi.org/assets/pdfs/farming_climate_impact.pdf (page 7 – "Storing and disposing vast quantities of manure can produce anthropogenic methane and nitrous oxide emissions. According to the Pew Center on Global Climate Change, farm animal manure management currently accounts for 25% of agricultural methane emissions in the United States and 6% of agricultural nitrous oxide emissions. As noted above, methane has 23 times the GWP of carbon dioxide, and its concentrations have increased by approximately 150% since 1750. Globally, farm animals are the most significant source of anthropogenic methane, responsible for 35-40% of methane emissions worldwide."

[9] See for example Szögi, A.A. and M. B. Vanotti (2007) Abatement of Ammonia Emissions from Swine Lagoons Using Polymer-Enhanced Solid-Liquid Separation, *Applied Engineering in Agriculture*, 23(6): 837-845; these authors measured for one anaerobic lagoon ammonia emissions of 13,633 kg /ha/yr. See also Kupper. T., C. Häni, A. Neftel, C. Kincaid, M. Bühler, B. Amon, A. Vanderzaag (2020) Ammonia and greenhouse gas emissions from slurry storage – A review, Agriculture, Ecosystems and Environment, 300: 106963; these authors report from a sample of 40 reports of ammonia emissions measurements from swine waste anaerobic lagoons an average emission of 13,000 kg-N/ha/yr. See also Aneja, V.P., S.P. Arya, D.-S. Kim, I.C. Rumsey, H.L. Arkinson, H. Semunegus, K.S. Bajwa, D.A. Dickey, L.A. Stefanski, L.Todd, K.Motlus, W.P. Robarge, C.M. Williams (2008) Characterizing Ammonia Emissions from Swine Farms in Eastern North Carolina: Part 1 – Conventional Lagoon and Spray Technology for Waste Treatment, Journal of the Air & Waste Management Association, 58:1130-1144 ; these authors report ammonia emissions from three anaerobic lagoons were temperature dependent, ranging from as low as 2.2 kg-N/ha/d in the winter to as great as 57.8 kg-N/ha/d in the summer. See also Nkoa. R. (2014) Agricultural benefits and environmental risks of soil fertilization with anaerobic digestates: a review, *Agronomy for Sustainable Developmen*t, Springer Verlag/EDP Sciences/INRA, 34 (2):473-492. 10.1007/s13593-013-0196-z hal-01234816; on page 480 - "NH_3 emission inventories from several countries have shown that agriculture produces approximately 90% of the total emission of NH_3 to the atmosphere."

[10] See Nkoa. R. (2014) Agricultural benefits and environmental risks of soil fertilization with anaerobic digestates: a review, *Agronomy for Sustainable Developmen*t, Springer Verlag/EDP Sciences/INRA, 34 (2):473-492. 10.1007/s13593-013-0196-z hal-01234816, page 481.

G. When anaerobic manure lagoon effluents and solids are land-applied, nutrients, oxygen-demanding materials, metals, odors, particulates, endotoxins, bacteria, ammonia, and other harmful pollutants are released into the environment. Ammonia and other pollutants emitted to the atmosphere can move downwind or deposit uncontrolled onto land, physical structures, or waterbodies nearby. Land-applied pollutants can run off from fields in surface drainages, move via groundwater, or through tile drainage flows to affect water quality.[11] In a recent study of the U.S. Geological Survey, an overall measurable effect of swine CAFO waste manures on stream water quality in watersheds containing swine CAFOs was reported. Land application of waste manure at swine CAFOs influenced ion and nutrient chemistry in many of the North Carolina Coastal Plain streams that were studied, and the effect was directly related to higher swine barn densities and (or) higher total acres available for applying waste manure at swine CAFOs.[12]

H. In a lagoon and spray system, including the system permitted for the subject swine CAFOs, waste application is typically completed using methods of application that spray waste through the air, for example, using a pump and reel or center pivot spray applicator. Less frequently, operators may choose to use alternative application techniques such as low height or drag hose spreading or injection. The operators at the subject swine CAFOs use a combination of spraying waste and drag hose spreading.

I. Spraying swine manure through the air results in significant ammonia emissions. Direct injection of manure, such as can be accomplished with Aerway spreaders, is one alternative to spray irrigation that can reduce potential for off-site transport of harmful pollutants in manures or anaerobic digester effluents. Reduction in hydrogen sulfide emissions is estimated to be between 50-75%, but there may be a slight increase in greenhouse gas emissions (up to 10%) owing a slight increase in nitrous oxide emissions from decomposition by soil microbes. Injection also results in greater preservation of nutrients (up to 90% reduction in ammonia volatilization compared to spray application), which reduces the amount of anaerobic lagoon effluent that must be applied to land to meet crop nutrient requirements. Lower mass of anaerobic lagoon effluent applied per land area means less pollutant loading and emissions.

2. **Well-designed anaerobic digestion technologies for swine manure treatment can reduce select environmental pollution and public health risks of concern relative to anaerobic lagoons, but may exacerbate others.**

   A. Anaerobic digestion is a rapidly growing technology for farm waste management in the United States. The process of anaerobic digestion uses microbes to produce biogas, which is a mixture of methane, carbon dioxide, and trace gases. While anaerobic digestion occurs in an anaerobic lagoon, an anaerobic digester differs in that it is covered with an impermeable material rather than left open to the atmosphere and it is not exposed to diluting rainfall. Because anaerobic digesters are covered, the methane, a powerful greenhouse gas with high emissions from anaerobic lagoons, is captured rather than emitted to the atmosphere, thus reducing emissions that contribute to global warming. Owing the absence of diluting rainwater and other efficiencies, anaerobic digesters are more efficient at waste decomposition than anaerobic lagoons. Gas capture in anaerobic digesters may also reduce the amount of pathogens in the waste.

   B. Nutrients in manure are conserved during anaerobic digestion, but are converted to more readily available and mobile forms with higher potential to move with water.[13] Organic nitrogen is converted to ammoniacal nitrogen, which is not only inhibitory of the anaerobic digestion process, but can also result in higher ammonia emissions during subsequent storage if left uncovered, and during land application if not incorporated when applied.[14] For example, relative to anaerobic lagoons, ammonia emissions from anaerobically digested swine manure stored in open lagoons in one study increased by 46%. This was hypothesized to be caused by reduced methanogenesis and its reduced effect on the chemical conversion of ammonium to dinitrogen gas.[15]

[13] See United States Department of Agriculture - Natural Resources Conservation Service, Conservation Practice Standard: Anaerobic Digester, Code 366, October 2017, 10 p. On page 6: "Consider the effects of digestion upon nutrient availability. Land application of digester effluent, compared with fresh manure, may have a higher risk for both ground and surface water quality problems. Compounds such as nitrogen, phosphorus, and other elements become more soluble due to anaerobic digestion and therefore have higher potential to move with water."

[14] See Westerman, P., M. Veal, J. Cheng, and K. Zering "Biogas Anaerobic Digester Considerations for Swine Farms in North Carolina" North Carolina State University, A&T University Cooperative Extension, 8 p.; See also Aguirre-Villegas, H., R.A. Larson, M.D. Ruark (2016) Dairy Anaerobic Digestion Systems and their Impact on Greenhouse Gas and Ammonia Emissions, Sustainable Dairy Fact Sheet Series, University of Wisconsin Extension, 5 p. See also Kupper. T., C. Häni, A. Neftel, C. Kincaid, M. Bühler, B. Amon, A. Vanderzaag (2020) Ammonia and greenhouse gas emissions from slurry storage – A review, Agriculture, Ecosystems and Environment, 300: 106963; p. 1 "Anaerobically digested slurry shows higher emissions during storage for NH_3 while losses tend to be lower for CH_4 and little changes occur for N_20 and CO_2 compared to untreated slurry. All cover types are found to be efficient for emission mitigation of NH_3 from stores."

[15] Harper, L. T.K. Flesch, K.H. Weaver, J.D. Wilson (2010) The effect of Biofuel Production on Swine Farm Methane and Ammonia Emissions, Journal of Environmental Quality, 39:1984-1992. In the abstract on pg 1984: "NH_3 emissions in the biofuel farms increased by 46% over the conventional farms. These studies show that what is considered an environmentally friendly technology had mixed results and that all components of a system should be studied when making changes to existing systems."

3. **Subject swine CAFO characteristics as currently operating and with modifications to the waste treatment system: minimal changes in the permits and certificates of coverage are not protective of air and water quality.**

A. Thousands of Smithfield hogs are being kept in each of the subject swine CAFOs as summarized in Table 2, along with the number and types of anaerobic lagoons at each site. Each of the subject swine CAFOs currently employ the lagoon and spray system of swine manure management. The subject swine CAFOs' irrigation records indicate that the predominant method of waste application is spraying using pump and reel and center pivots.[16] Murphy-Brown has indicated that there is also some limited use of drag hoses at these sites. Table 3 presents the basic characteristics of the proposed anaerobic digestion systems for each subject swine CAFO.

Table 2. Production characteristics and anaerobic lagoon characteristics of the subject swine CAFOs[17]

Facility	Operation type	Permitted hog counts	Number and type of anaerobic lagoons
Benson	Feeder to finish	6,120	One single stage
Goodson 2037/2038	Feeder to finish	20,992	One single stage and one 2-stage (primary and secondary)
Kilpatrick	Wean to Finish	13,336	One 2-stage (primary and secondary)
Merritt	Wean to Finish	5,083	One single stage
M&M	Wean to finish	12,308	Three single stage

Notes: Permitted hog count is the allowable annual average count calculated pursuant to the permit, not the number of hogs present at any particular time.

Table 3. Lagoon characteristics at each of the subject swine CAFOs[18]

[16] Data acquired from the most recent irrigation design plans provided including Benson: MB000788; Goodson 2037/2038: MB000127; Kilpatrick & Merritt: MB001143; M&M: MB001851. Document identification is by the first page number of the document.

[17] Data acquired from lagoon design information provided including Benson: MB000741; Goodson 2037/2038: MB000092 and MB000085; Kilpatrick & Merritt: MB001092 and MB001104; and M&M: MB001733, MB001741, and MB001748.

[18] Data acquired from the most recent nutrient utilization plans (NUPs), anaerobic digester permit applications, and permits or certificates of coverage issued by the DEQ provided for each of the subject swine CAFOs. These include (i) NUPs: Benson: MB000798; Goodson 2037/2038: MB000160 and MB000179; Kilpatrick: MB001154 and MB001184; M&M: MB001836; (ii) Permit / COC applications: Benson: MB000667; Goodson 2037/2038 MB000001; Kilpatrick: MB001016; M&M: MB001632; and (iii) DEQ Permits / COCs: Benson: MB000720; Goodson 2037/2038: MB000065; Kilpatrick: MB001090; M&M: MB001730 and MB001711. Note that the "MBXXXXXX" document identification is by the first page number of the document.

Facility	Proposed Anaerobic Digester (AD) Size *gallons*	New AD Construction or New anaerobic digester or Lagoon Cover	Proposed number of anaerobic digestate storage lagoons
Benson	1,693,156	New	One single stage, soil improved or clay lined
Goodson 2037/2038	5,044,114	New	One 2-stage, clay lined
Kilpatrick	9,121,716	Cover	One single stage, synthetically lined
Merritt	NA	NA	NA
M&M	2,672,790	New	One single stage synthetic, two single stage clay lined

NA = not applicable. Note that an anaerobic digester will not be installed to serve the Merritt farm, which will continue to be served by the existing single stage lagoon.

B. Reviewing the permit applications and permits issued by the North Carolina Department of Environmental Quality, it is evident that some discrepancies exist. For example, the DEQ issued permit for the Benson Farm indicates that one existing clay-lined lagoon will be used to store anaerobic digester effluent, whereas the permit application submitted by Cavanaugh & Associates on behalf of Smithfield Foods identifies the lagoon having a soil improved liner rather than a clay liner.[19] While investigation of historical satellite imagery catalogued on Google Earth could not reveal such detail, it does reveals an interesting feature of the lagoon, what looks to be a divide running through the center, the reduced volume for which is not reflected in the lagoon design information provided by Smithfield, and dated December 17, 2008.[20] Satellite imagery reported in Figure 1 dating from February 1998 through July 2018 clearly show a divide that is deep enough to affect water quality differences from one side of the lagoon to the other. Other discrepancies between permit applications and actual lagoon liner details for Goodson 2037/2038 and M&M Waters & Riverbank exist, but were corrected in the final permits.

[19] Compare the DEQ issued Permit no. AWI310039 dated March 31, 2021 (MB000720), page 3: "…consisting of a 1,693,156 gallon synthetically lined anaerobic digester with an 80 mil HDPE synthetic cover, one existing clay lined lagoon, one influent pump station…") to the permit application stamped MB000667 and dated 12-19-19, page 2, which identifies the existing lagoon having a soil improved liner.

[20] See the Benson Farm Anaerobic Waste Lagoon Design document dated 12/17/08 (starting on MB000741).

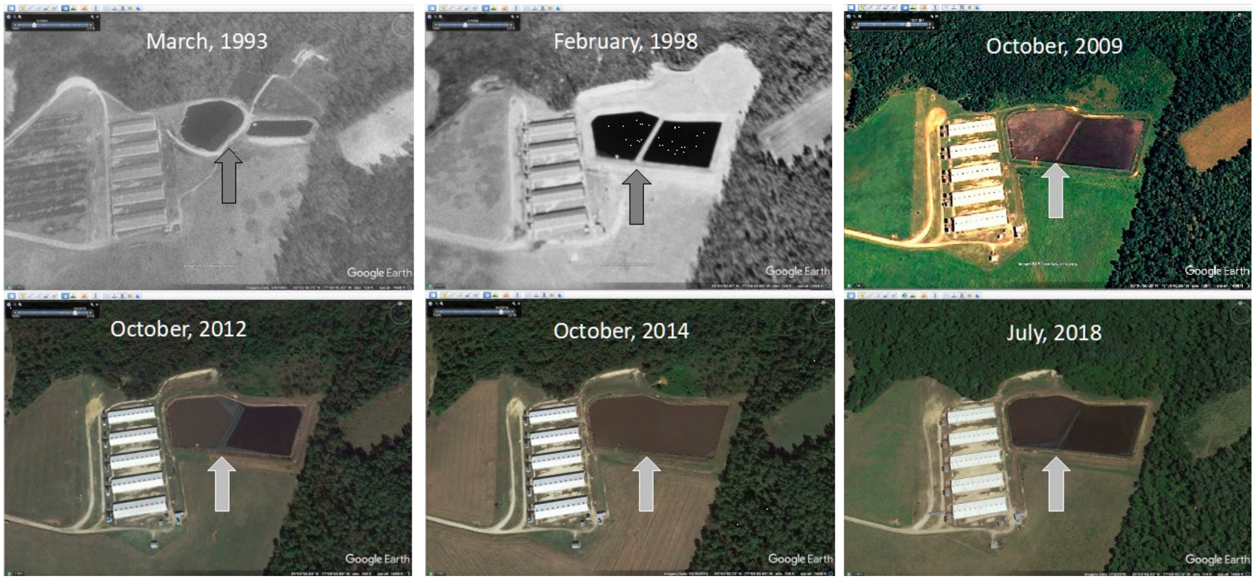

Figure 1. Google Earth historical satellite imagery of the Benson swine CAFO anaerobic lagoon showing a divide in the lagoon center (see February 1998) that roughly correlates to a historic drive (see March 1993), and which is large enough to also be visible and cause water quality differences between the two sides of the lagoon as seen in the subsequent images. This divide is not accounted or in the calculation of the lagoon design volume as reported in in documents provided by Smithfield (see Benson Lagoon Design, dated December 17, 2008 and identified MB000741 on page 1).

C. Permits in North Carolina prohibit siting of the swine CAFO housing units and waste treatment systems in the 100-year flood plain; the same is not true for swine manure application areas. These areas are subject to increased risk of leaching manure pollutants into the waters of North Carolina during and following rainfall. Figure 2 shows satellite imagery of the Goodson 2037 and 2038 swine CAFO and spray fields. As can be seen in the image to the left of this figure, the 100-year flood plain intersects portions of spray fields at this swine CAFO. Historical satellite images suggest that these spray irrigation fields are subject to flooding.

Figure 2. Satellite imagery of the Goodson 2037 / 2038 swine CAFO and manure spray fields. Left: overlay of the 100-year flood plain and the irrigation system map reveals spray irrigation of swine manure occurs in areas subject to flooding, increasing runoff potential of manure pollutants. Right: Historical satellite images from Google Earth reveal recurrent saturation of spray fields within the 100-year flood plain.

D. The permits issued by the North Carolina State Department of Environmental Quality authorize the waste treatment systems of the subject swine CAFOs to change; however, the permits included very few substantive changes to accommodate the new anaerobic digestion waste treatment systems, even though the new technology can alter the waste composition and nutrients as described above. The subject swine CAFOs must continue to monitor their manure wastes as usual and adjust application rates based upon either total nitrogen or total Kjeldahl nitrogen results. Notably, increased ammonia volatilization from lagoon storage of anaerobically digested manure may increase uncontrolled air emissions of ammonia nitrogen, reducing the nitrogen content of the waste to be applied, and allowing for increased concentration of waste application considering that crop nutrient requirements will not change. Owing to changes in the form of the nutrients, increased mobilization may occur. The permits issued for Goodson 2037 & 2038 and Benson swine CAFOs mandate two years of quarterly monitoring and reporting of influent and effluent total nitrogen, total Kjeldahl nitrogen, nitrate nitrogen, ammonium nitrogen, total phosphorus, copper, sulfur, zinc, and fecal coliform bacteria. The nutrient management plans must be modified as needed based on performance of the anaerobic digestion system, and if performance is not as predicted, immediate measures must be taken. Regardless, these measures will only monitor changes in composition at the source. Notably, permits for swine CAFOs in North Carolina, including the four at issue here, do not generally require monitoring of nearby groundwater, surface water, or air emissions to detect potentially increased pollutant mobilization, and thus associated air and water quality degradation by such changes will go undocumented and unaddressed.

E. Other changes in the permits or Certificates of Coverage are not clearly related to changes in the swine manure waste treatment technology. For example, changes in the Certificate of Coverage at the Kilpatrick & Merritt and the permit for Benson swine CAFOs include a directive to review the facilities' CAWMP with respect to land application areas in landscape positions that are in close proximity to public roads, dwellings, and wells, and provide within 180 days a report to the division to describe what, if any, additional BMPs are to be implemented in these areas to improve protections and further reduce risk of off-site impacts. Nothing more is required than a paper exercise. The permit for the Benson swine CAFO also includes a mandate to limit application on fields with a high phosphorus loss assessment rating to crop nutrient requirements for phosphorus, and restricts swine manure application on fields with very high phosphorus loss assessment rating.

4. Biogas-compatible technologies that could mitigate environmental impacts from the subject swine CAFOs by decreasing nutrients in land-applied waste and reducing ammonia emissions are available.

A. Considerable progress has been made in manure treatment technology development in the last 24 years. There are several technologies readily available and in development that can reduce significantly gaseous emissions from anaerobically digested swine CAFO manure. At a basic level, impermeable covers could be installed on the lagoons that will store anaerobic digestate and reduce ammonia volatile losses from the lagoon by nearly 90%.[21] Volatile losses of ammonia can be reduced 70-90% upon application by injection of the anaerobically digested swine manure waste into the ground rather than spray applying. Conservation of the nitrogen in the manure rather than emission into the atmosphere can reduce nearby effects of uncontrolled ammonia deposition as well as public health risks.

B. Other treatment technologies are also available and currently used at other swine CAFO operations that can remove or recover nutrients, significantly reducing environmental and public health risks. One high achieving set of developments stemmed from the Super Soils / Terra Blue technology developed in North Carolina under the Smithfield Agreement.[22] Since that time, advancements from the research group have included development of more efficient two-stage and then one-stage ANAMMOX bioreactors to replace nitrification/denitrification and gas permeable membranes to recover ammonia and phosphate minerals from swine wastewater.[23] An advanced waste treatment technology developed in a joint venture with Embrapa (Brazil) known as Sistrates has successfully implemented the Terra Blue technology with anaerobic digestion at a 9,500 head swine CAFO in Brazil.[24] Swine waste anaerobic digestion-compatible membrane separations technologies have also matured, such as that of Digested Organics LLC which can recover nutrients in higher value streams and simultaneously produce water of sufficient quality for livestock.[25]

5. Conclusion.

A. For all of the reasons stated above, it is my opinion, within a reasonable degree of scientific certainty, that the anaerobic digestion systems to be implemented at the subject swine CAFOs are more likely than not to exacerbate ammonia emissions relative to the current anaerobic lagoon and spray system. Resulting unregulated emissions and

Life Cycle Environmental Impacts of Electricity from Biogas Produced by Anaerobic Digestion

*Alessandra Fusi[1], Jacopo Bacenetti[2], Marco Fiala[2] and Adisa Azapagic[1]**

[1] Sustainable Industrial Systems, School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester, UK, [2] Dipartimento di Scienze Agrarie e Ambientali – Produzione, Territorio, Agroenergia, Università degli Studi di Milano, Milan, Italy

The aim of this study was to evaluate life cycle environmental impacts associated with the generation of electricity from biogas produced by the anaerobic digestion (AD) of agricultural products and waste. Five real plants in Italy were considered, using maize silage, slurry, and tomato waste as feedstocks and cogenerating electricity and heat; the latter is not utilized. The results suggest that maize silage and the operation of anaerobic digesters, including open storage of digestate, are the main contributors to the impacts of biogas electricity. The system that uses animal slurry is the best option, except for the marine and terrestrial ecotoxicity. The results also suggest that it is environmentally better to have smaller plants using slurry and waste rather than bigger installations, which require maize silage to operate efficiently. Electricity from biogas is environmentally more sustainable than grid electricity for seven out of 11 impacts considered. However, in comparison with natural gas, biogas electricity is worse for seven out of 11 impacts. It also has mostly higher impacts than other renewables, with a few exceptions, notably solar photovoltaics. Thus, for the AD systems and mesophilic operating conditions considered in this study, biogas electricity can help reduce greenhouse gas (GHG) emissions relative to a fossil-intensive electricity mix; however, some other impacts increase. If mitigation of climate change is the main aim, other renewables have a greater potential to reduce GHG emissions. If, in addition to this, other impacts are considered, then hydro, wind, and geothermal power are better alternatives to biogas electricity. However, utilization of heat would improve significantly its environmental sustainability, particularly global warming potential, summer smog, and the depletion of abiotic resources and the ozone layer. Further improvements can be achieved by banning open digestate storage to prevent methane emissions and regulating digestate spreading onto land to minimize emissions of ammonia and related environmental impacts.

INTRODUCTION

The need to mitigate climate change and improve security of energy supply is driving a growing interest in renewable energy sources, with many world regions and countries setting ambitious targets. For example, the EU directive on the promotion of the use of energy from renewable sources (EC, 2009) sets the target of achieving a 20% share of energy from renewable resources by 2020, including biogas produced by anaerobic digestion (AD) of agricultural feedstocks.

Production of biogas is expanding rapidly in Europe. According to EurObserv'ER (2014), about 13.4 million ton oil equivalent (Mtoe) of biogas primary energy was produced in the EU during 2013, a 10% increase on the 2012 levels. Germany is the largest producer of biogas, not only in Europe but also in the world. In 2013, it had 7874 AD plants with a total installed electrical capacity of 3384 MW, which generated 27 TWh/year (EurObserv'ER, 2014; Fuchsz and Kohlheb, 2015). By comparison, the second largest world producer – China – generates just over one-quarter of that (7.6 TWh/year in 2009) (Chen et al., 2012). Italy follows closely in third place at 7.4 TWh of electricity per year produced by 1300 AD plants with a total installed capacity of 1000 MW (Brizzo, 2015). The plants are fed largely with maize grown specifically for this purpose, which in Italy occupies 10% of the total maize cultivation area (1,172,000 ha) (Casati, 2011). However, this is still only half the area in Germany (2,282,000 ha) where it covers one-third of the total maize land (Dressler et al., 2012).

The rapid expansion of biogas production in Europe is largely due to the feed-in-tariffs (FiT) schemes available in 29 countries (Whiting and Azapagic, 2014). For example, electricity generators in Italy using biogas produced in AD plants smaller than 1 MW are paid €280/MWh generated. In the UK, the subsidies are significantly lower, ranging from €130 to 210/MWh, depending on the plant size (Whiting and Azapagic, 2014). This perhaps explains why the deployment of AD was initially slower than in Italy, with only 180 AD plants installed so far, but with a further 500 projects currently under development (NNFCC, 2015). However, the FiT scheme in Italy has recently been changed, reducing the subsidy for electricity by 15–30% and introducing payments for utilization of heat and other coproducts (Ministero dello Sviluppo Economico, 2012). In the US, the growth of biogas production has also been slower than elsewhere, with only 244 AD plants currently in operation (Ebner et al., 2015); this is largely due to the absence of adequate subsidies.

Biogas produced by AD is considered to have a high saving potential with respect to greenhouse gas (GHG) emissions (EC, 2009). However, beyond that, other environmental implications of biogas production are still unclear despite quite a few life cycle assessment (LCA) studies having been carried out. This is due to several reasons. First, most previous studies of biogas have either focused on climate change or considered a limited number of impacts; for a summary, see **Table 1**. As far as the authors are aware, out of 26 studies found in the literature, only five have considered a full suite of impacts normally included in LCA studies, two of which are based in the UK (Mezzullo et al., 2013; Whiting and Azapagic, 2014), one in Argentina (Morero et al., 2015), one in Italy (Pacetti et al., 2015), and one in China (Xu et al., 2015). It is also apparent from **Table 1** that the goal, scope, life cycle impact assessment (LCIA) methodology, feedstocks, and geographical regions covered by the studies vary widely. Most studies are based in Europe with several in China and one each in Argentina, Canada, and the US. All plants have a capacity below 1 MW, with the majority being around 500 kW (where reported); some are electricity only and others combined heat and power (CHP) installations. Most studies have excluded the impacts of constructing and decommissioning the AD and power plants. Maize is the most commonly considered feedstock, followed by animal slurry. The functional unit is largely based either on a unit of feedstock used to generate biogas or a unit of energy (biogas, heat, or electricity). Most studies have relied on secondary foreground data to estimate the impacts or used only limited primary data. However, the greatest variation among the studies is found in the number of impacts considered and the methodologies used to estimate them. The former range from 1 to 18 and the latter cover almost all known LCIA methods, including EcoIndicator 99 (Goedkoop and Spriensma, 2001), CML 2001 (Guinée et al., 2002), Impact 2002+ (Olivier et al., 2003), and ReCiPe (Goedkoop et al., 2009). These and the other differences, including the credits for coproducts, have led to very different results among the studies, making it difficult to compare them, and draw any generic conclusions on the environmental sustainability of biogas.

This study aims to make further contributions to the discussion on the environmental sustainability of biogas. The paper considers life cycle environmental impacts of electricity generation in five real AD-CHP systems using biogas produced from differing mixes of four types of feedstock. The plants are situated in Italy. The novel aspects of the work compared to previous studies include:

- estimation of impacts associated with electricity generated from biogas using different feedstocks, including dedicated maize crops, their mixture with animal slurry, and agricultural waste as well as a mixture of slurry and waste;
- use of primary data for both the feedstock production and operation of the AD-CHP systems;
- consideration of the influence of different scales of the AD-CHP systems on the environmental impacts;
- inclusion of construction and decommissioning of AD and CHP plants;
- estimation of the avoided emissions from using the digestate instead of slurry as fertilizer; and
- comparison of impacts with grid electricity, natural gas, and renewable sources of electricity.

MATERIALS AND METHODS

The environmental impacts of biogas electricity were estimated using LCA as a tool. The study was carried out in accordance with the ISO 14040/44 methodology for LCA (ISO, 2006a,b). The systems were modeled using Gabi LCA software V6.11 (Thinkstep, 2015). The CML 2001 method (Guinée et al., 2002), April 2013 update, was followed to estimate the following 11 impacts considered in this method: abiotic depletion potential of elements (ADP elements), abiotic depletion potential of fossil fuels (ADP fossil), acidification potential (AP), eutrophication potential (EP), freshwater aquatic ecotoxicity potential (FAETP), global warming potential (GWP), human toxicity potential (HTP), marine aquatic ecotoxicity potential (MAETP), ozone layer depletion potential (ODP), photochemical oxidants creation potential (POCP), also known as summer smog, and terrestrial ecotoxicity potential (TETP). For further details on the estimation of the impacts, see Supplementary Material.

The next sections detail the goal of the study, the assumptions, and data used in the study.

Goal and Scope of the Study

The main goal of the study was to estimate the environmental impacts of electricity generated by different AD-CHP systems utilizing maize silage and agricultural waste. The results were compared with electricity from the grid, natural gas, and different renewables to help evaluate the environmental sustainability of biogas electricity relative to other available options.

Five real AD-CHP systems were considered using differing combinations of the following feedstocks: maize and maize ear silage; pig and cow slurry; and tomato peel and seeds (**Table 2**). The volume of the AD digesters ranged from 1650 to 2750 m^3 and the installed electrical capacity of the CHP plants from 100 to 999 kW. The plants are located at farms producing the feedstocks in Lombardy in Northern Italy, where the majority of the country's biogas plants are situated (Negri et al., 2014).

As indicated in **Figure 1**, the scope of the study was from "cradle to grave," including:

- production of maize silage (where used), comprising cultivation, transport from fields to the farm (1 km), and the ensiling;
- collection of slurry and tomato waste and delivery to the AD plants;
- construction and decommissioning of AD and CHP plants;
- production of biogas in the AD plants and its treatment (filtration, dehumidification, and desulfurization);
- cogeneration of electricity and heat in the CHP plants; the heat, except that used for heating the digesters, is considered as waste as it is not used;
- storage and subsequent use of digestate as fertilizer; note that all plants but no. 2 use open storage of digestate.

Electricity distribution and consumption were excluded from the system boundary.

The functional unit was defined as "generation of 1 MWh of electricity to be fed into the grid." Although heat is cogenerated with electricity, all the impacts were allocated to the latter as the excess heat not utilized in the system is discharged as waste.

Inventory Data

Feedstock Production

The inventory data for the production of maize silage are detailed in Tables S1 and S2 in Supplementary Material. As indicated in the tables, data for field operations were collected directly from the farms. The background data were sourced from Ecoinvent (Nemecek and Kägi, 2007) and modified to match the characteristics of the machinery used for maize cultivation in Lombardy, based on information in Bodria et al. (2006). No environmental impacts were considered for tomato waste and slurry as they are waste.

Ammonia and nitrous oxide emissions as well as nitrate leachates from the application of the digestate and urea as fertilizers were estimated according to Brentrup et al. (2000). Phosphate leachates and run-offs were calculated based on Nemecek and Kägi (2007). To estimate pesticide emissions to the environment, several factors need to be considered, such

TABLE 2 | Summary of the main characteristics of the AD-CHP plants considered in the study.[a]

Plant	Feedstock	Volume of AD digesters (m^3)	Dry matter content in digesters (%)	Organic loading in digesters (kg/day m^3)	Methane content in biogas (%)	Installed CHP power (kW)	Electricity generation (MWh/year)	Electricity consumption (MWh/year)	Heat generation (MWh/year)	Heat consumption by AD (MWh/year)

as the way in which a pesticide is applied, the soil type, and the meteorological conditions during application (EMEP/EEA, 2013). However, considerations of these parameters is often impractical in LCA studies due to a lack of detailed data (Milà i Canals, 2007). Thus, pesticide emissions to air, water, and soil were determined in accordance with Margni et al. (2002) and Audsley (1997), assuming the following partitioning of the active pesticide components: 85% of the total amount applied remains in the soil, 5% in the plant, and 10% is emitted into the atmosphere; furthermore, 10% of the applied dose is lost as a run-off from the soil into the water. This method is also recommended for use by Curran (2012) and was applied in some other LCA studies [e.g., Boschiero et al. (2014), Falcone et al. (2015), and Fantin et al. (2015)].

Land use change was not considered as the maize feedstock is grown on land previously used to cultivate cereals.

The transport and packaging of pesticides and fertilizers were not included in the system boundaries because of a lack of data. This is not deemed a limitation as some other studies found that their contribution was insignificant [e.g., Cellura et al. (2012)].

AD and CHP Plants

In all the AD plants evaluated in this study, the digestion takes place in continuously stirred reactors under mesophilic conditions at a temperature of 40°C (±0.2°C), which is controlled and monitored continuously. Therefore, the digesters are operated at the top end of the temperature scale, which for mesophilic digestion ranges from 30 to 40°C (Weiland, 2010). The digesters are made from iron-reinforced concrete and have an expanded polyurethane external insulation. The biomass is fed into the digesters every 90 min in small amounts and heated using the heat generated by the adjacent CHP. As indicated in **Table 2**, the dry matter content in the digester varies from 8.5 to 10.6%, and the organic loading rate from 0.58 to 3.4 kg/day m^3. The biogas composition is similar across the plants with the methane content ranging from 52 to 56% of the biogas volume.

The biogas is stored on top of the digesters in a gasometer dome with a spherical cap. Before being fed into the CHP plant, the biogas is filtered through a sand filter, dehumidified in a chiller, and then desulfurized using sodium hydroxide (NaOH). NOx emissions are controlled by a catalytic converter. The digestate is pumped from the bottom of the digesters and stored in open tanks in all the plants except for Plant 2, where it is stored in a covered tank.

The biogas is fed into the CHP plant to generate electricity and heat. Electricity is sold to the national grid while the heat is used for heating the digesters and the excess is dissipated by fan-coolers. The electricity consumption for operating the AD plants is sourced from the national grid to ensure continuous operation during the CHP downtimes. The amount of electricity used by the system ranges from 8.5 to 11% of the total electricity generated (**Table 2**).

Detailed inventory data for the AD and CHP plants can be found in **Tables 2** and **3**. The operational data (feedstock production, consumption of electricity and heat, electricity generation) were obtained from the owners. Chemical characterization of different types of feedstock and their biogas production potentials were determined by laboratory tests (Fiala, 2012; Negri et al., 2014; Bacenetti et al., 2015) and used to calculate the biogas production by the AD plants. The emissions from the CHP plants were calculated based on NERI (2010). The useful lifetime of the AD plants was assumed to be 20 years (Nemecek and Kägi, 2007). For the CHP plants, the lifespan is shorter, between 8 and 10 years because of the high content of hydrogen sulfide (Fiala, 2012). At the end of a plant's useful lifetime, its construction materials were assumed to be landfilled, except for plastic materials, which were incinerated; the influence on the impacts of recycling is explored in a sensitivity analysis later in the paper.

The background data on the construction materials, their transport (120 km by rail and 35 km in 20–28 ton trucks) and landfilling were sourced from the Ecoinvent database v2.2 (Ecoinvent, 2010). Since the data for construction materials for the AD and CHP plants in Ecoinvent correspond to a different plant size (300 m^3 for the AD and 160 kW$_{el}$ for the CHP plants), the environmental impacts from their manufacture were estimated by scaling up or down their capacity to match the sizes of the AD and CHP plants considered in this study. This was carried out following the approach used for cost estimation in scaling up process plants (Coulson et al., 1993) but instead of costs, estimating environmental impacts as follows (Whiting and Azapagic, 2014):

$$E_2 = E_1 \cdot (C_2 / C_1)^{0.6} \tag{1}$$

where E_2 environmental impacts of the larger plant (AD or CHP); E_1 environmental impacts of the smaller plant (AD or CHP); C_2 capacity of the larger plant (volume for the AD plant and installed power for the CHP plant); C_1 capacity of the smaller plant (volume for the AD plant and installed power for the CHP plant); 0.6 scaling factor.

Digestate Use and Methane Emissions Credits

In all the plants except no. 4, the digestate is used as fertilizer on the farms, replacing pig or cow slurries applied previously as part of a traditional slurry management method (see **Figure 2**). Both digestate and the slurry from Plants 1, 3, and 5 are stored in open tanks before application, during which they emit methane. However, the emissions from digestate are lower than from slurry storage (Amon et al., 2006; Wang et al., 2014), and the AD systems were credited for the avoidance of the emissions. Note that in Plant 2, the digestate is stored in covered tanks, with no emissions of methane (IPCC, 2006); thus, the net emissions from this system are negative (**Table 3**).

At Plant 4, a closed maize cycle is practiced, whereby the digestate is used as fertilizer for the maize which is fed into the same plant (**Figure 3**). The digestate at this plant is stored in open tanks.

Alternative Electricity Sources

Grid electricity was considered here as the main alternative to electricity from biogas. This is due to the latter being fed into the national grid, displacing an equivalent amount of grid electricity. The Italian electricity mix is shown in Figure S1 in Supplementary Material. Given that the electricity mix is dominated by natural gas (53%) (IEA, 2011), biogas electricity was also compared to this

option. Furthermore, as biogas is a renewable resource, it was also compared to the other renewables contributing to the Italian mix (see Figure S1 in Supplementary Material). The system boundary for all the alternatives was from "cradle to grave," and all the data were sourced from Ecoinvent (2010). As for the biogas electricity, distribution and consumption of electricity were not considered.

RESULTS

The results suggest that biogas electricity generated by Plant 5 is environmentally the best option among the five plants considered (**Figure 4**), largely because it does not use maize silage as a feedstock. The exceptions to this are the MAETP and TETP for which Plant 1 is slightly better because these impacts are not affected by maize silage (as discussed further below). Plant 1 is also the second best option for all other impacts apart from GWP and POCP, for which Plant 2 is better because of the lower methane emissions from digestate.

The differences in the impacts for Plants 2 and 4, which are fed with approximately the same amount of maize silage, are due to the differences in the digestate emissions and the capacities of the AD and CHP plants.

Despite the highest biogas production, Plant 3 is the worst option across all the impact categories because of the maize ear silage, which has impacts twice as high as maize silage owing to its lower yield (Table S2 in Supplementary Material). The exceptions to this are GWP and POCP, for which Plant 4 is worst because of the higher net methane emissions (**Table 3**).

The following sections discuss in more detail the impacts from the different plants (**Figure 4**) and the contributions of different life cycle stages (**Figures 5A–E**).

Abiotic Depletion Potential (ADP Elements and ADP Fossil)

Abiotic depletion of elements and fossil resources range from 142 to 243 mg Sb eq./MWh and from 1010 to 1570 MJ/MWh, respectively, with Plant 5 being the best and Plant 3 the worst option for both impacts.

As indicated in **Figures 5A–D**, the depletion of elements for Plants 1–4 is mainly due to the cultivation of maize and is associated with the materials used for agricultural machinery. For Plant 5, on the other hand, the major contributors are construction materials for the AD and CHP plants (**Figure 5E**); the latter is also a hotspot for Plant 1. This is due to economies of scale: they have smaller CHP plants and thus a higher consumption of resources per megawatt hour electricity generated.

As also shown in **Figures 5A–D**, the major contributors to fossil depletion for Plants 1–4 are the fuel used in the agricultural machinery for maize cultivation and the electricity for the AD plants. For Plant 5, the grid electricity used to operate the AD plant accounts for the majority of this impact (**Figure 5E**).

Acidification and Eutrophication Potentials

The estimated AP varies from 2.6 to 5.5 kg SO_2 eq./MWh and EP from 0.2 to 1.9 kg PO_4 eq./MWh. As for ADP, biogas electricity generated by Plant 5 is the best and by Plant 3 the worst option for these two impacts. For Plants 1–4, maize cultivation is responsible for the large majority of AP and EP (**Figure 5A–D**), whereas for Plant 5 (**Figure 5E**), it is the ammonia emitted during the digestate storage as well as the emissions of acid gases and nutrients in the life cycle of the grid electricity used for AD.

Global Warming Potential ($GWP_{100\ years}$)

The values for GWP range from −395 to 408 kg CO_2 eq./MWh, with electricity from Plant 5 being the best option and from Plant 4 the worst. The vast majority of GWP (64%) is due to methane emissions from the digestate during its storage. For Plant 2, GWP is mainly from the maize silage (**Figure 5B**). The negative contributions shown in the figure are due to the methane credits for the avoidance of the traditional slurry management, as described in Section "Digestate Use and Methane Emissions Credits." For Plant 5, the methane credits are higher than the methane emissions from the digestate, leading to a negative impact of −395 kg CO_2 eq./MWh (**Figure 5E**). Note that carbon dioxide emissions from biogas combustion in the CHP plant are not considered as they are biogenic in nature.

Human Toxicity Potential

This impact is lowest for electricity generated by Plants 1 and 5 [79 kg dichlorobenzene (DCB) eq./MWh] and highest for Plant 3 (114 kg DCB eq./MWh). For Plants 1–4, the main contributor is the production of maize silage and the emissions from biogas combustion, in particular chromium and thallium (see **Table 3**). For Plant 5, HTP is mainly affected by CHP operation, followed by AD operation and plant construction (**Figure 5E**).

Ecotoxicity Potentials (FAETP, MAETP, and TETP)

The lowest FAETP is estimated for Plant 1 (198 kg DCB eq./MWh) and the highest for Plant 3 (413 kg DCB eq./MWh). The

Negative values represent the credits for the avoidance of methane emissions by using digestate as fertilizer instead of animal slurry.

production of maize silage and the plant operation are the main contributors to this impact for Plants 1–4. This is mainly due to the emissions of pesticide used for maize cultivation (**Table 3**) and metals (nickel, beryllium, cobalt, and vanadium) emitted in the life cycle of the grid electricity. It can be noted that Plant 1 has lower MAETP and TETP, which is due to the efficiency associated with economies of scale as these impacts are mainly influenced by the plant operation (**Figures 5A,E**).

Unlike HTP, the best option for MAETP is Plant 5 at 55 ton DCB eq./MWh but, as for HTP, Plant 3 has the highest impact (77 ton DCB eq./MWh). The main hotspot is grid electricity used for AD because of the emissions of beryllium and hydrogen fluoride in the life cycle of electricity generation.

The same trend is found for TETP, with Plant 5 being the best option (2 kg DCB eq./MWh) and Plant 3 the worst (2.5 kg DCB eq./MWh). Maize silage and CHP operation are the main contributors to TETP for Plants 1–4. Like HTP, the latter is mainly due to the emissions of chromium and thallium from biogas combustion. For Plant 5, CHP operation is the main hotspot (biogas combustion), followed by AD operation and plant construction.

Ozone Layer Depletion Potential

At 7 mg R11 eq./MWh, Plant 5 has the lowest ODP and, as for most other impacts, Plant 3 the highest (11.3 mg R11 eq./MWh). The main contributors are halons emitted in the life cycle of grid electricity used in AD (related to natural gas transportation), followed by the emissions from diesel used in the machinery during maize cultivation (Plants 1–4).

Photochemical Oxidants Creation Potential

The POCP ranges from −73 g C_2H_4 eq./MWh for Plant 5 to 70 g C_2H_4 eq./MWh for Plant 3. For Plants 1, 3, and 4, the impact is largely due to the emissions of methane from the digestate and the methane losses from the AD plant. The negative contributions (**Figure 5**) are due to two reasons: first, according to the CML 2001 method, nitrogen oxides emitted during the cultivation of maize reduce POCP (Plants 1–4); and second, because of the methane credits (Plant 5).

Comparison with Alternative Electricity Sources

The biogas electricity is compared to electricity from the grid, natural gas, and renewables in **Figure 6** and the ranking of different options with respect to each impact is summarized in the heat map in **Figure 7**.

As can be seen in **Figure 6**, grid electricity has higher impacts than electricity from biogas for seven out of 11 categories: ADP fossil, FAETP, GWP, HTP, MAETP, ODP, and POCP. This is mainly due to the high contribution of fossil fuels in the Italian electricity mix. An exception to this is Plant 3 which has a higher HTP than the grid because of the toxic emissions in the life cycle of maize ear silage.

Electricity from the grid also has lower AP (by 10–57%) and EP (32–72%) than biogas electricity; this is due to maize cultivation which contributes significantly to these two impacts (see **Figure 5**). The exception to this is Plant 5 which has lower impacts than grid electricity (by ~60%) because it does not use maize silage.

Two further impacts are lower for grid electricity: depletion of elements and TETP. This could be explained by the greater economies of scale of the plants on the grid, which require a lower amount of resources and thus have lower toxic emissions on a life cycle basis per unit of electricity generated than the agricultural machinery and the AD-CHP plants.

Unlike grid electricity, electricity from natural gas is environmentally more sustainable than biogas for most categories, except ADP fossil, GWP, ODP, and POCP (**Figure 6**). In comparison to the renewables, biogas electricity has mostly higher impacts, with a few exceptions. For example, biogas has a lower AP than geothermal power across all the AD-CHP plants considered. Furthermore, Plant 5 has lower GWP and Plant 2 lower POCP than any other renewable option. Biogas is also better than solar PV in terms of ADP elements, HTP, FAETP, MAETP, ODP, and

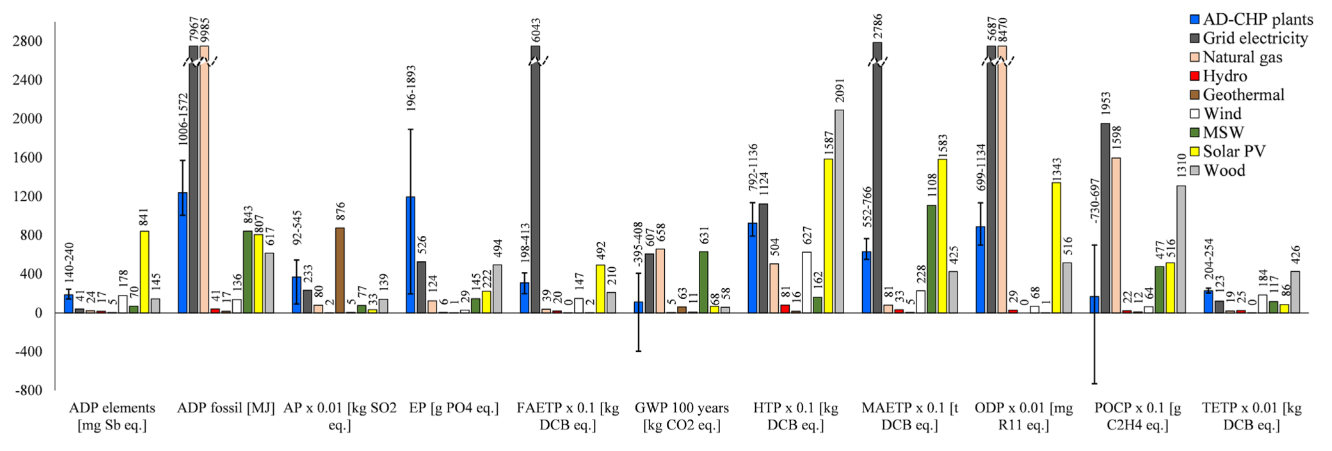

FIGURE 6 | **Comparison of biogas electricity with the alternatives**. All impacts expressed per megawatt hour of electricity. For the AD-CHP plants, the average results are shown, with the error bars representing the impacts ranges for different plants. For impacts nomenclature, see **Figure 5**. The worst option is set at 100% and the others are expressed as a percentage of impact relative to the worst option. Waste, municipal solid waste; MSW, municipal solid waste; wood, wood chips in a CHP plant; solar PV, solar photovoltaics. For impacts nomenclature, see **Figure 5**.

POCP. It also has a lower MAETP than electricity from municipal solid waste and it outperforms wood for HTP, POCP, and TETP.

With a specific reference to GWP, the main driver for biogas production, Plant 5 is the best option overall, sequestering 395 kg CO_2 eq./MWh. All other plants generate higher GHG emissions than any of the renewable options considered here. The only other impact for which biogas electricity is a better option than any other is POCP, but again only for Plant 5; however, this plant has the highest TETP than any other alternative.

These results are summarized in **Figure 7**, which shows the percentage difference between the worst option and the rest of the alternatives for each impact. Overall, assuming equal importance of all the impacts, hydropower could be considered the best option and grid electricity the worst, with biogas being on average a middle-ranking option.

Comparison with Other Studies

As discussed in the Section "Introduction," comparison of the results from different studies is not easy for the reasons outlined there. The only studies for which comparison is possible are those by Blengini et al. (2011), Dressler et al. (2012), Meyer-Aurich et al. (2012), Bacenetti et al. (2013), Whiting and Azapagic (2014), and Ingrao et al. (2015); for a summary of these studies, see **Table 1**.

As can be inferred from **Figure 8**, the results from the current study compare favorably in terms of AP, EP, GWP, and POCP, given the different assumptions, system credits, and geographical locations across the studies. However, the average GWP estimated in this work appears to be lower than in the other studies, mainly because of Plant 5 which has a negative value for this impact. Nevertheless, the impact for the AD-CHP system using pig slurry reported by Bacenetti et al. (2013) compares well with Plant 5 which uses cow slurry (−368 and −395 kg CO_2 eq./MWh, respectively). The GWP in Blengini et al. (2011) is consistent with that estimated for Plant 4, while the values found by Dressler et al. (2012), Meyer-Aurich et al. (2012), Bacenetti et al. (2013), and Ingrao et al. (2015) agree well with the results for Plants 1 and 3. It should be noted that, unlike other studies, Meyer-Aurich et al. (2012) have considered land-use change (associated with maize cultivation), finding that it increases GWP by 20%; however, differences in other assumptions cancel out this effect and, consequently, the results still agree with those in the current study.

The comparison of the other impacts is only possible with the study by Whiting and Azapagic (2014), since the other authors did not consider them. As can be seen in **Figure 8**, the results agree for HTP but differ for ADP, FAETP, MAETP, ODP, and TETP. The reason for these differences could be due to the different updates of the CML method and Gabi software, as well as the different assumptions, credits for fertilizers, and geographical locations. On the other hand, both studies are in agreement that the contribution of the AD and CHP plants construction is significant for ADP elements and the toxicity-related impacts.

Sensitivity Analysis

Because of their significant contribution to the impacts, the following parameters are considered in the sensitivity analysis:

(i) maize yield;
(ii) heat utilization;
(iii) recycling of AD and CHP construction materials; and
(iv) covered storage of digestate in Plant 4.

The results are discussed in the following sections.

Maize Yield

To explore the effect of this parameter on the impacts, the maize yield was varied by ±15% against the baseline shown in Table S2 in Supplementary Material. The results in **Figure 9** suggest that the overall effect of maize yield on the environmental impacts is

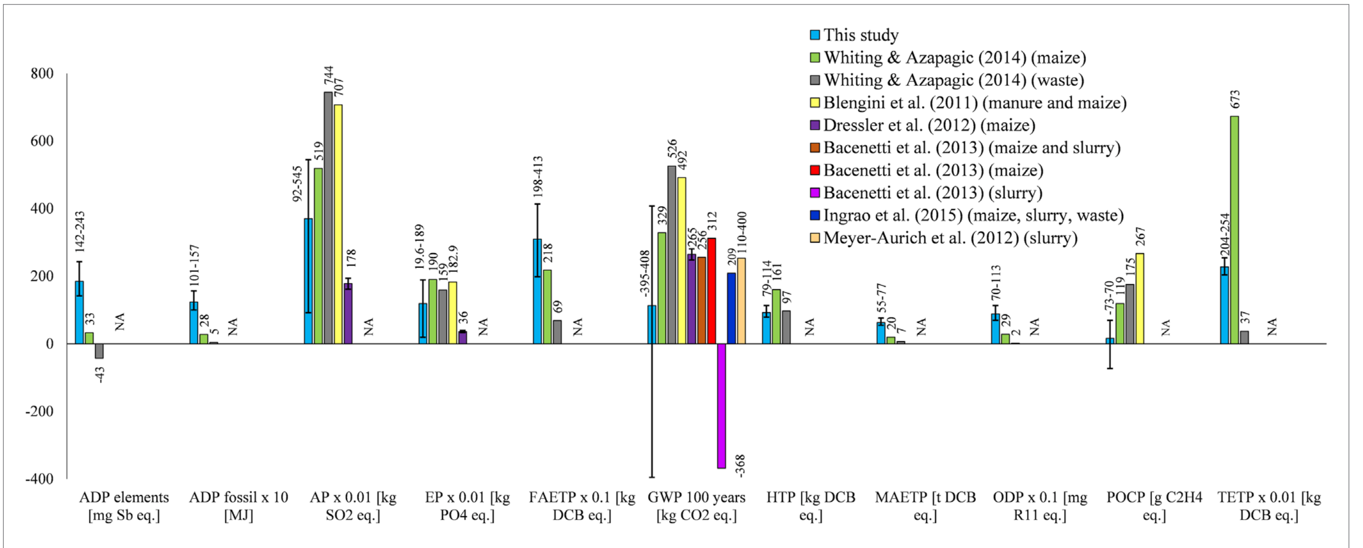

FIGURE 8 | **Comparison of the results with the literature**. All impacts expressed per megawatt hour of electricity. The error bars represent the range of results for the different plants. NA, not available. Waste, agricultural. For impacts nomenclature, see **Figure 5**.

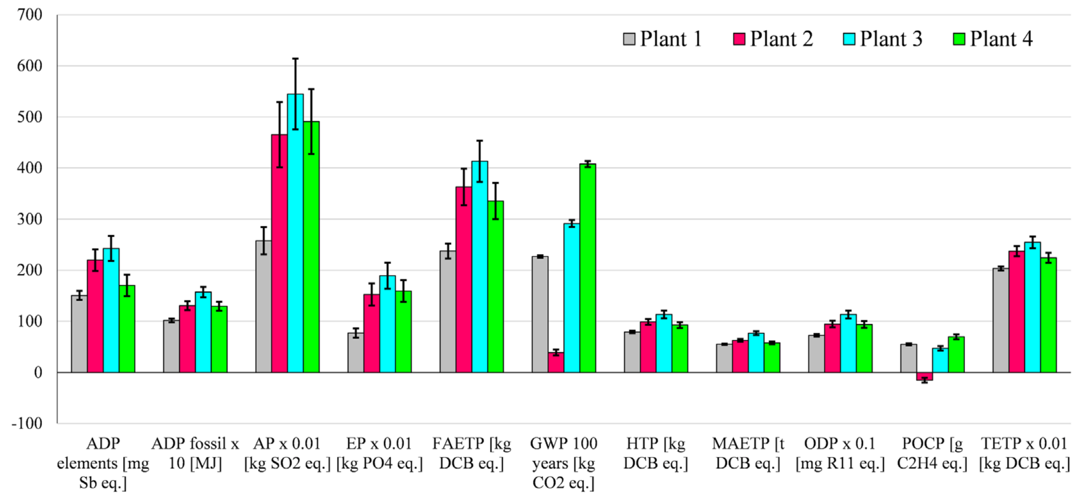

FIGURE 9 | **Sensitivity analysis assuming different maize yields for biogas produced in Plants 1–4**. All impacts expressed per megawatt hour of electricity. The height of the columns corresponds to the yield indicated in Table S2 in Supplementary Material. The error bars refer to the yield variation of ±15%. For impacts nomenclature, see **Figure 5**.

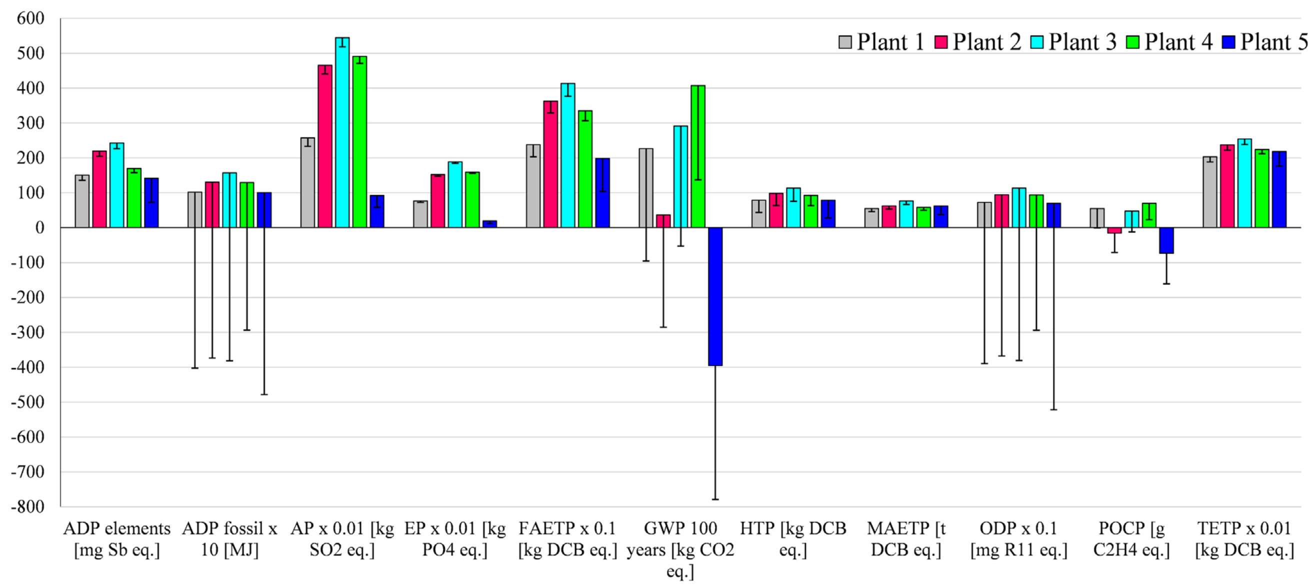

FIGURE 10 | **Sensitivity analysis assuming the net heat produced is used and substitutes a gas boiler**. All impacts expressed per megawatt hour of electricity. Capacity of boiler: >100 kW for Plants 1–4 and <100 kW for Plant 5. For impacts nomenclature, see **Figure 5**.

small for most impacts, except for AP and EP which change by up to 14%. This is to be expected given the high contribution of maize cultivation to these categories.

The ADP elements and FAETP results are also affected for Plant 4, varying by up to 12%, because of the change in the resource requirements for the agricultural machinery and the related toxicity of the construction materials. Despite these changes, the variation in the maize yield considered here does not affect the comparison of biogas with the alternative electricity sources discussed in Section "Comparison with Alternative Electricity Sources."

Heat Utilization

This part of the sensitivity analysis considers a scenario in which the net heat produced by the CHP plants is used instead of being wasted. This is motivated by the introduction of subsidies for heat (see Introduction), which aim to stimulate its utilization. It was assumed that the heat generated by the CHP substitutes a gas boiler for which the AD-CHP systems were credited. The LCA data for the boiler were sourced from Ecoinvent (2010).

As indicated in **Figure 10**, if the heat were utilized all of the impacts would be reduced, some of them significantly, across the different plants: ADP fossil would be lower by four to six times, GWP up to nine times, ODP by five to eight times, and POCP two to four times. This means that biogas electricity from all five plants would have lower impacts for these categories than any other renewable option considered here. However, there would be no change in ranking with respect to grid electricity because ADP elements, AP, EP, and TETP remain higher for biogas electricity.

Recycling of Construction Materials

As mentioned earlier, it was assumed that all the construction materials apart from plastics are landfilled after decommissioning of the plants. Since the construction of the plants has a significant contribution for some impacts, particularly for Plants 1 and 5 (**Figures 5A,E**), the sensitivity analysis considers if and how they would change if concrete, steel, iron, and platinum (in the CHP catalytic converter) were recycled. For these purposes, the recycling rates for the former three materials were assumed equal to current recycling rates in Italy: 60% for concrete (UNI, 2005) and 74% for steel and iron (Fondazione per lo sviluppo sostenibile, 2012). As there are no data for platinum recycling, a recovery rate of 90% was assumed. Plastic materials were not considered for recycling as their quantity is small.

The results are presented in **Figure 11** for the impacts that are affected by the recycling. The greatest reduction would be achieved for ADP elements (up to 39%) and POCP (up to 13.5%), followed by AP and FAETP (~8%); MAETP would also go down (~5%). The effect on the other impacts is small (<2%).

Covered Storage of Digestate

As discussed in Section "Results," biogas electricity from Plant 4, which uses maize silage as the AD feedstock, has higher GWP and POCP than any other plant. Given that much of that is due to methane emissions from the open storage of digestate

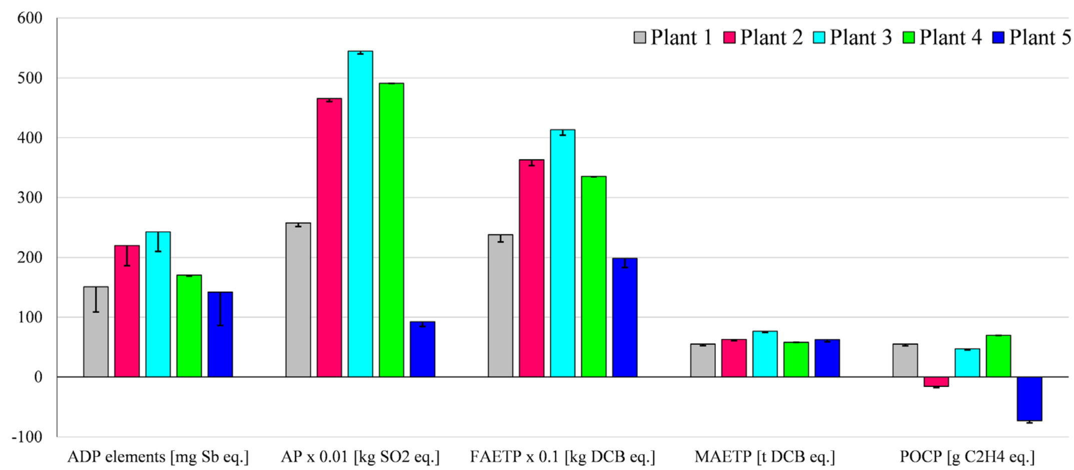

FIGURE 11 | Sensitivity analysis assuming recycling of construction materials. For impacts nomenclature, see **Figure 5**.

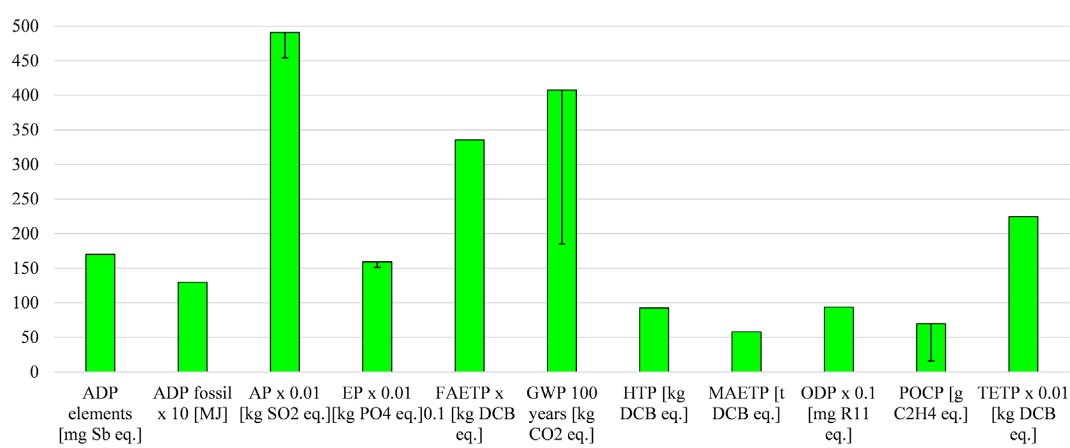

FIGURE 12 | Sensitivity analysis assuming the covered storage of digestate in Plant 4. All impacts expressed per megawatt hour of electricity. For impacts nomenclature, see **Figure 5**.

(**Figure 5D**), it is important to consider by how much the impacts would change if the digestate were stored in covered tanks, as in Plant 2.

The results in **Figure 12** suggest that both impacts would decrease significantly: GWP by two times and POCP threefold. In that case, Plant 4 would have lower impacts than Plant 1 and 3 but still higher than Plant 2. The AP and EP results would also be reduced, by 7 and 5%, respectively, because of the avoided ammonia emissions. This would make Plant 4 a better option than Plant 2 for these two impacts.

With respect to grid electricity, Plant 4 would have half the GWP. It would also be a better option for POCP with respect to solar PV and waste power plants.

CONCLUSION

The aim of this study was to evaluate the life cycle environmental impacts associated with generation of electricity from biogas produced by AD of agricultural products and waste. Five real AD-CHP plants situated in Italy were considered and compared to electricity from the national grid, natural gas, and different renewable technologies.

The results suggest that the main contributors to the impacts from biogas electricity are the production of the maize silage and the operation of the anaerobic digester, including open storage of digestate. Therefore, the system using animal slurry (Plant 5) is the best option among the five plants considered, except for marine and terrestrial ecotoxicity potentials for which the best system is the one utilizing slurry, agricultural waste, and a small amount of maize silage (Plant 1). The plant fed with maize ear silage (Plant 3) is the worst option because of the high impacts of the feedstock, which are almost double that of maize silage.

In reference to the size of AD-CHP plants, larger capacity does not appear to have a positive effect on environmental impacts despite the higher efficiencies typically associated with economies of scale. This is due to the larger plants requiring a high organic load to make them viable, which can only be achieved with cereal feedstocks as they have much higher biogas yield than slurry or agricultural waste. For example, a 1 MW CHP plant requires around 50 ton of maize silage per day but 400–800 ton of slurry. As this amount of slurry cannot be supplied by a single farm, it would have to be collected from different farms and transported to the plant which would not be economically and environmentally viable. Furthermore, the digester would be impractically large (20,000–40,000 m^3 assuming a hydraulic retention time of 50 days) and thus expensive. Therefore, as the results of this work suggest, it is better to have smaller plants using slurry and waste rather than bigger installations: the latter may be more efficient but require cereal silage, which in turn leads to higher environmental impacts. On the other hand, smaller plants require more resources for construction per unit of electricity generated, so there are some trade-offs.

The results also suggest that utilizing the heat generated by the CHP plant would reduce all the impacts, some of them significantly (specifically depletion of fossil fuels and the ozone layer, global warming, and summer smog), making biogas electricity a better option for these categories than any other renewable alternatives considered here. Recycling the AD and CHP construction materials would reduce the depletion of elements, acidification, freshwater, and marine toxicity as well as summer smog. The latter would also improve in addition to global warming if digestate was stored in covered tanks.

Biogas electricity is environmentally more sustainable than electricity from the grid for seven out of 11 impacts considered. This is due to the high contribution of fossil fuels in the Italian electricity mix. The remaining four impacts, for which grid electricity is a better option, are depletion of elements, acidification, eutrophication, and terrestrial ecotoxicity. Thus, biogas electricity reduces GHG emissions compared to the grid, as intended by government and the European Commission, but aggravates some other impacts.

However, in comparison with natural gas, seven out of 11 impacts are higher for electricity from biogas. It also has mostly higher impacts than the renewables, except for solar PV for which six out of 11 impacts are higher than biogas. Furthermore, biogas is a better option than geothermal power for acidification across all the feedstocks considered. If only slurry is used (Plant 5), it also has lower global warming and summer smog potentials than geothermal. Moreover, marine ecotoxicity is greater for electricity from municipal solid waste than that from biogas.

Focusing on global warming potential which drives biogas production, using slurry as a feedstock (Plant 5) is the best option across all the electricity options considered here, sequestering 395 kg CO_2 eq./MWh. All the other biogas systems generate higher greenhouse emissions than any of the renewable options considered here. The only other impact for which biogas electricity is a better option than any other is summer smog, but only for the slurry feedstock; however, it also has higher terrestrial ecotoxicity than any other electricity alternative.

In summary, biogas electricity can help reduce GHG emissions relative to fossil-intensive grid electricity such as that of Italy; however, some other impacts are increased. On the other hand, if mitigation of climate change is the main aim, then other renewables have a greater potential to reduce GHG emissions. If, in addition to this, other impacts are considered, then hydro, wind, and geothermal power are better alternatives to biogas. However, if the subsidies for heat utilization are successful, the environmental sustainability of biogas electricity would improve significantly, particularly for global warming, summer smog, and depletion of the ozone layer and abiotic resources. Further policy changes should include a ban on open digestate storage to prevent methane emissions and regulation on digestate spreading on land to minimize emissions of ammonia and related environmental impacts.

Finally, it should be noted that the results obtained in this study correspond to mesophilic digestion at 40°C and may differ from the results for other operating conditions. Furthermore, the analysis did not consider other environmental aspects, such as habitat destruction and biodiversity loss, as they are outside the scope of LCA. These and other impacts could be evaluated in future research alongside economic costs and social impacts as part of a broader sustainability assessment.

AUTHOR CONTRIBUTIONS

AA and MF conceived and supervised the work; JB collected the data; AF carried out the LCA study; AA, AF, and JB wrote the paper.

ACKNOWLEDGMENTS

This work was funded by the UK Engineering and Physical Sciences Research Council (EPSRC), grant no. EP/K011820/1. This funding is gratefully acknowledged. The authors are also grateful to the editor and the reviewers for their comments that helped to improve the paper. We would also like to thank Dr. Laurence Stamford and Ellen Gleeson at the University of Manchester for proofreading the manuscript and Dr. Martyn Jones, also at Manchester, for his assistance with the figures.

Abstract

Renewable natural gas (RNG) is a fuel comprised of essentially pure methane, usually derived from climate-neutral (e.g. biogenic or captured) carbon dioxide (CO_2). RNG is proposed as a climate friendly direct substitute for fossil natural gas (FNG), with the goal of enabling diverse natural gas users to continue operating without substantial infrastructure overhauls. The assumption that such substitution is climate friendly relies on a major condition that is unlikely to be met: namely, that RNG is manufactured from waste methane that would otherwise have been emitted to the atmosphere. In practice, capturable waste methane is extremely limited and is more likely to be diverted from a flare than from direct atmospheric release in a climate-conscious policy context, which means that RNG systems need to be more destructively efficient than a flare to provide climate benefits versus the likely alternative management strategy. Assuming demand levels consistent with the goal of using existing FNG infrastructure, RNG is likely to be derived from methane that is either intentionally produced or diverted from a flare, so essentially any methane leakage is climate additional. Further, in a decarbonizing system, RNG will likely compete with lower-emissions resources than FNG and thus provides fewer net emissions benefits over time. Anticipated leakage is climatically significant: literature estimates for methane leakage from biogas production and upgrading facilities suggest that leakage is in the 2%–4% range (mass basis), up to as much as 15%. Policy makers should consider that under reasonable leakage and demand assumptions, RNG could be climate intensive.

1. Introduction

Climate change motivates an urgent global transition away from the use of fossil fuels for energy (Intergovernmental Panel on Climate Change 2014, Geels *et al* 2017, Mccauley and Heffron 2018, Davis *et al* 2018). Fossil fuels account for 85% of global commercial energy consumption (2018) (BP 2019) and dominate global energy infrastructure. Given the scale, costs, and economic implications of abandoning infrastructure before the end of its useful life, and given the challenge of transitioning energy systems quickly, there is substantial interest in the idea of renewable drop-in fuels (Rye *et al* 2010, Horvath 2016, Lynd 2017) that can use existing infrastructure without creating the problems of fossil fuel use. This interest is particularly salient in the context of end uses that use specific fossil fuels directly. For example, transportation services currently rely primarily on refined oil, and many industrial and other heating applications directly burn natural gas. These direct users of fossil fuels are often unable to accommodate alternative fuels without abandoning functional infrastructure (e.g. internal combustion engine cars and natural gas-fired water heaters) in favor of infrastructure compatible with the new fuels (e.g. electric cars and electric water heaters).

This work assesses renewable natural gas (RNG) (Götz *et al* 2016, Gasper and Searchinger 2018), here referring both to biomethane (Parker *et al* 2017, Paolini *et al* 2018) and power-to-gas (Götz *et al* 2016, Collet *et al* 2017), as a direct substitute for fossil natural gas (FNG). Drop-in substitutes for FNG specifically are valued due to the diversity of uses, and thus infrastructure, for FNG. In the United States (US), FNG accounts for about 30% of primary energy consumption (EIA 2018), split relatively evenly among power generation (~40%), industrial uses (~30%), and commercial and residential uses (~30%) (Energy Information Administration 2020). RNG has been proposed as a way to decarbonize this system while leveraging existing fossil infrastructure, including pipelines and end use equipment like home and industrial heating devices (Washington State University Energy Program 2018, Bataille 2019). This substitution is particularly relevant for non-electricity uses because they are often more difficult to decarbonize (Davis *et al* 2018, Bataille 2019), though RNG is also valued as an electricity fuel because RNG plants could provide fully dispatchable electricity generation that could reduce the need for costly electricity storage or demand management (Tarroja *et al* 2020). Similarly, like hydrogen, RNG manufacturing has been proposed as a sink for excess variable electricity that can be stored for later use, in the form of power-to-gas schemas (Götz *et al* 2016).

Like FNG, RNG is primarily methane (Gasper and Searchinger 2018), a potent greenhouse gas (GHG) (Intergovernmental Panel on Climate Change 2014) second only to carbon dioxide (CO_2) in its overall contribution to climate change (Weyant *et al* 2006). When RNG is produced from waste methane, converting it to CO_2 by burning it has climate benefits because of methane's much higher climate forcing potential (Intergovernmental Panel on Climate Change 2014) relative to CO_2. If the waste methane were going to be emitted to the atmosphere anyway, any system leakage (i.e. methane emissions) is a lost opportunity but not a climate stressor; otherwise, it contributes to climate change. This analysis shows that 1) RNG from intentionally produced methane, even from climate-neutral CO_2 sources, has substantial climate impacts at methane leakage levels observed in the existing, mature biogas industry (Pertl *et al* 2010, Flesch *et al* 2011, Whiting and Azapagic 2014, Ravina and Genon 2015, Hijazi *et al* 2016, Liebetrau *et al* 2017, Paolini *et al* 2018, Vo *et al* 2018, Ramírez-Islas *et al* 2020); (2) for any meaningful system scale, RNG is likely to be derived from intentionally produced methane; and (3) even RNG from waste methane can have negative climate impacts relative to the most likely alternative of flaring, not venting, the methane when leakage from RNG production and use exceeds flaring loss rates.

2. Methods

This analysis evaluates the GHG intensity of RNG, focused on three methane feedstock pathways for RNG production: (1) from waste methane that would have otherwise been emitted to the atmosphere; (2) from waste methane that would have otherwise been flared; and (3) from intentionally created methane that would otherwise not have existed. The carbon for RNG is assumed to be climate neutral, for example, biogenic or sourced from a carbon capture activity. Reported GHG intensities use IPCC's Fifth Assessment Report (AR5) 20- and 100-year GWPs with climate-carbon feedback, distinguishing between fossil and nonfossil methane GWPs (see Working Group 1, chapter 8, Tables 8.7 and 8.A.1). For comparison, the GHG intensity of FNG, generic resources with life cycle 2050 GHG intensity consistent with 2 °C warming (Pehl *et al* 2017), and zero carbon resources are also included. Full details and calculations are available in the Supplementary Data File.

The absolute GHG intensity of RNG is assumed to derive from methane leakage only (because combustion GHG emissions for RNG are climate neutral by assumption), drawing the system boundary at the point when the methane is diverted from the alternative management strategy (venting, flaring, or not existing) and excluding embodied GHGs in infrastructure or any of the production feedstocks. For example, power-to-gas pathways are implicitly assumed to use GHG-neutral power in facilities with zero embodied GHGs. GHG intensity is given as kilograms (kg) of carbon dioxide equivalent (CO_2e) per gigajoule (GJ) of methane consumed—that is, the denominator is the amount of methane that is ultimately delivered to the entity that combusts it, which is less than the amount of methane that is produced or withdrawn if system leakage exceeds 0%. Emissions associated with leakage are thus calculated as follows:

$$\begin{aligned}&\text{absolute leakage} - \text{related GHG intensity} = \\ &(\text{mass CH}_4\text{ produced} \times \text{system leakage} \times \text{GWP}_{\text{CH}_4}) \\ &= \frac{\text{mass CH}_4\text{ delivered}}{(1 - \text{system leakage})} \times \text{system leakage} \times \text{GWP}_{\text{CH}_4}\end{aligned} \tag{1}$$

where system leakage is mass methane emitted/mass methane produced. Net emissions relative to the alternative fate for methane are calculated by subtracting the counterfactual methane emissions. For Path 1 (waste methane would have otherwise been emitted to the atmosphere), counterfactual emissions are that system leakage = 100%. For Path 2 (waste methane would have otherwise been flared), counterfactual emissions are that system leakage = (1-flare efficiency). For Path 3 (methane would not otherwise have existed), counterfactual emissions are 0. Thus, net emissions are given as:

$$\begin{aligned}&\text{net leakage emissions} = (\text{mass CH}_4\text{ produced} \\ &\quad \times \text{GWP}_{\text{CH}_4}) \times (\text{system leakage} - \text{counterfactual leakage})\end{aligned} \tag{2}$$

For the three paths, Equation 2 becomes:

$$\text{Path 1, net leakage emissions} = (\text{mass } CH_4 \text{ produced} \times GWP_{CH_4}) \times (\textit{system leakage} - 1) \quad (3)$$

$$\text{Path 2, net leakage emissions} = (\text{mass } CH_4 \text{ produced} \times GWP_{CH_4}) \times (\text{system leakage} - \text{flare leakage}) \quad (4)$$

$$\text{Path 3, net leakage emissions} = (\text{mass } CH_4 \text{ produced} \times GWP_{CH_4}) \times (\text{system leakage} - 0) \quad (5)$$

Note that because of the presentation of results per unit of methane combusted by a user and the fact that methane production = methane delivered/(1—system leakage) (equation (1)), equation (3) reduces to (mass CH_4 delivered $\times -GWP_{CH_4}$) and is independent of leakage rate. For Path 2, emissions upstream of the flare are not considered because waste methane that is vented prior to diversion to the flare is not diverted to the flare, thus falling under Path 1.

Leakage from the RNG system is evaluated as a range because of substantial uncertainty about what leakage levels would be under future conditions, particularly if newer RNG pathways (e.g. power-to-gas) became widespread. This work considers the implications of RNG system leakage between 0%–15% mass leakage/mass produced in order to inform consideration of potential RNG futures. The range is most proximately based on Scheutz and Fredenslund's (2019) evaluation of 23 biogas plants, including seven facilities encompassing production through biogas upgrading to biomethane, where facility leakages from 0.4 to 14.9% of production were observed (see Supplementary Data File for details). Specific leakage sources are not always evident but might be correlated with plant complexity (e.g. number of units), maintenance regimes, and the status of biogas production as a core or non-core function (Scheutz and Fredenslund 2019). Published values in other studies and GHG protocols reflect ranges generally narrower than but consistent with Scheutz and Fredenslund's findings (Flesch *et al* 2011, Liebetrau *et al* 2013, 2017, Hrad *et al* 2015, Vo *et al* 2018, Bartoli *et al* 2019).

Leakage downstream of production and processing (i.e. during transportation, storage, and end use) is assumed to be identical for FNG and RNG. Although it is challenging to assign a value for these processes due to the diversity of end uses, lack of information about leakage during end uses, differential use of transmission, storage, and distribution by end users, and the dependence of transportation leakage on distance, a value of 0.8% (mass leaked per mass withdrawn or produced) was chosen in service of estimating absolute GHG intensities for comparison with zero-GHG systems. This value is based on assumptions and data from the literature (Liebetrau *et al* 2013, Lavoie *et al* 2017, Alvarez *et al* 2018) (see Supplementary Data File for details). For FNG, this value is added to an estimate of production and processing leakage of 2.1% mass leakage/mass withdrawn (Alvarez *et al* 2018), and for RNG, it is assumed to be included in the assessed 0%–15% range for full system potential leakage rates.

3. Results

3.1. GHG intensity of renewable natural gas

Table 1 shows the estimated GHG intensity of RNG for three production pathways as a function of system methane leakage: (1) RNG produced from waste methane that would have otherwise been emitted to the atmosphere (Path 1); (2) RNG produced from waste methane that would have otherwise been flared with 99% destructive efficiency (Path 2); and (3) RNG produced from intentionally created methane (Path 3).

In all cases, this analysis assumes that the CO_2 emitted from burning RNG is climate neutral for the RNG user, e.g. because it is sourced from biogenic or captured carbon that was taken up from and returned to the atmosphere over a period of time that is short from a climate perspective. Further, to emphasize the particular challenge posed by methane leakage, this analysis assumes RNG has no GHG intensity other than that associated with net impacts from methane leakage or destruction—that is, inputs to RNG production like electricity, hydrogen, and support infrastructure are assumed to be climate neutral. This assumption is consistent with the notion that zero-GHG electricity or hydrogen are potential alternatives to RNG. Note that because conversion processes are never 100% efficient, any GHG intensity for RNG associated with electricity or hydrogen inputs would exceed that of the electricity or hydrogen available for use.

As table 1 shows, the GHG intensity of RNG is driven by the counterfactual—that is, what would have otherwise happened to the source methane. Path 1, waste methane diversion from the atmosphere, is highly GHG negative because the counterfactual is that all utilized methane would have been emitted as methane. Leakage is irrelevant to GHG impact per unit of utilized methane because any leaks are methane that would have escaped anyway. Although Path 2 also uses waste methane, the counterfactual is that the waste methane would have been nonproductively burned in a flare, so RNG is GHG negative in this case only if the RNG system's total leakage is lower than leakage from the flare (1%), which is unlikely given that a best-guess estimate of downstream emissions alone is 0.8%. Path 3 uses intentionally produced methane. Here, the counterfactual is that no methane would have been released to the atmosphere, so any system leakage is GHG positive.

Table 1. Renewable natural gas carbon dioxide equivalent intensity by pathway, assuming climate-neutral combustion emissions of carbon dioxide.

(a) GWP-100, kg CO2e/GJ methane productively consumed							
system leakage (mass CH4 emitted/mass CH4 produced)	0	0.025	0.05	0.075	0.1	0.125	0.15
Path 1: Waste methane diverted from emission to atmosphere	−680	−680	−680	−680	−680	−680	−680
Path 2: Waste methane diverted from a 99% efficient flare	−7	10	29	48	68	89	112
Path 3: Intentionally produced methane used	0	17	36	55	76	97	120
(b) GWP-20. kg CO2e/GJ methane productively consumed							
system leakage (mass CH4 emitted/mass CH4 produced)	0	0.025	0.05	0.075	0.1	0.125	0.15
Path 1: Waste methane diverted from emission to atmosphere	−1720	−1720	−1720	−1720	−1720	−1720	−1720
Path 2: Waste methane diverted from a 99% efficient flare	−17	26	72	121	172	226	283
Path 3: Intentionally produced methane used	0	44	91	139	191	246	304

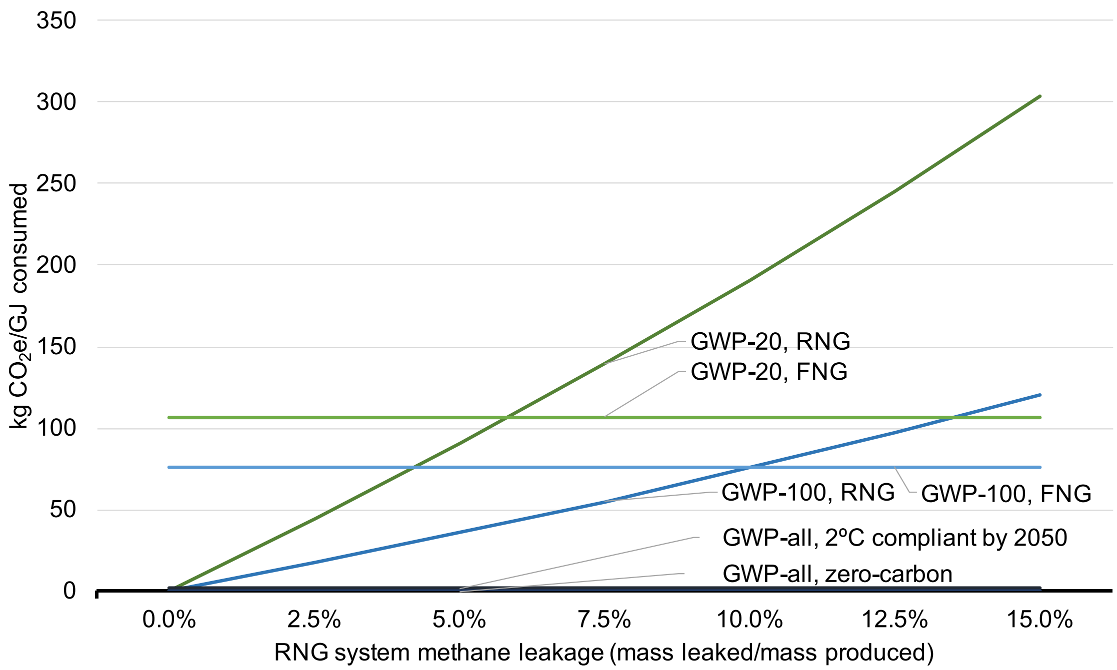

Figure 1. Greenhouse gas intensity of renewable natural gas from intentionally produced methane as a function of system methane leakage. GWP-20 and GWP-100 are shown for intentionally produced RNG for RNG system methane leakage of 0–15%, with GWP-20 and GWP-100 of FNG shown for reference.

3.2. Intentionally produced methane for RNG

A major finding of this analysis is that, as with FNG (Brandt *et al* 2014, Alvarez *et al* 2018, Grubert and Brandt 2019, Zhou *et al* 2019), RNG can have significant climate impacts associated with system methane leakage if the methane is intentionally produced (Path 3; table 1). Figure 1 shows the GHG intensity (kg CO_2e/GJ CH_4 productively consumed, e.g. for heat or electricity generation) of RNG from intentionally produced methane as a function of RNG system methane leakage.

As figure 1 shows, RNG from intentionally produced methane is always GHG positive unless total system leakage is 0. Given demonstrated transportation and end use leakage values on the order of 0.4–0.8% (Liebetrau *et al* 2013, Lavoie *et al* 2017, Alvarez *et al* 2018), RNG from intentionally produced methane cannot outperform zero-GHG hydrogen or electricity systems on GHG intensity. Although this analysis does not consider non-operational, non-methane GHGs, note that both hydrogen and electricity are likely inputs to intentionally produced methane for RNG, which therefore inherits and amplifies embodied emissions. The estimated methane-only GHG footprint of such RNG exceeds the combustion plus methane leakage GHG footprint of FNG when RNG system leakage is higher than about 10% (GWP-100) or 6% (GWP-20) on a mass leaked per mass produced basis. Accounting for IPCC stated uncertainty in the GWP of methane (Intergovernmental Panel on Climate Change 2014), the estimated leakage range within which RNG becomes more GHG intensive than FNG is about 9.1–11.1% (GWP-100) or 5.0–6.6% (GWP-20). Although power-to-gas systems and evaluations remain rare enough that data on leakage are not widely available (though leakage has been discussed (Vo *et al* 2018)), such leakage rates—particularly for a full system—are not uncommon for biogas to RNG systems (Liebetrau *et al* 2013, 2017, Scheutz and Fredenslund 2019). For electricity, assuming the heat rate of a US natural gas combined cycle power plant and GWP-100, RNG's operational methane GHG intensity surpasses the 15 kg CO_2e/MWh total life cycle 2050 GHG intensity consistent with a 2 °C warming limit (Pehl *et al* 2017) for system leakage of 0.3%, which is less than some observed leakage from power plants alone (Lavoie *et al* 2017). Calculations can be found in the Supplementary Data File.

3.3. At scale, most methane feedstocks for RNG would likely be intentionally produced

How much RNG is likely to come from intentionally produced methane, which includes all power-to-gas RNG and RNG produced from feedstocks that would not degrade anaerobically (i.e. to methane rather than CO_2) absent intentional intervention (Meyer-Aurich *et al* 2012, Börjesson *et al* 2015, Agostini *et al* 2015)? The answer depends on assumptions about total demand and the availability of waste methane for diversion to RNG production. If the goal is to maintain the usefulness of FNG infrastructure, one potential assumption for RNG demand is that it would match current FNG demand. In 2017, US consumer consumption was 27.2 exajoules (EJ) of FNG, including 10.1 EJ for electric power and 8.7 EJ for often difficult-to-decarbonize industrial uses (see Supplementary Data File). The energy content of 2017 US uncontrolled methane emissions was about 1.6 EJ/year, about 0.3 EJ of which were emitted from biogenic sources (as opposed to, say, the FNG system) that could reasonably be captured (wastewater treatment plants and landfills, not enteric fermentation) (US EPA 2019, Grubert 2020), not all of which would become consumable RNG (i.e. due to parasitic energy requirements, conversion losses, etc). Thus, although some capturable waste methane (Paths 1 and 2) clearly exists, the degree to which RNG systems can depend on such resources at scale is low (<1%) relative to current natural gas demand.

One important observation for contextualizing these values is that not all methane from waste is waste methane. For example, the National Renewable Energy Laboratory (NREL) estimates that the energy content potential from methanogenic US wastes is about 5% the size of the US natural gas system (National Renewable Energy Laboratory 2013), including a methane potential estimate from wastewater (2.3 million tonnes/year) (National Renewable Energy Laboratory 2013) that is four times the US Greenhouse Gas Inventory (GHGI) estimate for methane emissions from wastewater treatment plants as of 2017 (0.57 million tonnes/year, Table 2–2) (US EPA 2019). Why? Unintentionally produced waste methane typically results from natural anaerobic digestion of wet organic wastes, like animal manure, sewage, and landfilled wastes, but this digestion process does not completely convert carbon wastes to methane. Rather, digestion produces biogas, a blend of methane and CO_2 that can then be upgraded into near-pure biomethane, a form of RNG. Crucially, in part because biogas and biomethane can generate revenue, it is not only possible but expected to intervene in biological systems to increase methane production beyond what would have happened anyway when there is an incentive to do so (Hijazi *et al* 2016, Ferreira *et al* 2019, Garcia *et al* 2019). Thus, a single facility might produce both Path 1 (GHG-negative) and Path 3 (GHG-positive) methane from the same wastes.

Despite its limited availability, Path 1 methane is so GHG negative (table 1) that it is reasonable to investigate whether climate benefits can be retained if small amounts of very climate-negative RNG are blended with RNG from intentionally produced methane. Figure 2 shows GHG intensity of RNG for blends of 0%–100% Path 3 methane (intentionally produced) with Path 1 methane (waste methane diverted from release).

Figure 2 suggests that blending very GHG-negative RNG with GHG-positive RNG can enable a fairly large RNG system that is overall at least somewhat GHG-negative, assuming leakage levels within a typically observed range (see Supplementary Data File for detailed calculations and values). Assuming all 0.3 EJ of uncontrolled methane emissions from landfills and wastewater treatment plants could be captured and converted to consumer-ready RNG, either current industrial demand or electric power demand for FNG could be fulfilled by an RNG system with up to about 3% system leakage and theoretically remain GHG-negative (GWP-100; see Supplementary Data File). As the next section shows, however, such an outcome is unlikely because of the actual nature of waste methane management.

3.4. Capturable waste methane would be flared, not vented

The possible conclusion that sufficient highly GHG negative methane exists to support a large (e.g. FNG electricity system-sized) GHG negative RNG system is based on the assumption that waste methane is diverted from emission to the atmosphere (Path 1). This assumption is flawed if one also assumes that GHG emissions reductions are a policy priority, as existing practice is not the appropriate baseline for determining the counterfactual management practice for waste methane that could be available for RNG production (Haya *et al* 2019). Specifically, if the methane can be captured for RNG production, it can be captured for diversion to a flare, and it is unrealistic to assume that capturable methane would be vented under a GHG conscious policy regime. Even without federal climate regulation, the US regulates methane emissions from new landfills (US EPA 2016),

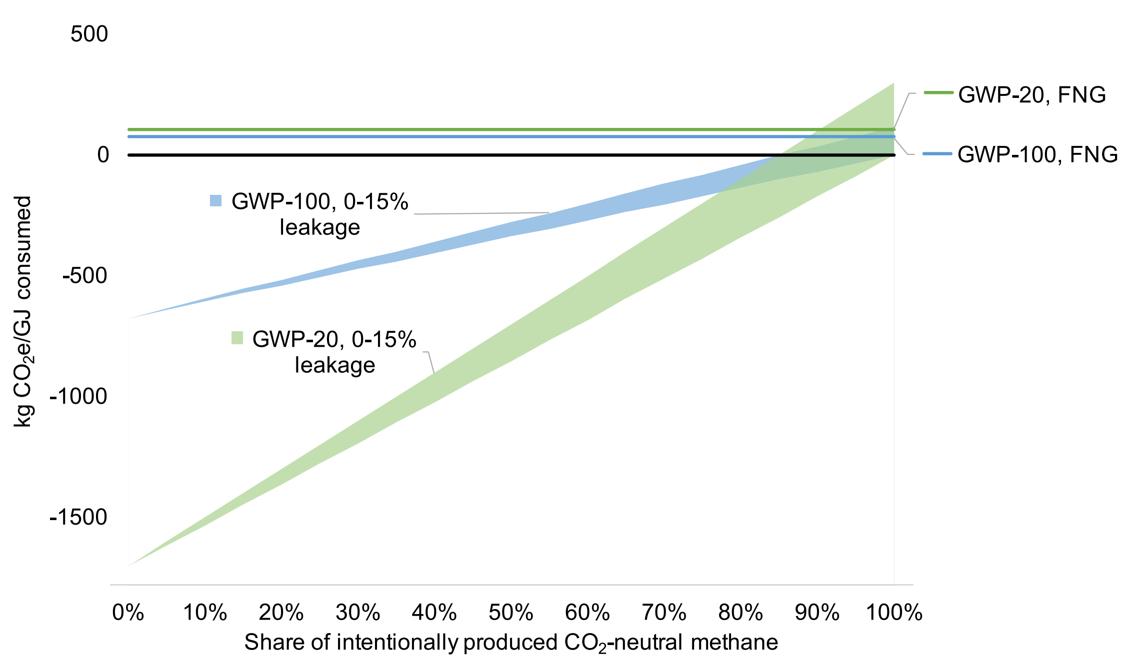

Figure 2. Greenhouse gas intensity of RNG systems that blend waste methane that would otherwise have been released to the atmosphere with intentionally produced methane, for 0%–15% system leakage. Lower bound of shaded areas = 0% system methane leakage for RNG; upper bound of shaded areas = 15% system methane leakage for RNG. GWP-20 and GWP-100 for RNG and FNG are shown for blends of 0% to 100% RNG from intentionally produced methane.

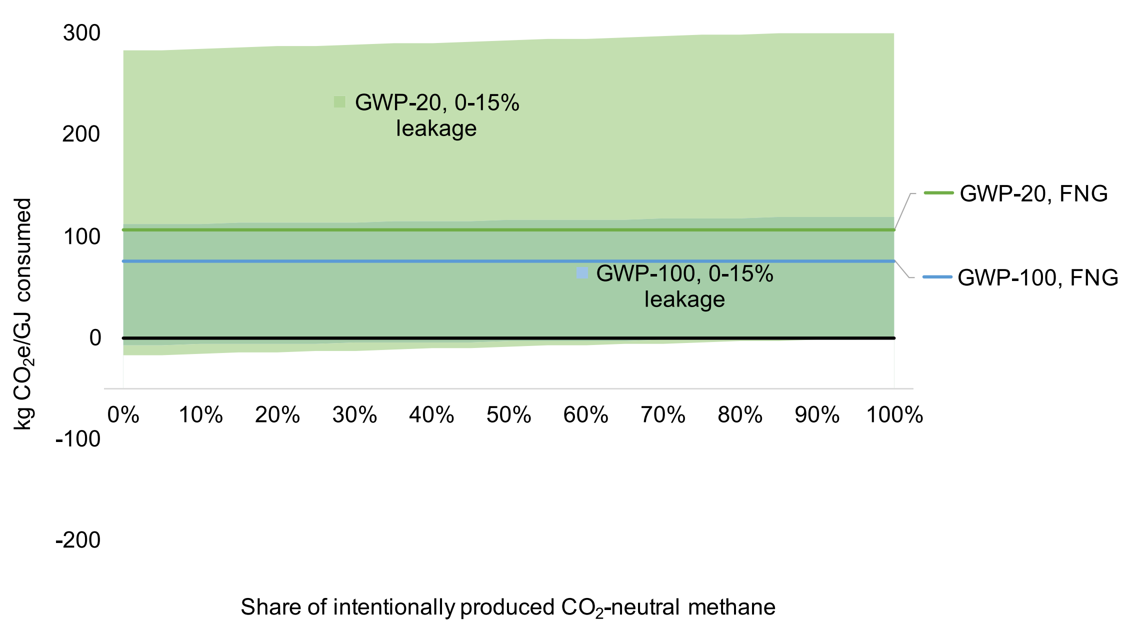

Figure 3. Greenhouse gas intensity of RNG systems that blend waste methane that would otherwise have been flared with intentionally produced methane, for 0%–15% system leakage. Panel A: Flare with 99% destruction efficiency. Panel B: Flare with 86% destruction efficiency. Lower bound of shaded areas = 0% system methane leakage for RNG; upper bound of shaded areas = 15% system methane leakage for RNG. GWP-20 and GWP-100 for RNG and FNG are shown for blends of 0% to 100% RNG from intentionally produced methane.

and many methanogenic facilities use methane capture with flares for safety reasons. Flaring destroys the methane with the same destructive benefit as combusting the methane productively. Figure 3 updates the assumptions used in figure 2 to show the same results, but assuming that RNG using Path 3 (intentionally produced) methane is blended with RNG using Path 2 (waste diverted from flare) rather than Path 1 (waste diverted from release) methane. Figure 3 assumes 99% flare efficiency, described in the GHGI as a median value (US EPA 2019). Figure S1 (available at stacks.iop.org/ERL/15/084041/mmedia) shows results assuming the GHGI's lower flare efficiency bound of 86 (US EPA 2019).

As figure 3 shows, conclusions about the viability of a large, GHG-negative RNG system change radically when the more realistic counterfactual of methane destruction rather than methane venting is applied. RNG system leakage would need to be essentially 0 (that is, lower than the flare's leakage) to be GHG-negative versus typical flare performance. Based on literature values for leakage, including the estimate of 0.8% leakage for processes downstream of production and processing, productive use of waste methane is unlikely to be more destructively efficient than a flare. Although waste methane being diverted for productive use arguably would not have been captured without the financial incentive of energy sales, given that capture infrastructure is not free, flaring is most likely the less GHG intensive alternative for waste methane once it has been captured. In a decarbonized energy system where RNG would be less likely to be replacing GHG-intensive fuels (and thus offsetting their emissions), and when a policy regime requiring or incentivizing destruction of GHG-intensive wastes might reasonably be expected to be in place, expected levels of methane leakage suggest that RNG is unlikely to be a low GHG energy resource relative to alternatives.

4. Discussion

RNG is not inherently climate friendly. Based on consideration of both the source of methane used to produce RNG and the likely alternative fate of that methane, and using reasonable assumptions about likely system methane leakage, it is unlikely that an RNG system could deliver GHG-negative, or even zero GHG, energy at scale. Substantial GHG benefits can be attained when waste methane is genuinely diverted from emission to the atmosphere, but the availability of such methane is low (Liu and Rajagopal 2019, US EPA 2019) relative to potential demand for climate friendly RNG, especially when considering that the alternative fate of capturable methane is more likely flaring than venting in a GHG-conscious setting. Under some system leakage rates that have been observed for biogas systems (Liebetrau *et al* 2017, Scheutz and Fredenslund 2019), RNG might not even meet the less stringent threshold of outperforming FNG from a GHG perspective.

Designing a system that depends on RNG, or delaying transition to a system that does not depend on natural gas because of the promise of RNG, could delay climate mitigation because of induced demand for intentionally produced methane. Particularly given that past experience demonstrates that policy can rapidly drive resource allocation to RNG (Bartoli *et al* 2019), RNG's environmental performance should be carefully compared with that of its likely long-term competitors—not just FNG—before resources are allocated. Current literature on RNG often assumes the context of a fossil-based system (see e.g. the reference systems for papers included in a review of LCA of biogas production (Hijazi *et al* 2016)), which leads to the crediting of lower environmental burden relative to this context (e.g. when RNG is given credit for avoided GHG impacts from FNG consumption (Scheutz and Fredenslund 2019, Ramírez-Islas *et al* 2020)). Such fossil-linked benefits disappear in a context where RNG could be substituting for zero-GHG alternatives like zero-GHG electricity or hydrogen rather than FNG, petroleum fuels, and GHG-intensive electricity.

Even beyond GHG emissions, environmental burdens associated with RNG that are acceptable relative to FNG merit deeper investigation when the alternative is, e.g. zero-GHG electricity. RNG is designed to be effectively indistinguishable from FNG at the point of use, so local combustion impacts are likely to be similar for clean RNG, and potentially worse for less pure RNG (Paolini *et al* 2018). Upstream of use, RNG would likely have different socioenvironmental impacts than FNG. Although RNG can use existing pipeline and user infrastructure, for example, it would obviate the need for FNG's production infrastructures, which have substantial socioenvironmental impacts (Jacquet *et al* 2018). RNG production facilities using primarily waste products (e.g. agricultural wastes, landfill gas, wastewater treatment gas, excess electricity generation) would likely not qualitatively change socioenvironmental impacts from those activities, though making certain practices financially viable could extend their life and extent (Haya *et al* 2019). Relatedly, having access to RNG could extend the life of existing fossil infrastructure, with mixed socioenvironmental outcomes.

To the extent that RNG facilitates lower impact energy systems, e.g. by avoiding the need for mineral (Sovacool *et al* 2020)- and cost-intensive electricity storage to help match supply and demand (Tarroja *et al* 2020), some of the marginal impacts of RNG could be offset by system benefits. These benefits are not guaranteed, however. As demonstrated by experience with renewable drop-in transportation fuels, the potential for drop-in renewable fuel use might not actually lead to renewable fuel use (Pouliot and Babcock 2017), and the renewable fuels themselves might have undesirable environmental characteristics (Liu and Rajagopal 2019). This work shows that RNG needs to be carefully evaluated in the context of expected long-run system conditions before it is adopted as a component of a zero GHG energy system, particularly given its potential for methane leakage-related climate pollution.

Analysis of greenhouse gas emissions from 10 biogas plants within the agricultural sector

J. Liebetrau, T. Reinelt, J. Clemens, C. Hafermann, J. Friehe and P. Weiland

ABSTRACT

With the increasing number of biogas plants in Germany the necessity for an exact determination of the actual effect on the greenhouse gas emissions related to the energy production gains importance. Hitherto the life cycle assessments have been based on estimations of emissions of biogas plants. The lack of actual emission evaluations has been addressed within a project from which the selected results are presented here. The data presented here have been obtained during a survey in which 10 biogas plants were analysed within two measurement periods each. As the major methane emission sources the open storage of digestates ranging from 0.22 to 11.2% of the methane utilized and the exhaust of the co-generation units ranging from 0.40 to 3.28% have been identified. Relevant ammonia emissions have been detected from the open digestate storage. The main source of nitrous oxide emissions was the co-generation unit. Regarding the potential of measures to reduce emissions it is highly recommended to focus on the digestate storage and the exhaust of the co-generation.

Key words | biogas, greenhouse gas emissions, quantification of emission sources

INTRODUCTION

The production of renewable energy from biogas plants plays an increasingly important role in Germany with close to 6,000 plants and an installed capacity greater than 2,000 MW at the end of 2010. One of the main targets of the implementation of the subsidies for energy production from renewable sources is the reduction of greenhouse gases originating from the energy sector. The evaluation of the efficiency regarding the reduction of the effects on the climate is usually done by means of a life cycle assessment (LCA). However, the assessment can only produce reliable data if it is based on a precise determination of the process related greenhouse gas emissions.

In particular methane emissions have a large influence on the LCA results due to the CO_2 equivalent of methane of 25 (IPCC 2007). With the background of current discussions about sustainability criteria for energy from biomass, the identification of greenhouse gas emission along the whole production process gains more and more importance.

So far, the overall emissions of biogas facilities have been estimated by theoretical assumptions, but actually only by means of direct measurement of emissions does a veritable analysis become possible. There are in general two methods to determine the emissions of a large industrial facility or areas with diffuse emission sources. One way is to attempt to capture the overall emissions of the facilities by means of concentration measurements in the surroundings and the application of inverse dispersion models (Flesch *et al.* 2011) or radial plume mapping (Hashmonay *et al.* 2008). These methods allow the determination of the overall emissions of a large area with uncertain sources of emission. These methods do not allow the location of single sources and allocation of a certain quantity to them. However, for further efficient measures to reduce emissions it is very important to identify and quantify the emission sources on site. For this reason the methods used in this study focus on the identification and quantification of single sources. The results of the investigation presented were obtained within a project in which the state of the art of biogas plants were investigated, representative plants were selected and the occurring emissions were determined. The aim of the investigation was the determination of emission quantity from the most relevant technical components (substrate storage, feed in devices, digesters, digestate storage, gas transportation and utilization units) within the production process.

doi: 10.2166/wst.2013.005

This paper presents data obtained from a measurement program investigating the greenhouse gas emissions of 10 biogas plants. The program included two measurement periods in each plant, in which all plant components, from substrate storage to digestate storage were investigated. Further analysis will include a LCA and the development of proper measures for emission reduction. Based on the measured data and knowledge of the state of the art of the biogas industry it will be possible to calculate emission factors with a greater precision.

METHODS

Table 1 shows the features of the 10 investigated plants. All plants are continuously operated except plant no. 5 which is operated in batch mode with a garage style dry fermentation system. Furthermore eight of the 10 plants convert the biogas into electricity. Plant nos. 8 and 9 inject the biogas to the natural gas grid after an upgrading process.

The method adopted for the emission measurements of different technical components from a biogas plant is based on a survey of the plant targeting leakages or sections of increased concentration. Typical diffuse leakages appear on gas pipe adapters, the connection of the digester foil cover with the digester wall or on inspection windows. The leakage detection is carried out by means of two different gas detection methods, tunable diode laser absorption spectroscopy (TDLAS) and flame ionization detection (FID).

After the identification of a spot with a potential leakage, the area is encapsulated to form an aerated chamber. This measurement method is often used to investigate the emissions of diffuse area sources such as manure storages or lagoons (e.g. Husted 1994; Aneja *et al*. 2001). The application of this method on technical components requires a flexible enclosure made of a gas tight foil. The chamber has an input and output pipe and a connected blower to produce a constant air flow through the chamber. The gas from the emission source (leakage) and the fresh air are mixed in

the space of the chamber and the concentration of the target gas is analysed by sampling the gas in the in- and output stream of the chamber. Methane is detected by gas chromatography with a flame ionization detector (FID), nitrous oxides by gas chromatography and with an electron capture detector (ECD) and ammonia by absorption in an acid solution. The flow rate is measured by a vane anemometer or a Pitot tube. Then the quantity of the emission source is calculated from the concentration difference and the flow rate of the blower by using the following equation.

$$F = Q \cdot \rho \cdot (c_{\mathrm{out}} - c_{\mathrm{in}}) \tag{1}$$

F, emission flow rate ($\mathrm{mg} \times \mathrm{h}^{-1}$); Q, air flow rate ($\mathrm{m}^3 \times \mathrm{h}^{-1}$); ρ, density of the target gas ($\mathrm{kg} \times \mathrm{m}^{-3}$); c_{out} exhaust gas concentration ($\mathrm{mg} \times \mathrm{kg}^{-1}$); c_{in}, background gas concentration ($\mathrm{mg} \times \mathrm{kg}^{-1}$).

The surface of an open digester storage tank is investigated optionally by a closed (for CH_4, N_2O) or an aerated chamber (for NH_3). The aerated chamber (Figure 1) uses the same measuring principle as described above. It is a floatable unit with a surface area of 0.25 m^2. Due to the defined surface area of the chamber a specific emission flow rate ($\mathrm{mg} \times \mathrm{m}^{-2} \times \mathrm{h}^{-1}$) is calculated. In order to measure the ammonia emissions the air flow rate within the aerated chamber is adjusted to 18–36 m^3/h by a blower. An aliquot from the exhaust of the chamber is directed through a wash bottle with an acid solution of 0.05 mol/L H_2SO_4. The ammonia concentration within the solution is determined by a photometric kit. The quantity of the emissions is calculated according to German technical guideline VDI 3496 (VDI 1982) – the emissions from the tank are calculated according to the area ratio between chamber and tank. In case of partial swimming layer, both surfaces (swimming layer and liquid surface) are investigated.

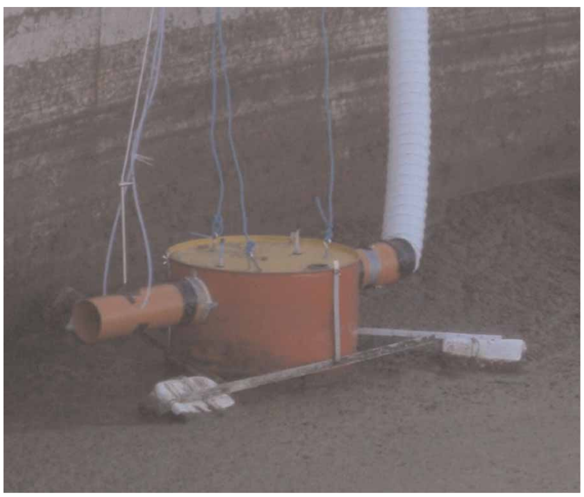

Figure 1 | A floating chamber on an open digestate storage tank.

The closed chamber system is based on a different measuring principle. Once the closed chamber is placed on the emission surface, the gradually increasing concentrations of CH_4 and N_2O under the chamber can be used for calculation of the flow of the gases into the chamber and consequently for the emissions occurring under the defined area of the chamber. Samples are taken after defined time intervals (0, 10, 20, 30 min). The emission rate can be calculated from the slope of the gas concentration, the chamber volume and the encapsulated surface area (0.25 m^2) with Equation (2).

$$F = \frac{\partial c}{\partial t} \cdot \frac{V}{A} \tag{2}$$

F, emission flow rate ($\mathrm{mg} \times \mathrm{m}^{-2} \times \mathrm{h}^{-1}$); $\partial c/\partial t$, slope of the gas concentration ($\mathrm{mg} \times \mathrm{m}^{-3} \times \mathrm{h}^{-1}$); V, chamber volume (m^3); A, encapsulated surface area (m^2).

Similar measurements to investigate diffuse CH_4 emissions from area sources such as soils, landfills or manure storages by using the closed chamber method are described, for example, in Jäkel & Mau (1999), Cardellini *et al.* (2003), Rodhe *et al.* (2009) or Rochette & McGinn (2005).

For the covered, but not gas tight covered digestate storage tanks the measurement of the emissions is carried out differently. Since the surface is not accessible for the chamber measurement, the whole headspace of the tank is aerated by a blower with a defined flow rate (400–500 m^3/h). After the gas under the cover is replaced by fresh air, the exhaust of the tank is sampled for methane and nitrous oxide and a distinct volume is sampled for ammonia concentration as described above.

In the case of gas utilization, in particular, the combined heat and power unit (CHP), the flow and the concentration were evaluated directly in the exhaust pipe according to German technical guideline VDI 4200 (VDI 2000).

On every plant, there were two measurement periods. Each of the periods usually lasted one week per plant. Within this week the several plant components were investigated consecutively. If given as average, the results of the two periods were averaged.

Due to a limited number of possible measurements it was decided to focus on the identification of major sources. The evaluation of plants for a longer period of time would give a better insight into the driving factors of emission, but require a longer period of analysis on site. In order to get more results from different plants it was decided to analyse more plants in short periods of time. In order to ensure comparable results, the plants were only investigated under full load operation. In doing so, no malfunction situation and resulting emissions such as from flaring or overpressure valve releases were evaluated. Any evaluation of malfunction situations should be linked with an investigation regarding the frequency of such occurrences, otherwise the representativeness of the results will be difficult to estimate. The emissions of each component have been set in relation to the installed capacity in order to get an emission value according to the energy output (g CH_4/kWh_{el}). In the case of the investigated plants, the installed capacity matched the actual output at the moment of the measurement.

For reasons of clarity the numbers of methane emissions have been converted into percentage of the utilized methane. The amount of utilized methane is estimated by assuming an electric efficiency of 40% of the co-generation unit and an energy yield of methane of 10 $kWh \times m^{-3}$.

RESULTS AND DISCUSSION

The measurements of the emissions on the plants have been sorted according to the investigated plant components. The following plant components were separately analysed and the results are presented in the following sections:

- Silage storage
- Feeding systems
- Digester
- Digestate storage tanks (sealed, not gas tight covered, open)
- Gas utilization (co-generation units or gas-upgrading facilities).

Silage storage

Methane emissions from the silage were proven to be negligibly low. The average of eight plants where measurements were carried out accounts for 1.25×10^{-3} g CH_4/kWh and the averaged loss of methane was about 0.69×10^{-3}% (eight plants). Emissions of ammonia were also very low, at 2.52×10^{-3} g NH_3/kWh (seven plants evaluated). There were no detectable N_2O emissions.

Feeding systems

There are several types of input systems used within the biogas industry. The following were investigated:

- Screw conveyor (feeds via an open pit, where the solid material is stored and a screw system directly into the digester, under the liquid surface).
- Substrate storage tank (tank, mostly open, where manure is stored prior to feeding).
- Mixing tank (tank, mostly open, where manure, silage and digestate is mixed prior to feeding).

Due to the low pH the silage was quite stable, therefore relevant emissions only occurred in case of mixing the fresh substrate before feeding with manure or digestate in an open tank. The results of the measurements of the feeding systems are shown in Table 2.

The emissions from one screw conveyor, two mixing tanks and one substrate storage tank appeared to be

Table 2 | Methane emissions from feeding system

						10 (2)	33.8×10^{-2}	0.189

n, number of measurements.

elevated. In case of the screw conveyer, it was suspected that the end of the feeding pipe was not under the liquid surface. The substrate storage tank of plant 4 is quite large (500 m^3) and contains swine manure. On the site of plant number 10, digestate was mixed with silage in a 20 m^3 open tank prior to feeding.

All feeding components emit on average 15.4×10^{-2} g CH_4/kWh which equals 8.6×10^{-2}% of the utilized methane (11 feeding units). Ammonia emissions account for 7.58×10^{-3} g NH_3/kWh (10 feeding units). Emissions of nitrous oxide have been detected, but they were also low. The mean of N_2O-emissions at the feeding units adds up to a negligible 2.5×10^{-4} g N_2O/kWh (nine feeding units).

Apparently the feeding system doesn't produce great amounts of greenhouse gas emissions. However, the highest emissions occur as to be expected in the case of using open tanks for substrate storage or mixing. In regard to the emissions these systems are to be considered as inferior to closed systems.

Digester

Since the main target of a biogas plant is gas utilization, a gas tight cover of the digester is a crucial part of the whole concept. Besides two cases of detected leakages (see Table 3), which are classified as malfunction, the emissions released from the digesters have been quite low. The leakages are a poorly maintained service opening (major leakage) and a badly manufactured lead through of a pipe.

Table 3 | Methane emissions from digesters with a foil cover

n, number of measurements.
nm, not measured.

After taking care of the leakages, no emissions have been detected in the second measurement period. Besides this, digester tanks with a concrete roof don't show detectable emissions at all.

Digesters with foil cover emissions have been reported occasionally. The greatest emissions released from a digester were 4.38×10^{-2} g CH_4/kWh which translates into 2.44×10^{-2}% of the utilized methane. At five plants no emissions at all were detected.

The connection of the foil and the digester were identified as emission sources. The air in the double layer foil cover systems showed occasionally high methane concentrations. The sources could not be identified due to limited access to the covers. The membrane material itself has been checked but no emissions have been found there.

The gas tight constructed digestate storage tanks were analysed like the digesters, since the construction features are very similar. No emissions were detected.

Emissions of ammonia were very low at 0.06×10^{-3} g NH_3/kWh (eight plants) and no emissions of nitrous oxide occur (eight plants).

Digestate storage tanks

The investigation of the digestate storage tanks (not gas tight covered) gives interesting, but not very consistent results (see Table 4). The values obtained in the different programs differ in some cases substantially. Since the emissions from digestate tanks are dependent on the temperature, wind, atmospheric pressure, filling level of the tank and the process parameter of the plant, it is quite difficult to determine an average emission by means of measurement, which can only represent a very short period of time. However the results show that some of the storage tanks can produce substantial emissions, whereas others show very little emissions. Further investigations will be needed to identify the driving factors for the emissions. On plant 5 – a garage style digestion system – the highest emissions (as average) occurred, the digested material having been stored outside the digester, waiting to be used as inoculum for the next filling or to be distributed on arable land. The emission factor of the digestate tank on plant 4 has a high uncertainty due to the missing measurement in period 2. All storage tanks except plants 4 and 5 emitted on average 6.25 g CH_4/kWh (six plants) which equals 3.5% of the utilized methane.

For comparison, some literature values have been evaluated. Woesch-Gallasch *et al.* (2007) found a gas production in the digestate storage which equaled 1.9% of the energy production of the plant. Berghold (2008) showed that the

gas tight cover of the digestate storage had increased the energy output of two facilities by 1.9 and 3.5% respectively. Balsari *et al.* (2010) evaluated a storage tank for separated liquids of digestate. The methane production from the tank added up to approximately 3% of the methane converted by the 1 MW co-generation unit installed at the facility.

Weiland *et al.* (2009) investigated the gas potential of digestates of 60 biogas plants at 20–22 °C and found an average 3.5% of the methane production for one stage processes and 1.5% for two stage processes. These values represent the maximum possible emissions at this temperature and are yet much lower than some results obtained here for real emissions.

Looking at the gas potential of the digestate (see Table 5) it is obvious that by comparing the plants with elevated methane emissions from the digestate storage (no. 4,5,7,10) plants 4 and in particular 5 show elevated gas potentials also in the digestate – but 7 and 10 do not. The order of magnitude of the emissions from plants 4 and 7 seems high in comparison to the gas potential of the digestate. The reasons for that could not be identified. One explanation could be particular weather conditions such as falling atmospheric pressure on the day of measurement.

Very often the retention time is named as one of the major factors influencing the remaining gas potential of the digestate and consequently potential emissions from the open storage. Weiland *et al.* (2009) and Reinhold & Gödeke (2011) concluded from their investigation of digestates that a significant reduction of the gas potential of the digestates can be achieved by retention times in the fermentation system greater than 100 days. However, due to a great variability of other process parameters, this estimation does not give a clear answer to the options within the process design which might lead to a similar reduction. Both investigations – as does this one too – displayed data in which low gas potentials in digestates can also be achieved under comparable low retention times.

Table 5 | Digestate characteristic gas potentials (methane) over 60 days from the investigated plants

Plant no.	Digester output[a] TS %	VS % wm	Gas potential at 39 (20) °C l_N CH_4/ kg wm
1	8.1	6.3	4.7 (2.6)
2	6.4	4.8	2.6 (0.7)
3	6.5	5.2	4.5 (1.3)
4	7.6	6.1	8.2 (3.6)
5	19.1	13.5	26.9
6	13.6	11.7	18.3 (6.2)
7	7.0	5.2	5.0 (2.0)
8	9.7	7.6	6.5 (2.7)
9	6.8	5.2	6.2 (3.1)
10	10.5	7.9	5.4 (1.3)

[a]Samples taken at the outlet of the last step of the fermentation process; wm = wet mass; l_N = litres (dry and standard conditions 273.15 K, 1013.25 mbar).

The temperature of the stored digestate has a great influence on the emissions as well. Laboratory tests within the studies of Weiland *et al.* (2009) and Reinhold & Gödeke (2011) showed that depending on the temperature of the digestate during storage, the emission potential can be significantly reduced. In this study, the average methane potentials obtained at 20 °C represent 39% of the methane potential obtained at 39 °C.

Reinhold & Gödeke (2011) found that at 25 °C the methane production is reduced to 40–50% of the value obtained at 37 °C and at 10 °C the methane production goes down to even 1%.

The temperature profile of digestate storage tanks can vary quite a bit. In Gioelli *et al.* (2011) the average ambient temperature was 16.6 °C, the digestate temperature in the storage tank was 29.2 °C. In our case, the investigations at the lagoon of plant number 7 showed that the average digestate temperature was 18.5 °C over a period of 38 days, with an average ambient temperature of 7.4 °C. However, these data do not allow a clear estimation of the emission to be expected. But it can be concluded that the digestate temperatures can be quite high as can the occurring emissions subsequently.

The highest ammonia emissions (plants 7 and 10) were caused by digestates with the highest ammonia concentration in the liquid phase. Both plants use chicken manure as substrates.

The results from the open digestate storage tanks clarify that the open tanks have the potential to represent a substantial emission source. The variability of the results and the contradictions in the gas potential analysis in some cases show that a precise determination is rather difficult due to the many factors influencing the emissions from open tanks. For further investigations the method needs to be evaluated and additional information needs to be included in the analysis. Additionally, longer measurement periods are necessary in order to determine the fluctuation of the emissions over time.

Gas utilization (co-generation units or gas-upgrading facilities)

Following the open digestate storage the gas utilization is the second major emission source. Due to incomplete combustion the engines emit on average from 0.40 to 3.28% of the utilized methane. The co-generation units emit on average 3.11 g CH_4/kWh (11 co-generation units), which equals 1.74% of the utilized methane.

In the literature, similar results can be found. Woesch-Gallsch *et al.* (2007) found methane concentrations of 1,100 mg/m³ methane from a co-generation unit which correlates to 1.79% CH_4 of the utilized methane. Aschmann *et al.* (2006) measured averaged 290 mg/m³ C_nH_m (0.5% methane slip) from gas engines and averaged 560 mg/m³ C_nH_m (0.9% methane slip) from pilot injection gas engine. Aschmann *et al.* (2009) reported 1–2% for gas engines and 2–3% for pilot injection engines. For a single occasion they also reported a high emission of 6.7 $g_{total-C}/kWh_{el,}$ which is close to the maximum value in Table 6. The literature values fit to the results obtained in this study. The slip cannot be avoided and only a secondary oxidation step in the exhaust gas can reduce these methane emissions. The two gas upgrading units displayed quite high emissions. For plant number 8 the post-treatment of the exhaust gas was supposed to be not functioning during the measurements.

The concentrations of nitrous oxide from the co-generation units of plant 7 showed during all four measurements very high values. This could be linked with the high ammonia concentration in the liquid which can lead to an increased ammonia concentration in the biogas. In case this is oxidized within the co-generation unit, an elevated nitrous oxide production could be the result.

Miscellaneous

The emissions occurring during the separation process were low. The stored solids also emitted only negligible amounts of methane. On two occasions major leakages were detected (Table 7). One of them emitted approximately 5% of the converted gas from a not properly closed service opening. The matter points to the fact that a frequent leakage detection might help to avoid losses of methane and even dangerous release of greater amounts of methane. In another case the leakage could be reduced by a factor of two by taking immediate measures, in the second period, no emissions occurred at this digester. The biofilter was used for the exhaust gases from the garage style system. The value is an average since the opening of the garages produced for a short period of time quite high emissions.

Biogas plants in comparison

Figure 2 displays the methane emissions according to the sources. It shows in summary the methane emission factors from three sources of typical biogas plants in Germany. The storage of digestate in open or not gas

[a]Measurement only in period 1.

tight covered tanks generates the highest measured methane emissions. Plants equipped (e.g. 1 and 6) with gas tight storage tanks show much lower emissions, which shows the high effectiveness of a gas tight cover for emission reduction. The methane slips from the CHP or gas upgrading units are the second important source, creating high methane emissions. Those emissions could only be avoided by means of a post treatment of the exhaust gas. Miscellaneous sources generate negligible methane emissions in comparison to the digestate storage and the methane slip of the gas utilization.

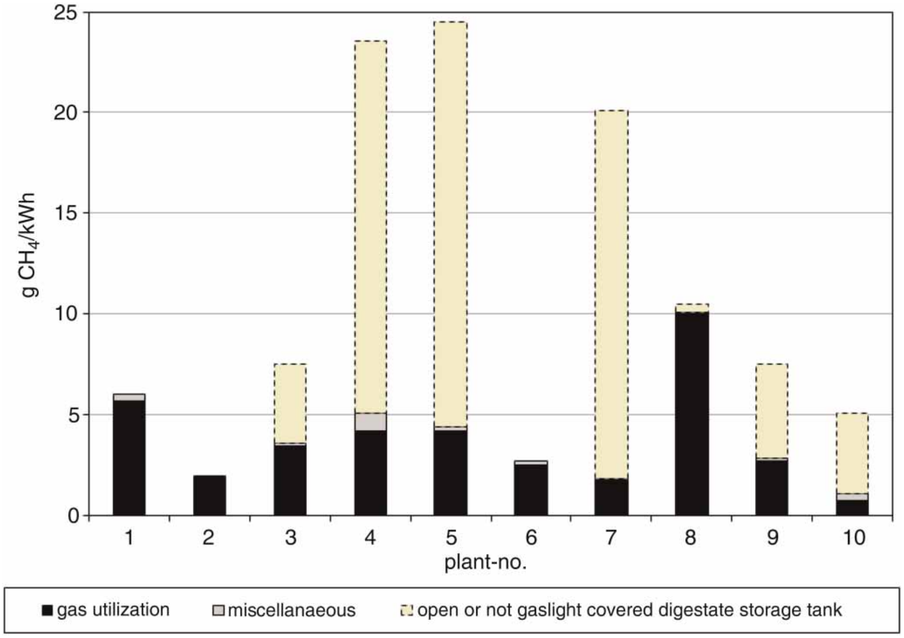

Figure 2 | Main emission sources for methane of the investigated biogas plants.

CONCLUSIONS

The measurement program focused on an evaluation of the constructively conditioned emissions and emissions due to leakages within the biogas production and utilization process. The program was set up in a way to obtain results for a variety of plants, consequently long term analyses could not be realized within this project. For every plant, two measurement programs were carried out.

Looking at the overall methane emissions of the plants, it appears to be clear that the main emission sources are the open digestate tanks and the gas utilization system (Figure 2). However, the results for the open digestate tanks need to be interpreted carefully, since they cannot represent an average emission over a longer period of time. Nevertheless, for the purpose of emission reduction a gas tight cover of any open digestate storage will have a great effect on the emissions. The reduction of the methane emissions of the co-generation unit can only be achieved by means of a secondary oxidation process. There are units available for this purpose, but the investment costs are quite high preventing a widespread application. Emphasizing on these two components any measures to reduce the emissions will show the most pronounced effect.

Nitrous oxide has been found only in the exhaust gas of the co-generation unit.

The results from some components display varying emissions (in particular open digestate tanks), but these variations could not be explained by the available data. A long term investigation at several plants combined with a full mass balance and weather data would help to identify the factors influencing the emissions in detail.

It has been shown that leakages can cause major emissions without recognition by the operators. Therefore a frequent check for leakage identification is recommended.

The ammonia emissions are relevant if the digestate is stored in open tanks and the ammonia content within the digestate is elevated.

The investigation focused on plants under full load conditions. Further investigation might also look into the emission situation in case of disturbances or partial load conditions.

ACKNOWLEDGEMENTS

ABSTRACT

Methane losses from biogas plants are problematic, since they contribute to global warming and thus reduce the environmental benefits of biogas production. Total losses of methane from 23 biogas plants were measured by applying a tracer gas dispersion method to assess the magnitude of these emissions. The investigated biogas plants varied in terms of size, substrates used and biogas utilisation. Methane emission rates varied between 2.3 and 33.5 kg CH_4 h^{-1}, and losses expressed in percentages of production varied between 0.4 and 14.9%. The average emission rate was 10.4 kg CH_4 h^{-1}, and the average loss was 4.6%. Methane losses from the larger biogas plants were generally lower compared to those from the smaller facilities. In general, methane losses were higher from wastewater treatment biogas plants (7.5% in average) in comparison to agricultural biogas plants (2.4% in average). In essence, methane loss may constitute the largest negative environmental impact on the carbon footprint of biogas production.

1. Introduction

Biogas from anaerobic digestion, using various substrates such as manure, food waste, organic industrial waste and sludge from wastewater treatment, may result in several greenhouse gas (GHG) mitigation effects, including fossil fuel substitution, the possible balancing of energy sources in a supply system with a high proportion of wind and solar power and a reduction in methane (CH_4) emissions from manure management (Clemens et al., 2006; IPCC, 2011; Sommer et al., 2004). Fugitive CH_4 emissions from biogas plants, however, will reduce the environmental benefits of biogas production, mainly because of the relatively high global warming potential of CH_4, in that releasing just 1 kg of CH_4 into the atmosphere has the same effect with regards to global warming as the release of 28 kg of carbon dioxide (CO_2) integrated over a 100-year period (not including climate feedback) (Myhre et al., 2013). Data on the magnitude of these emissions are sparse, which in turn causes uncertainty with regards to the environmental assessment of biogas production concerning global warming (Meyer-Aurich et al., 2012; Møller et al., 2009). Recent studies suggest that the extent of CH_4 emissions expressed as a fraction of production lost to the atmosphere (also referred to as "CH_4 loss") may vary between facilities. Liebetrau et al. (2013), for instance, monitored CH_4 emissions from ten German biogas plants, using an on-site approach where individual leaks were identified and emission rates were subsequently measured. It was found that CH_4 emissions relative to the energy output of the biogas plants varied by approximately one order of magnitude between plants, and that open digestate storage tanks in many cases were the most significant emission source. Other sources of CH_4 emission from biogas plants may include unburnt CH_4 from gas engine exhausts, pressure relief valves, biogas upgrading units, ventilation from buildings, leaks in pipes, tanks, etc. (Kvist and Aryal, 2019; Angelidaki et al., 2018; Fredenslund et al., 2018; Liebetrau et al., 2013; Reinelt et al., 2017, 2016; Samuelsson et al., 2018).

An important step in understanding and subsequently reducing CH_4 emissions in the biogas sector is the reliable identification and quantification of single emission sources and the quantification of overall plant emissions. In general, two main approaches can be used for gas emission quantification: on-site and ground-based remote sensing approaches. The on-site approach measures emissions from various single sources at the plant, and it is the method most commonly used (Reinelt et al., 2016; Daniel-Gromke et al., 2015; Westerkamp et al., 2014; Liebetrau et al., 2013). Often a two-step procedure is followed where the first step includes a leakage search performed by using infrared cameras or handheld methane analysers. The second step includes quantification of each identified leakage or emission source often using the stationary or dynamic flux chamber technique. The ground-based remote sensing approach includes different methodologies and measures emissions from a good distance (for example one kilometre) away from the plant, thus providing plant-integrated emission numbers (Fredenslund et al., 2018; Delre et al., 2017; Groth et al., 2015; Yoshida et al., 2014; Hrad et al., 2014; Westerkamp et al., 2014; Flesch et al., 2011). Ground-based remote sensing techniques

encounter inverse dispersion techniques using for instance open-path lasers and tracer gas dispersion methods. Recent measurement comparison studies have found that methods measuring the plant's total CH_4 emission often result in a higher emission rate in comparison to on-site measurements, where the total emission is obtained by summing up those measured from single sources (Fredenslund et al., 2018; Reinelt et al., 2017). The reason for the discrepancy between on-site and ground-based remote sensing approaches is most likely that single sources are overlooked and/or not identified, or they are technically not quantifiable when using a particular measurement technique (e.g. open tanks). For GHG emission reporting or environmental assessment, the plant's total emissions are important; however, if the purpose of measuring CH_4 emissions at a biogas plant is to identify mitigation options, and thereby provide options to improve the environmental benefits of biogas production, on-site methods are needed.

The objective of this study was to quantify CH_4 emission rates and losses from full-scale biogas plants. The study focused primarily on large, centralised, manure-based biogas plants, which produce the bulk of biogas in Denmark. Production capacity at this type of facility was in the expansion phase nationally at the time of this study. In addition, CH_4 emission rates and losses were measured at biogas plants located at wastewater treatment plants (WWTPs). Landfill gas extraction and utilisation sites were not included. The paper compiles the results taken from several biogas plants, in order to provide an estimate of CH_4 losses from biogas production and to assess the importance of minimising this issue. CH_4 emissions were measured using the tracer gas dispersion method, which measures plant-integrated emission rates. The environmental importance of fugitive CH_4 emissions from biogas plants was evaluated by performing CO_2 footprint calculations for a generic, manure-based agricultural biogas plant.

2. Methodology

2.1. Site descriptions

The biogas plants included in this study all utilise continuously stirred anaerobic digesters to produce biogas, and they all are commercially operated facilities. They varied in terms of feedstocks, size, rate of gas production, type of gas utilisation and other factors. Table 1 provides an overview of the main characteristics of the plants.

Thirteen of the biogas plants (plants 1–13) are categorised herein as "agricultural", which means that the feedstocks consist mainly of manure, energy crops and agricultural waste, though they can also receive other feedstocks such as slaughterhouse waste or food waste. Out of the 13 agricultural plants, nine receive manure as the main feedstock (>75% of dry matter input is manure), whereby organic waste (organic industrial waste and/or food waste) is used as a supplement to increase gas production. Two biogas plants (plants 8 and 12) rely on energy crops (grass, maize silage and forage rye), one (plant 5) receives mainly organic waste (~80% of dry matter input) but also receives manure and one plant (plant 13) mainly uses food waste. Plant 13 (and possibly also plant 5) could depending on definition be termed a waste treatment biogas plant as it mainly treated slaughterhouse waste, food industry waste and household food waste. However, as this plant was the only one of this type and also as the generated digestate is spread on farmland, the plant was included in the agricultural biogas plant category.

Five of the agricultural biogas plants (plants 1, 2, 5, 6 and 8) were recently constructed (constructed in 2013 or later), whereas the remaining agricultural plants generally were constructed in the 1980s or 1990s. For a number of reasons, the 2000s saw very low levels of investment in Danish biogas production (Raven and Gregersen, 2007), whereas increases and diversification in subsidies in recent years have led to a "second wave," with most new production capacity emanating from large facilities that upgrade and inject the biogas into the Danish natural gas distribution grid. At the smaller and older plants, it is more common that the biogas is utilised on-site in a combined heat and power (CHP) unit.

Biogas plants 14–23 are categorised herein as "wastewater treatment biogas plants". These plants utilise sludge from wastewater treatment to produce biogas, and they are all located on the grounds of the WWTP from where the sludge originates. They can thus be considered part of a larger plant, the primary function of which is to remove pollutants from wastewater before discharge to a recipient, with energy production as secondary function. The biogas plants categorised as "agricultural biogas plants" all rely on gas production for revenue. Although the wastewater treatment biogas plants receive revenue from their gas production, their primary function is to stabilise and reduce the volume of sludge, and thereby the costs of further sludge treatment. The WWTPs may thus arguably have less incentive to minimize loss of methane compared to the agricultural biogas plants.

The size of the plants varied in size in terms of treated feedstocks, from 30,000 to 600,000 tonnes (wet weight) per year for agricultural biogas plants, while the WWTPs treated between 60,000 and 805,000 PE, which corresponded to a load to the on-site biogas plants of between 3,000 and 112,000 tonnes (wet weight) per year.

The biogas plants differ with regards to gas utilisation (Table 1). At 12 plants, all or some of the produced biogas is utilised on site in a CHP unit. At plants 3, 4 and 7 some of the gas (~20–30%) is used on site in a CHP unit providing process heat for the biogas reactors. The generated electricity is sold to the grid. The remaining part of the gas is routed off site to a nearby power plant (where it is used in a CHP unit). At eight plants, all or some of the biogas is upgraded to biomethane, using technologies such as water scrubbers or chemical scrubbers. At these facilities, the gas is either compressed and transported off site or is injected into a natural gas distribution network. At four plants (5, 11, 14 and 21), all gas utilisation occurs off site. An example of this type is plant 5, where the biogas is led to a nearby power plant (and used in a CHP unit) to generate electricity to the grid and heat to a district heating network.

Open digestate storage units may be significant emitters of CH_4 from biogas plants (Samuelsson et al., 2018; Reinelt et al., 2017; Baldé et al., 2016; Liebetrau et al., 2013). Table 1 lists those facilities, which store digestate in open tanks on site. All biogas plants were equipped with gas storage units with capacities typically corresponding to ~1 to 2 days gas production.

In all, the 23 biogas plants included in this study represent a variety of continuously stirred reactor biogas plant types with regards to amounts of feedstock utilised, feedstock types, gas production rates and gas utilisation.

2.2. Tracer gas dispersion method

CH_4 emission rates from each biogas plant were quantified using a tracer gas dispersion method, whereby a gaseous tracer (here acetylene gas – C_2H_2) is continuously released at the biogas plant, and concentrations of CH_4 and C_2H_2 are then measured while traversing the CH_4/C_2H_2 plume at distances up to ~2 km away, using a vehicle-mounted, high-precision gas analyser. The method has been applied to quantify fugitive emissions from various facilities such as landfills, composting facilities, WWTPs and biogas plants (Andersen et al., 2010; Fredenslund et al., 2018; Mønster et al., 2014; Scheutz et al., 2011; Yoshida et al., 2014). An advantage of this method compared to on-site methods, where emission sources are quantified individually, is the measurement

Table 1
Overview of the main characteristics of the investigated biogas plants.

Agricultural biogas plants	Type of feedstock and annual total amount treated at the plant (in tonnes wet weight per year)	On site gas utilisation (CHP[1]/biogas upgrade)	Digestate storage (open/closed)
1*	Manure, maize silage, organic waste (600,000)	Biogas upgrade: chemical scrubber, gas grid injection	Closed
2*	Manure, slaughterhouse waste (240,000)	Biogas upgrade: water scrubber, gas grid injection	Closed
3	Manure, organic waste (300,000)	CHP (partly off site)	Closed
4	Manure, slaughterhouse waste, other organic waste (235,000)	CHP (partly off site)	Closed
5*	Industrial waste, manure (200,000)	None – routed for off-site use in a CHP	Closed
6*	Manure, maize silage (118,000)	Biogas upgrade: chemical scrubber, gas grid injection	Closed
7	Manure, slaughterhouse waste, other organic wastes (225,000)	CHP (partly off site)	Closed
8*	Maize silage, forage rye	CHP and biogas upgrade: chemical scrubber, gas grid injection	Closed
9	Manure, organic waste, maize silage (170,000)	CHP	Closed
10	Manure, organic waste (37,000)	CHP	Closed
11	Manure, maize and grass silage, glycerol (30,000)	None – routed for off-site use in a CHP	Closed
12	Grass and maize silage, manure	CHP	Open
13	Organic waste (slaughterhouse waste, industrial food waste and household food waste) (104,000)	Biogas upgrade: chemical and water scrubber, gas to vehicle fuel	Open
Wastewater treatment biogas plants	**Feedstock (amount given in person equivalent)**	**On site gas utilisation (CHP[1]/biogas upgrade)**	**Digestate storage (open/closed)**
14	Sludge from wastewater treatment (750,000 PE[2])	None – routed for off-site biogas upgrading	Closed
15	Sludge from wastewater treatment (265,000 PE)	CHP	Open
16	Sludge from wastewater treatment (150,000 PE)	CHP	Closed
17	Sludge from wastewater treatment (420,000 PE)	Biogas upgrade: chemical scrubber, gas grid injection	Closed
18	Sludge from wastewater treatment (95,000 PE)	CHP	Closed
19	Sludge from wastewater treatment (60,000 PE)	CHP	Open
20	Sludge from wastewater treatment (125,000 PE)	CHP	Closed
21	Sludge from wastewater treatment (805,000 PE), industrial food waste and sewage sludge from small WWTPs	None – routed for off-site biogas upgrading, gas to vehicle fuel	Open
22	Sludge from wastewater treatment (95,000 PE), food waste	Biogas upgrade: chemical scrubber, gas to vehicle fuel	Open
23	Sludge from wastewater treatment (120,000 PE)	Biogas upgrade: chemical scrubber, gas to vehicle fuel	Open

[2] PE: Person equivalent.
* Constructed in 2013 or later.

of the biogas plant's total CH_4 emission, with little risk of underestimating them due to undetected emission sources (Fredenslund et al., 2018).

The method and instrumentation are described in detail in Mønster et al. (2014) and Yoshida et al. (2014). The overall error of the method has been the subject of a recent validation study, and it was found very likely to be less than 20% (Fredenslund et al., 2019). The potential error of the tracer gas dispersion measurement technique was determined to 15% by establishment of an error budget including the analytical error, error in the tracer gas release rate, data processing, and error in tracer gas placement and source simulation. The error of a measurement is the combined error of the method and the variability of the quantification, which was found to be about 20% in a controlled release test and comparable to the error obtained by comparison of the measured emission rate and the known controlled release rate (Fredenslund et al., 2019).

Emission rates are calculated using Eq. (1):

$$E_{target} = Q_{tracer} \times \frac{\int_{plume\ start}^{plume\ end} C_{target} - C_{target,backgruound})dx}{\int_{plume\ start}^{plume\ end} C_{tracer} - C_{tracer,backgruound})dx} \times \frac{MW_{target}}{MW_{tracer}} \tag{1}$$

where E_{target} is the emission rate of CH_4 in kg h^{-1}; Q_{tracer} is the release rate of the acetylene tracer gas in kg h^{-1}; C_{target} and C_{tracer} are the measured downwind concentrations in parts per billion (ppb); $C_{target,\ background}$ and $C_{tracer,\ background}$ are the measured background concentrations in parts per billion (ppb) and MW_{target} and MW_{tracer} are the molar weights of the two gases.

The measurements were taken by driving through the downwind plumes several times (typically 10 to 20 traverses per measurement campaign). Each plume traverse resulted in one CH_4 emission measurement, calculated using Eq. (1). The CH_4 emission rate (in kg h^{-1}) was calculated as the average value of the individual plume traverses, and any uncertainty was estimated as the standard error of the mean of the measurements (Fredenslund et al., 2019).

CH_4 loss (%) was determined as the ratio of the measured CH_4 emission to the CH_4 production of the biogas plants, logged the day the measurement was performed.

2.3. Measurement campaigns

The measurements were performed July 2013 through June 2018. At six biogas plants, this happened on a single day, whereas for the remaining 17 plants, measurements were repeated up to a maximum of six days (Table 2).

All measurements were performed using the same analytical equipment and the method described in Section 2.2. The measurements were performed during normal operation of the biogas plants. No malfunctions were reported by the plants for the periods of measurement. As implementation of the method required certain adjustments in each case, some variability with regards to tracer gas release rates and number of release points exists.

Table 2
Overview of measurements performed.

Plant number	Days of measurement campaigns	Number of plume traverses	Tracer gas release rate (kg C_2H_2 h^{-1})
Agricultural biogas plants			
1	1	20	2.24
2	2	66	1.07
3	1	14	2.29
4	3	54	1.90
5	2	32	1.44
6	2	42	0.97
7	3	54	0.83
8	5	166	1.32
9	2	39	1.24
10	1	17	0.91
11	2	29	1.50
12	4	138	1.51
13	2	21	0.44
Wastewater treatment biogas plants			
14	6	82	0.57
15	1	21	0.92
16	4	63	0.51
17	2	37	1.68
18	2	40	0.93
19	4	89	0.48
20	1	16	0.90
21	1	16	–
22	3	81	0.91
23	3	82	0.78

The average tracer gas release rate varied between 0.11 and 2.29 kg C_2H_2 h^{-1}, and the number of tracer gas release points varied between one and three. The measurement distance varied from a few hundred metres up to more than 1 km, according to the availability of drivable roads downwind and the detectability of elevated concentrations of CH_4 and C_2H_2 in the plume – low emission rates and high wind speeds increase dilution, and so it may be necessary to traverse the plume closer to the source of emission.

2.4. Impact of methane emissions on the overall CO_2 footprint of biogas plants

The impact of CH_4 loss on the overall CO_2 footprint of biogas plants was evaluated by using a calculation model provided by the Danish Ministry of Environment for environmental impact assessments of biogas projects (Danish Nature Agency, 2014). The model considers the following factors in determining the overall CO_2 footprint of biogas plants:

Substitution of fossil fuels
Substitution of chemical fertiliser
Transportation of feedstock and digestate
Change in manure management compared to conventional storage and use of manure in agriculture (fewer GHG emissions from manure storage at farms when manure is digested before storage)
Energy use of the biogas plant
Direct GHG emissions from biogas production and utilisation

Emissions and savings were determined by considering five levels of direct CH_4 loss from an agricultural biogas plant: 1%, 2%, 5%, 10% and 20%. Losses of produced biogas contribute directly (CH_4 emitted into the atmosphere) and indirectly (less substitution of fossil fuel as a result of lost biogas production), so both losses were included in the model.

In this assessment, we considered a generic agricultural biogas plant receiving 50,000 tonnes yr^{-1} of cattle manure, 60,000 tonnes yr^{-1} pig manure and 5000 tonnes yr^{-1} organic waste, which in combination produced 2.2 million m^3 CH_4 yr^{-1}. This calculation example is similar to one described by The Danish Nature Agency (2014). Two biogas utilisation options were considered: CHP and biogas upgrade and injection into the natural gas grid.

Table 3 provides an overview of emission factors as well as energy use and CHP energy conversion efficiencies. Two emission factors regarding the use and production of electricity were considered in terms of CHP gas utilisation, namely average and marginal. The average emission factor corresponds to the average emissions associated with the provision of electricity in Denmark, whereas the marginal factor is derived from an estimate of which electricity sources are reduced when production from (for example) biogas plants is increased – also in Denmark. The provision of electricity, on average, consisted of 17% coal, 6% natural gas, 55% wind, hydro and solar, 18% waste incineration, biomass and biogas, 1% oil and 3% nuclear – as reported by the Danish national authority on electricity production (Energinet.dk, 2018), whereas the provision of marginal electricity consisted of 80% coal, 15% natural gas and 5% renewables from a recent study on CO_2 emissions caused by

Table 3
Overview of parameters used in carbon footprint calculations.

Parameter	Value	Reference
Emission factors		
Provision of electricity (average)[a]	0.053 kg CO_2-eq. MJ^{-1}	Energinet.dk (2018)
Provision of electricity (marginal)[b]	0.24 kg CO_2-eq. MJ^{-1}	Ea Energianalyse (2016)
Provision and consumption of natural gas	0.057 kg CO_2-eq. MJ^{-1}	Danish Energy Agency (2018)
Provision of heat (district heating, Danish average value)[c]	0.056 kg CO_2-eq. MJ^{-1}	Danish Nature Agency (2014)
Production of N fertiliser	7.0 kg CO_2-eq. kg N^{-1}	Danish Nature Agency (2014) and Wood and Cowie (2004)
Production of P fertiliser	0.5 kg CO_2-eq. kg P^{-1}	Danish Nature Agency (2014) and Wood and Cowie (2004)
Transportation of digestate, manure, etc.	0.09 kg CO_2-eq. $tonne^{-1}km^{-1}$	(Danish Nature Agency, 2014)
Emission of CH_4	28 kg CO_2-eq. kg CH_4^{-1}	Myhre et al. (2013)
Manure management, cattle	−15 kg CO_2-eq. tonne $manure^{-1}$	Danish Nature Agency (2014)
Manure management, pigs	−23 kg CO_2-eq. tonne $manure^{-1}$	Danish Nature Agency (2014)
Other factors		
Process heat	8.4% of energy output	Danish Energy Agency (2017a)
Electricity use, biogas plant	3.7% of energy output	Danish Energy Agency (2017a)
Electricity use, biogas upgrade and compression	5.3% of energy output	Danish Energy Agency (2017a)
Electrical efficiency, CHP unit	44%	Danish Energy Agency and Energinet.dk (2014)
Total efficiency, CHP unit	92%	Danish Energy Agency and Energinet.dk (2014)

[a] Provision of electricity, average: 17% coal, 6% natural gas, 55% wind, hydro and solar, 18% waste incineration, biomass and biogas, 1% oil and 3% nuclear.
[b] Provision of electricity, marginal: 80% coal, 15% natural gas and 5% renewables.
[c] Average value of Danish district heating networks utilising various energy sources (waste incineration, solar, surplus heat from coal and biomass electricity production and more).

increasing electricity demand in Denmark (Ea Energianalyse, 2016). The differences in energy mix in the provision of average electricity, and provision of marginal electricity cause a relatively large difference in emission factors at 0.053 kg CO_2-eq MJ^{-1} (average) and 0.24 kg CO_2-eq MJ^{-1} (marginal). In the scenario considering the biogas upgrade, for simplicity we only considered the average emission factor for electricity use. In all scenarios, the consumption of heat by the biogas plant was presumed to be in the form of natural gas. In both CHP scenarios, the same emission factor for heat substitution was used, namely an average value of district heating networks in Denmark.

Both feedstock and digestate were assumed to be transported 5 km to and from the biogas plant. The anaerobic digestion of organic waste and the land application of digestates, and thereby recycling of the contained nutrients, was assumed to result in the reduced use of chemical fertiliser at 10 tonnes N yr^{-1} and 5 tonnes P yr^{-1}. The nutrient content of the manure was not considered to contribute to the reduced use of chemical fertiliser, since these nutrients would be applied to agricultural land anyway as raw manure without digestion.

3. Results and discussion

3.1. Measured CH_4 emission rates

Table 4 lists the measured CH_4 emission rates and losses for the 23 biogas plants in this study. The table also lists the biogas production rate of each plant, which was reported by individual plant operator in each case in the form of average daily production at the time of measurement. In those cases where CH_4 emission rates were measured over several campaigns, the listed CH_4 emission rates, gas production rates and CH_4 losses are average values.

Overall, the average CH_4 emission rates varied between 2.3 and 33.5 kg CH_4 h^{-1}. CH_4 losses (CH_4 emission relative to CH_4 production) varied between 0.4 and 14.9%, with the average being 4.6%. These results are comparable to Liebetrau et al. (2013), who found CH_4 losses from single, dominant sources (CHP units and open digestate storage) equating to between 0.22 and 11.2% of the utilised gas at 10 biogas plants. They are also comparable to the results of a study of a Canadian biodigester, where losses under normal operating conditions corresponded to 3.1% of CH_4 production (Flesch et al., 2011).

In general, CH_4 losses were higher from wastewater treatment biogas plants (average 7.5%) than from agricultural plants (2.4%) (Table 4). At seven of the 23 biogas plants, the average measured CH_4 loss was higher than the overall average (4.6%) (Table 4). Of these seven plants, six were WWTPs. The agricultural biogas plant that emitted more than 4.6% (plant 11, Table 4) actually had the lowest level of biogas production (Table 4). Of the agricultural plants, the highest CH_4 loss was 8.4% (biogas plant 11). The reported loss was based on two measurement campaigns, which both showed high CH_4 emissions. There was no on-site gas utilisation and no open mixing tanks, digestate storage tanks or similar. A specific reason as to why the biogas plant had a higher loss than

Table 4

the average agricultural biogas plant was thus not identified. In general, the CH_4 emission rate relative to production seemed to correlate with the size of the biogas plant (Fig. 1), in that units with the highest gas production emitted proportionally less CH_4 compared to plants with relatively low output. One reason for this finding may be that the larger facilities have more economical resources for maintenance, re-investment and employment of highly proficient plant operators. Another reason may be that the number of potential emission sources (number of process units, pipes, joints, valves, etc.) is not necessarily proportional to the rate of biogas production. There was also the tendency that the larger agricultural plants were built more recently and thus may better represent the most up-to-date technology. CH_4 emission from biogas plants is not regulated directly in Denmark, so no regulatory explanation for the difference in methane loss for small biogas plants compared to larger plants was found. CH_4 losses from plants built within approximately the last 5 years (plants 1, 2, 5, 6 and 8) were relatively low (0.4, 1.8, 0.6, 2.6 and 0.6%, respectively). Two of the 13 agricultural plants were solely energy plants, where the input was mainly crops grown specifically for energy production, and both had CH_4 losses lower than the average for all plants.

As mentioned previously, agricultural biogas plants rely mostly on revenue from energy production for their existence, whereas energy production is a secondary activity in the case of wastewater treatment biogas plants. The economic incentive to maximise energy production, and therefore minimise leaks, may therefore be stronger for agricultural biogas plants. Finally, it should be noted that in this study total CH_4 emissions from the plants were measured. Wastewater treatment plants are more complex in structure than agricultural biogas plants, as they also have a water treatment operation in addition to sludge management and biogas production. Therefore, CH_4 emission rates measured at wastewater treatment biogas plants could also encounter CH_4 emissions from the water treatment line and from the open storage of sludge, which is more common at WWTPs in comparison to agricultural plants. However, at WWTPs, the main CH_4-emitting source will be biogas activities, even though CH_4 emissions can also occur from the plant inlet and from aeration tanks. Samuelsson et al. (2018) quantified CH_4 emissions from various unit processes at a WWTP and found that overall, about 81% of the CH_4 emissions quantified on site were released from the sludge treatment line. Delre et al. (2017) came to a similar conclusion based on on-site screenings of atmospheric CH_4 concentrations, where the highest elevated intensities were seen in the vicinity of sludge treatment activities. Sludge (un-digested or digested) storage in open tanks or basins can be a potential source of CH_4, which is challenging to quantify due to the large open surface area. At some of the WWTPs, open digestate storage of sludge could explain (but only partly) the higher emission rates. As an example, the average CH_4 loss at WWTPs with open storage was 9.2% in comparison to plants without on-site open storage (6.1%).

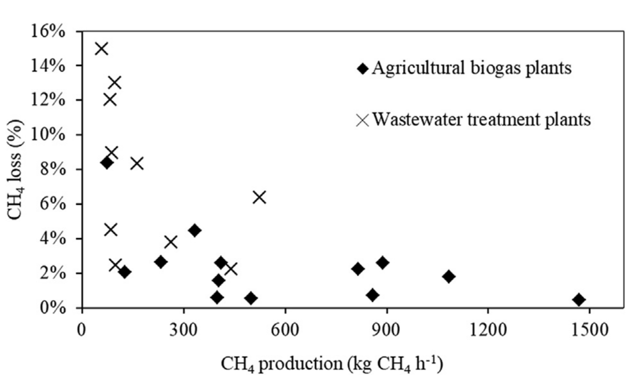

Fig. 1. Average CH_4 loss as a function of the average gas production at biogas plants.

Finally, it should be noted that at four of the plants (5, 11, 14 and 21) all gas utilisation occurs off site and at three of the plants part of the gas utilisation (~70–80%) occurs off site (plants 3, 4 and 7). For these plants, any CH_4 emission from the off site utilisation was therefore not included in the measured total CH_4 emission and thus the total CH_4 emission from the combined production and utilisation could be higher than the values reported in Table 4. At two of the plants (WWTPs 14 and 21) the generated biogas is routed off site for biogas upgrading. CH_4 emission factors from biogas upgrading units vary depending on technology applied. An average CH_4 slip of 0.81% was recently reported based on measurements of nine biogas upgrading units located in Denmark (Kvist and Aryal, 2019). The highest (1.97%) CH_4 slip was detected in the water scrubber methane upgrading technology, while the lowest (0.04%) CH_4 loss was detected in an amine based chemical scrubber (Kvist and Aryal, 2019). At five of the plants (agricultural plants 3, 4, 5, 7 and 11) the generated biogas is used (or partly used) in a CHP located off site. Liebetrau et al. (2013) found biogas co-generation units to emit on average 1.74% of the utilized methane with losses ranging from 0.40 to 3.28% (based on measurements at 10 biogas plants).

3.2. Contribution of methane emissions to the overall CO_2 footprint

Applying the methodology described in Section 2.4, the importance of various levels of CH_4 loss on the environmental performance of an agricultural biogas plant was assessed (Fig. 2). The impact in terms of GHG emissions (reported in CO_2-eqvivalents) of the different levels of CH_4 loss was assessed for three scenarios. In scenario A, biogas is upgraded to biomethane and substitutes for natural gas. In scenario B, biogas is utilised in a CHP unit, whereby electricity is supplied to the grid, and heat is used for district heating. In scenario B, the average emission factor regarding the production and consumption of electricity was used, as described in Section 2.4. In scenario C, biogas is also used in a CHP unit, but here the marginal emission factor for the production and consumption of electricity (Section 2.4) was used, meaning in this case that electricity production replaces more fossil fuel.

In all scenarios, CH_4 losses from biogas plants had a significant effect on the overall CO_2 footprint (Fig. 2). At 5% loss, CH_4 emissions make a greater contribution to the CO_2 footprint burden (positive CO_2 emission) compared to the other individual positively contributing emissions, namely energy consumption and the transportation of feedstock and digestate in all scenarios.

In scenarios A and B, a CH_4 loss of 20% caused the net GHG emissions to be positive, meaning that the biogas plant can be considered a net emitter of GHG, despite the substitution of fossil fuels, the reduction of GHG from manure storage and the substitution of chemical fertiliser. This is seen similarly in Table 5, where emission factors are listed for the three scenarios and five levels of CH_4 loss. These emission factors are the calculated net GHG emissions of the biogas production per one tonne of feedstock (wet weight) derived from the calculation example described in Section 2.4. The emission factors vary significantly in cases where CH_4 loss is relatively low (1–2%), to cases where the loss is relatively high (10–20%). The results also show that the emission factors in scenario B (CHP, average) vary highly in comparison to scenario C (CHP, marginal). The cause of this difference is the much lower electricity emission factor in the average mix of electricity sources (0.053 kg CO_2-eq. MJ^{-1}) compared to the marginal emission factor (0.24 kg CO_2-eq. MJ^{-1}) (Table 3).

The average CH_4 emission from the 13 agricultural biogas plants equated to 2.4% of the daily plant production (Table 4). Comparing this average CH_4 emission to implications on the total CO_2 foot-

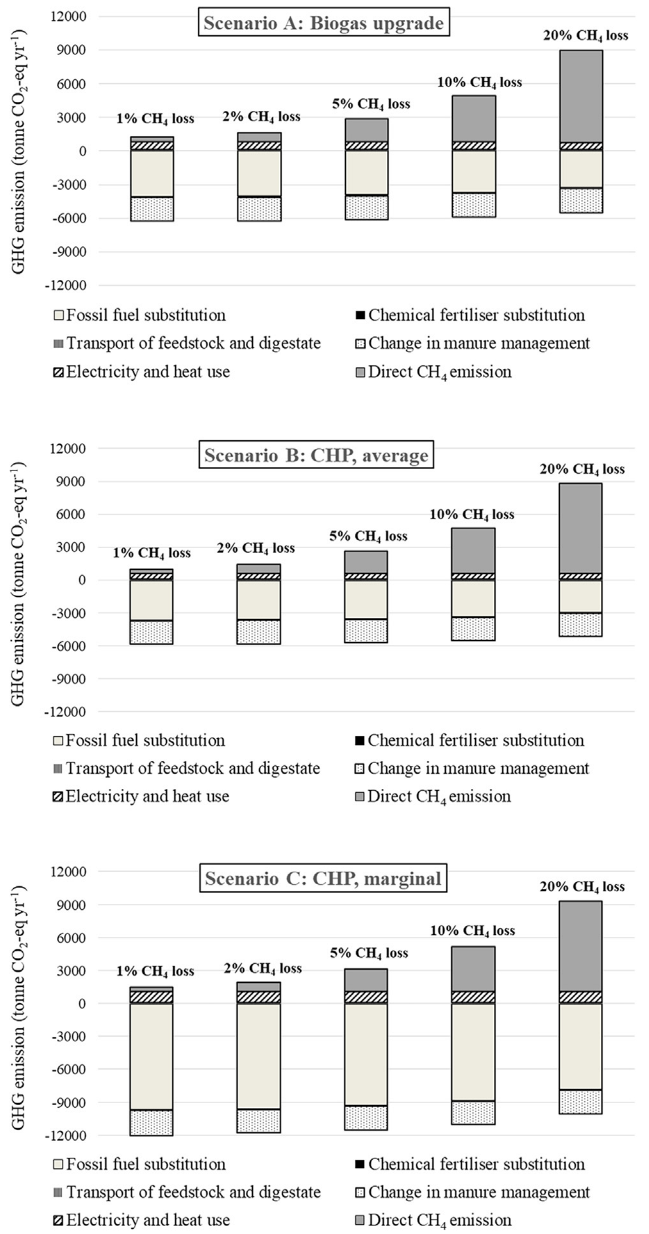

Fig. 2. Greenhouse gas (GHG) emissions calculated for an agricultural biogas plant, considering different biogas utilisation scenarios and five levels of methane (CH_4) loss. CHP: Combined heat and power.

print shown in Fig. 2, this relatively low loss indicates that the production of biogas is a net benefit with regards to GHG emissions. Since CH_4 emission rates compared to production varied greatly between biogas plants (Table 4), it is also likely that the CO_2 footprint of each individual plant will do so, too. Biogas plants, where the loss is particularly high (more than ~15%), may be net emitters of GHG, which underlines the importance of minimising CH_4 emissions from these facilities.

In this study, the carbon footprint of WWTPs was not determined, mainly because the primary purpose of a WWTP is not biogas generation but wastewater treatment, which implies that the services provided by the two types of plants are not comparable. Furthermore, not only CH_4 but also N_2O (another potent GHG) is emitted from WWTP,s primarily from the water treatment line, which needs to be included in footprint calculations. For an evaluation of the carbon footprint for biogas plants located at WWTPs, we instead refer to a recent study by Delre et al. (2019), which assessed carbon footprints for seven Scandinavian WWTPs, including some of the plants in this study. The study showed net carbon footprint values between 0.15 and 0.66 kg CO_2 eq. (Mg of input material)$^{-1}$, depending on the treatment facility. Direct CH_4 and N_2O emissions were the main contributors to the carbon footprint, accounting for between 44 and 71% of the total emission burden (Delre et al., 2019).

3.3. Fugitive methane emissions from Danish biogas production

Danish biogas producing facilities can be divided into four categories: agricultural (centralised and farm-scale) biogas plants (mainly treating manure), industrial biogas plants, wastewater treatment biogas plants (treating sewage sludge) and landfill gas. In total, 165 biogas-producing plants exist in the form of 82 agricultural (28 centralised and 54 farm-based), 51 wastewater treatment biogas, five industrial biogas and 27 landfill gas facilities (Danish Energy Agency, 2017b). The production of biogas has increased from 266 TJ (~5328 tonnes of CH_4) in 1990, to 7899 TJ (~157,985 tonnes of CH_4) in 2016 (Nielsen et al., 2018). In 2016, 86% of the generated biogas was based on manure/organic waste, 12% on sludge from wastewater treatment and only 2% came from landfills (Nielsen et al., 2018). Biogas production at the plants from which emissions were measured in this study represented about between 41% (agricultural) and 45% (WWTPs) of the annual Danish total (in 2016). National CH_4 emissions from Danish biogas production were estimated by applying the measured CH_4 emission factors to nationally generated CH_4 production, distinguishing between emission factors from agricultural and WWTP biogas plants, respectively. Two sets of CH_4 emission factors were used: a plant average and a weighted production average. The plant average was an average of CH_4 losses measured at the plants (sum of CH_4 losses divided by the number of plants), whereas the weighted production average was the sum of all CH_4 emission rates divided by the sum of all plants' CH_4 production rates (cf. Table 4). The plant average represents the biogas technology, whereas the weighted production average represents the combined biogas production in Denmark. Table 6 shows the estimated national CH_4 emissions (tonnes CH_4) for agricultural and WWTP biogas plants, and the total. The total estimated CH_4 emissions are between 3409 and 4683 tonnes, with emissions from agricultural biogas plants making up 6870%, while 30–32% originate from WWTPs (Table 6).

The 2006 IPCC Guidelines consider emissions from biogas plants (anaerobic digestion) as part of the waste sector. According to the IPCC Guidelines, emissions of CH_4 from biogas facilities, due to unintentional leakages during process disturbances or other unexpected events, will generally be between 0 and 10% of the

Table 5
Greenhouse gas emission factors (kg CO_2-eq tonne feedstock^{-1}) calculated for different biogas utilisation scenarios and five levels of CH_4 loss. A negative value implies an overall benefit to the environment, while a positive value implies an overall burden to the environment.

Scenario	1% loss	2% loss	5% loss	10% loss	20% loss
	(kg CO_2-eq tonne feedstock^{-1})				
Scenario A: Biogas upgrade	−44.6	−40.7	−29.0	−9.4	29.7
Scenario B: CHP, average	−42.1	−38.2	−26.5	−7.0	32.0
Scenario C: CHP, marginal	−89.7	−85.3	−72.0	−49.9	−5.7

Table 6
Estimated national CH_4 emissions from the anaerobic digestion of organic waste in agricultural biogas plants and biogas plants at wastewater treatment plants (WWTPs) in 2016 (excluding landfill gas). Numbers in brackets give the percentage out of total CH_4 emissions (excluding landfill gas).

Biogas plant type	Agricultural biogas plants	WWTP biogas plants	Total
CH_4 production, tonnes	135,867	18,958	154,825
CH_4 emission, tonnes (Plant average; $EF_{Agricultural}$ = 2.4% and EF_{WWTP} = 7.5%)	3261 (70%)	1422 (30%)	4683
CH_4 emission, tonnes (Production average; $EF_{Agricultural}$ = 1.7% and EF_{WWTP} = 5.8%)	2310 (68%)	1100 (32%)	3409

amount of CH_4 generated. In the absence of further information, a default value of 5% for the CH_4 emissions should be used (Eggleston et al., 2006).

CH_4 emissions from biogas production are reported in the Danish national greenhouse gas inventory as being a part of the waste sector's GHG emissions (Nielsen et al., 2018). CH_4 emissions were reported at 6635 tonnes in 2016, using an average adopted emission factor (EF) set equal to 4.2% for all types of biogas plants. This emission factor was based on a Danish project where CH_4 leakages were measured at nine biogas plants in Denmark, using on-site point measurement methods (Danish Energy Agency, 2015). Five of the plants were small, single-farm plants, while the other four were larger, centralised agricultural plants. The results were that the CH_4 losses varied from nil to 10% of production, resulting in a weighted average of 4.2%, which was adopted in the national inventory reporting for biogas production independently of the type of biogas plant. Our study shows a lower emission factor from agricultural plants, whereas the emission factor from biogas plants at WWTPs is higher than 4.2%. However, as the share of biogas generated at WWTPs is lower (12%) in comparison to agricultural plants (86%), the combined CH_4 emissions from these two types of facilities are almost comparable, resulting in a national emission of 3409 to 4683 tonnes of CH_4, which is close to the nationally reported figure.

The Danish Biogas Association is a trade organisation representing the Danish biogas sector, with members including plant owners, suppliers, agriculture and energy companies. Within the last few years, this organisation has initiated a voluntary measurement programme with the aim of keeping CH_4 loss at a minimum via a target of 1% loss for the sector. Our results indicate that some improvements are needed to reach this goal. However, the production weighed average loss was just 1.7% for the agricultural biogas plants, where most gas is produced and where production capacity is expanding, and thus the 1% target for the sector as a whole seems to be within reach. However, at plant level, emission rates are higher.

4. Conclusions

Methane losses were measured at 23 biogas plants and found to vary between 0.4 and 15.0% of the production total. Comparing those measured losses to an evaluation of the impact of methane loss on the overall carbon footprint of biogas production, it may be the case that methane loss is the largest positive contributor to greenhouse gas emissions for many biogas plants compared to other factors, such as energy use and the transportation of biomass.

Acknowledgements

This paper presents results from several research projects as well as measurements performed to develop a voluntary measurement programme to monitor CH_4 emissions from biogas plants in Denmark. The Danish Energy Agency, the COWI foundation and the owners of some the biogas plants included in this study are acknowledged for funding the measurements. We thank plant managers and personnel for their cooperation.

The False Promises of Biogas: Why Biogas Is an Environmental Justice Issue

Phoebe Gittelson,* Danielle Diamond, Lynn Henning, Maria Payan, Lynn Utesch, and Nancy Utesch

ABSTRACT

Years of community-driven research and participatory action have shed an important light on the copious negative health issues burdening communities adjacent to industrial agriculture. Rural communities in Wisconsin and Delaware have helped us in establishing an emerging source of pollution toward environmental justice communities—biogas. Biogas is being falsely marketed as a renewable energy solution to solve the problems of an already polluting industry, Concentrated Animal Feeding Operations (''CAFOs''). This greenwashing is problematic for many reasons and is in itself an environmental justice issue. The production of biomethane from manure-to-energy projects, such as manure digesters, is hazardous to local communities, locks farmers into more debt, and perpetuates the expansion of our current harmful agriculture practices, while increasing fossil fuel infrastructure by entrenching CAFOs with pipelines for the gas that is produced. In this article, we breakdown why biogas is not sustainable, how manure-to-energy projects perpetuate environmental injustices, examine current state policies on manure-to-energy projects, and how policy can be improved to protect frontline communities and farmers.

Keywords: CAFO, biogas, manure digesters, biomethane, environmental justice, factory farm

INTRODUCTION

There is a suite of social science and public health studies that have documented environmental injustices in rural areas stemming from industrialized agriculture and other extractive industries.[1] A pattern of negative pollution and public health consequences of industrial animal agriculture facilities threatening environmental justice communities in rural areas has been established.[2]

Ms. Gittelson is a J.D. Candidate at City University of New York School of Law, Long Island City, New York, USA (May 2021) and a Research Assistant and Intern for Danielle Diamond at the Socially Responsible Agricultural Project. Ms. Diamond is the Senior Director of Research and Resources at the Socially Responsible Agriculture Project in Golden, Colorado, USA and is also a Research Associate at Department of Anthropology, Northern Illinois University, DeKalb, Illinois, USA. Ms. Henning is a Director of Field Operations at the Socially Responsible Agricultural Project, Golden, Colorado, USA. Ms. Payan is a Regional Field Associate at the Socially Responsible Agricultural Project, Golden, Colorado, USA. Research has shown that improving sustainable healthy rural communities is found to be dependent on integrating socioeconomic development and environmental protection.[3] The concentration and industrialization of agriculture are associated with economic and community decline locally and regionally,[4] and one of the most significant social impacts of Concentrated Animal Feeding Operations (''CAFOs'') is found to be the disruption of quality of life for neighboring residents.[5] Furthermore, it has been established that CAFOs are disproportionally located in communities of color and, or low income communities—a form of environmental injustice that has negative impacts on community health.[6]

We identify a growing problem in this realm that is disguised as a solution to the waste problems caused by CAFOs—biogas or manure-to-energy projects. Although the agribusiness industry, government, and even public interest environmental organizations have touted this technology as beneficial to the environment, farmers, and rural communities, we find the opposite to be true. We bring to light government regulatory failures, failures in environmental justice initiatives, and the reality of environmental harms that are exacerbated by biogas systems.

Our research seeks to bridge the divide between social science and public health research with laws and policies that perpetuate the problem, as opposed to address it. We offer policy solutions to address some of the problems rural communities are experiencing as a result of the false promises of biogas technology.

BACKGROUND

Dr. Sacoby Wilson's groundbreaking research in ''Environmental Injustice and the Mississippi Hog Industry'' revealed that living near industrial hog operations is a major public health concern for disproportionately burdened communities.[7] This study and others also referenced herein indicate that emissions from swine confinement houses are associated with adverse respiratory problems and a decline in quality of life for communities in their proximity.[8] The high density of hogs grown in confinement houses produce vast amounts of waste,[9] and community members who live close to these operations may have adverse health effects such as irritation to their eyes, noses, and throats; decline in quality of life; and possible mental health disorders. There are also water quality problems associated with leakage from the manure lagoons, and runoff from the spray fields that can contaminate surface and groundwater.[10] Some of the environmental contaminants emitted into the atmosphere include ammonia, hydrogen sulfide, volatile organic compounds, particulates, and other pollutants.[11] Wilson's research reveals the disproportionate amount of CAFOs in Black communities and how these hazardous operations adversely impact the physical, mental, and economic health of rural communities.

Dr. Wilson continued to expand on this research in ''An Ecologic Framework to Study and Address Environmental Justice and Community Health Issues'' (2009).[12] In this study, Wilson discusses the history of environmental justice and expands the vocabulary needed to accurately describe the many layers of intersecting structural oppression. He states as follows:

> I introduce the terms ''environmental slavery'' and ''environmental servitude'' as interchangeable conceptualizations that capture the experience of disadvantaged and vulnerable communities who are differentially exposed to unhealthy environmental conditions and resource-poor settings. Vulnerable communities are used (directly or indirectly) to host social and environmental disamenities and externalities through planning, zoning, industrial siting, infrastructure and development inequities; while communities consisting of dominant racial and class populations benefit from the inequities, access to more amenities, and the ecological goods and services of host communities. There is an underdevelopment and/or destabilization in the growth, health, and quality of life of host communities overburdened by environmental and social externalities and spatially and socially bounded by limited access to environmental amenities. Moreover, the footprints (ecological, economic, and social) of dominant racial and class populations lead not only to the use of host communities as sinks, but also the use of individual community members as sinks for environmental and psychosocial stressors.[13]

[9]The new trend of large-scale production involves a high density of hogs grown in confinement houses and producing vast amounts of waste. The hog waste is collected and stored through different systems, including below-floor slurry storage (deep pit), underground slurry storage, anaerobic lagoons, and oxidation pits. One of the most popular methods is the storage of the waste in anaerobic cesspools, commonly called ''lagoons,'' where it undergoes microbial digestion. The hog waste effluent is later sprayed onto fields. Ibid at 195.

[13]Ibid.

Research'' (2006), the authors examine the significant racial and socioeconomic disparities associated with hazardous sites, and the variation within the disparities found.[14] Their study addresses the failures of current methods used to assess environmental disparities adequately in accounting for the proximity between the hazard under investigation and nearby residential populations.[15]

Christopher W. Tessum expands on these inequities in ''Inequity in Consumption of Goods and Services Adds to Racial–Ethnic Disparities in Air Pollution Exposure'' (2019). This seminal study found that Black and Hispanic communities on average bear a ''pollution burden'' of 56% and 63% excess exposure, respectively, relative to the exposure caused by their consumption.[16] $PM_{2.5}$ air pollution is disproportionately induced by the racial–ethnic majority and disproportionately inhaled by racial–ethnic minorities.[17]

Dr. Wilson lays out a holistic framework to address environmental justice and health issues by reiterating that we must take an ''ecological systems approach to community health, [which] incorporates spatial and temporal concepts on the social organization of our living environments, considers ecologic features of the built and social environments that influence health, and utilizes contextual expertise to address environmental justice and health issues at the community level.''[18]

Although social and public health scientists have identified rural areas as a geo-special dimension of environmental justice research,[19] rural environmental injustices have lacked proper attention by the environmental justice movement as a whole. Notably there is a void of adequate legal and policy solutions available to rural people.[20]

Correspondingly, research is revealing how government-driven agricultural policies legalize pollution and the differential treatment of rural people. The greenwashing of biogas as a solution to the environmental hazards associated with CAFOs is an example of this kind of legalized pollution.

METHODS

Our research is community driven in nature—in that questions about whether farmers should invest in manure-to-energy projects, and how and why governments are supporting them, were questions that needed immediate answers in communities already burdened by manure-to-energy projects. In collaboration with our community partners significant data was collected through publicly available government records, or records obtained from various governmental agencies through the Freedom of Information Act. We also researched government laws and regulations; scientific and other kinds of peer-reviewed journals, biogas industry trade magazines and other types of publications. In addition, we incorporate both participant observation and participatory action research conducted via community engagement with the Socially Responsible Agriculture Project (''SRAP''), and the rural communities in which SRAP works. We participated with our community partners in the engagement of public officials and regulatory entities to try to address problems or anticipated problems from CAFO biogas facilities. For example, we explored how California's cap-and-trade program generates carbon-offset credits for factory farms with biogas digesters in Wisconsin. From this background research,[21] we were able to better understand the motivation for the expansion of biogas infrastructure to factory farms. Through these methods we observed how harmful biogas projects were being perpetuated in part through government action, despite the sunlight being shown on their false promises.

FINDINGS

One of our major findings that became apparent throughout our engagement was the government's lack of understanding and lack of transparency regarding how industrial agriculture facilities, and their waste streams, directly harm rural communities that are fenceline to CAFOs. In this article, we shine a light on the budding issue of manure-to-energy projects because rural communities are alarmed by the transformation of CAFOs into combined factory farms and biogas facilities under the guise of ''green energy'' or ''compost projects.'' In this study, we explain how a lack of oversight, regulation, and transparency perpetuates the expansion of industrial agriculture in already burdened environmental justice communities. We argue that biogas is not a solution and

examine current policy while also suggesting policy recommendations that shift away from this polluting industry and instead invest back into communities.

Biogas is an environmental justice issue

Biogas is not sustainable. Although biogas comes from organic materials such as animal waste or food waste, it is hardly ''clean'' or ''green'' in the way most people understand those concepts.[22] Biogas is flammable, highly toxic, and potentially explosive.[23] Harmful compounds and air contaminants are introduced into the environment during biogas production and use through both combustion processes and diffusive emissions.[24] Burning manure-produced gas emits the same air contaminants as the combustion of fossil fuels. To make matters worse, the factory farms that produce the biomethane can emit harmful pollutants into the air and discharge nitrates into groundwater.[25]

Manure-to-energy projects, specifically manure digesters,[26] are sold as a solution to farmers to help them mitigate the costs of production by turning excess animal waste into energy through biogas. The installation of a manure digester on a factory farm is the first step for farmers in the process of turning their manure into a revenue stream, but it is also the first step in entrenching factory farms in more fossil fuel infrastructure, as producing and transporting biogas requires pipelines, fleets of trucks, and interconnection with the local power grid.[27] Furthermore, gas pipelines and other infrastructure leak tremendous volumes of methane that contribute to climate change, negating any alleged ''renewable natural gas'' savings.[28] Annual methane emissions have increased by about 50 million tonnes from the 2000–2006 average, mainly driven by agriculture and the natural gas industry,[29] and atmospheric concentrations of methane are now >2.5 times above preindustrial levels.[30] Although methane is only one component of total factory farm greenhouse gas emissions, these also include enteric methane, nitrous oxide (NOx) from fertilizer and manure application, and carbon dioxide from fuel combustion and input manufacture.[31]

Studies show that even if manure digesters were installed on every single dairy farm across the country and worked at optimal efficiency, this would still fall short of the industry's goal of reducing its total greenhouse gas emissions by 25%.[32] Similar to biogas, natural gas has been falsely marketed as a renewable and clean energy source, whereas in reality it destroys communities and has been proven to be a radioactive and hazardous energy source.[33] Biogas is the industry's next attempt at greenwashing another polluting fuel to save their industry. Fossil fuels, including natural gas fields and leaking pipelines, contributed 108 million tonnes of methane emissions in 2017, a rise of 17%.[34] Ultimately, biomethane is a false solution that perpetuates the expansion of big ag monopolies, the toxic, hazardous, and destructive practices of CAFOs and fossil fuel infrastructure.

Manure-to-energy projects perpetuate environmental injustices. Factory farms are inherently polluting entities that poison adjacent rural communities with toxic chemicals that eventually cause local public health disasters, economic hardship, and generational trauma.

[26]Manure digesters use anaerobic digestion to convert organic material into biogas, which can then be refined into biomethane and used to produce electricity. Three main substances come out of the process of manure digestion, methane gas, also known as biomethane, that can be used as an energy source; liquid manure that can be used for fertilizer; and solid manure that can be used for composting and animal bedding. Several studies have shown that a disproportionate number of CAFOs are located in low-income and nonwhite areas and near low-income and nonwhite schools.[35] These facilities and the hazardous agents associated with them are generally unwanted in local communities and are often thrust upon those sectors with the lowest levels of political influence.[36]

CAFOs can house anywhere from hundreds to millions of animals—the quantity of urine and feces from even the smallest CAFO is equivalent to the urine and feces produced by 16,000 humans.[37] The waste produced at factory farms contains antibiotics, hormones, pathogens, heavy metals, and other animal drugs and chemicals that contaminate significant ground and surface water across the country. Noxious gases are also released through ventilation systems from the CAFO confinement houses, and environmental contaminants are also released through volatilization from the waste decomposing in lagoons, spray fields, and other waste collection sites.[38] Furthermore, studies show that manure management activities are the third major category of U.S. agricultural emissions, releasing NOx and methane in quantities that total 16% of total U.S. agricultural emissions.[39]

Manure-to-energy projects have a direct negative impact on frontline communities. In a recent study, ''the Composition and Toxicity of Biogas Produced from Different Feedstocks in California,'' scientists found that the concentrations of minor chemical and biological components in biogas have ''the potential to be toxic to human health and the environment, to form toxic substances during the combustion process, or to form toxic substances after photochemical aging in the atmosphere.''[40] Furthermore, The California Air Resources Board (CA-ARB) and the Office of Environmental Health Hazzard Assessment compiled a list of 12 trace components potentially present in biogas at levels significantly above traditional fossil natural gas, including carcinogens (arsenic, p-dichlorobenzene, ethylbenzene, n-nitroso-di-n-propylamine, and vinyl chloride) and noncarcinogens (antimony, copper, hydrogen sulfide, lead, methacrolein, mercaptans, and toluene).[41] Because the composition of biogas varies so greatly between feedstocks, and being that there are so few studies on the differences in trace contaminates, it is irresponsible to invest in anaerobic digestion until the public health consequences are determined.

Although manure digesters might have the potential to reduce methane emissions, emissions of other air pollutants, such as NOx may increase to unacceptable levels.[42] Breathing air with a high concentration of NO_x can cause breathing problems, headaches, chronically reduced lung function, eye irritation, loss of appetite, and corroded teeth.[43] Community environmental air quality assessments have shown concentrations of hydrogen sulfide and gaseous ammonia that exceed U.S. Environmental Protection Agency (''EPA'') and Agency for Toxic Substances and Disease Registry recommendations.[44] Studies have reported that neighbors of confinement facilities experienced increased levels of mood disorders, including anxiety, depression, and sleep disturbances attributable to exposures to malodorous compounds.[45] Research has also found that lower concentration and secretion of salivary immunoglobulin among swine CAFO neighbors during times of moderate to high odor compared with times of low or no odor, suggesting a stress-mediated physiological response to malodor.[46] Such stressors, coupled with inadequate health-promoting infrastructure (e.g., supermarkets, parks, open spaces, and medical facilities), reduce the community's ability to defend against the adverse health consequences of their differential burden and exposure.[47]

One recent study, ''Mortality and Health Outcomes in North Carolina Communities Located in Close Proximity to Hog Concentrated Animal Feeding Operations'' (2018), explains that residents living in proximity to hog CAFOs are chronically exposed to contaminants from land-applied wastes and their overland flows, leaking lagoons, and pit-buried carcasses, as well as airborne

emissions, resulting in higher risks of certain diseases.[48] In fact, a previous survey based on studies of residential communities reported significant health risks for residents, including higher risks of bacterial infections, higher frequencies of symptoms of respiratory and neurological disorders, and depression.[49] This exposed that people living in southeastern North Carolina communities located near hog CAFOs had poorer outcomes for a variety of health conditions in different age groups than the residents of North Carolina communities located in zip codes without hog CAFOs; they had higher mortality due to infections, anemia,[50] kidney disease, and perinatal conditions, and higher rates of hospital admissions and emergency department visits for low birth weight infants.[51] The authors conclude that people who live in these types of rural fenceline communities may simultaneously be affected by multiple risk factors, including low income and education, higher smoking prevalence, and lower access to medical care.

In addition, manure digesters installed at CAFOs require supplementary fossil fuel infrastructure, such as miles of pipelines stretching from the CAFO to the refinement facility. This funnels more pollution into and through already burdened local communities. Odor abatement, noise mitigation, truck queuing, effluent discharge, gas pipeline usage, and interconnection with the local power grid requires both physical hookups, and net metering agreements that can impact the health and wellness of neighboring families.[52]

Incentivizing farmers to install manure-to-energy projects instead of encouraging farmers to shift to sustainable farming practices solely profits developers, while locking communities into a cycle of sickness, loss, injury, and destruction. For example, from 2010 through 2019 fifteen Wisconsin dairy CAFOs received 1,317,236 carbon credits for their manure digesters,[53] despite the fact that in May of 2017 the CA-ARB's Environmental Justice Advisory Committee (EJAC)[54] made a priority recommendation to the Board to: ''[S]top investing in dirty energy [and] [e]liminate subsidies and financing for fossil fuels and in technologies such as corn-based biofuels, agricultural methane, biomass burning, waste-to-energy, or other unsustainable technologies that result in negative impacts on environmental justice communities.''[55] In addition, the EJAC advised against committing California ''Cap-and-Trade through the Clean Power Plan,'' since ''carbon trading cannot be verified…''[56] Furthermore, these funds are supposed to be aimed at ''Improving public health, quality of life and economic opportunity in California's most burdened communities at the same time they're reducing pollution that causes climate change.[57]'' Expanding any polluting industry in areas already burdened by factory farms perpetuates the systemic oppression of environmental justice communities.

Manure-to-energy projects are rarely beneficial for farmers. Manure-to-energy projects are expensive, temperamental, and require farmers to produce more waste to

[54]The California Environmental Protection Agency (Cal/EPA) Advisory Committee on Environmental Justice was formed in 2001 to help Cal/EPA incorporate environmental justice into all of its programs and policies. Three key recommendations called for Cal/EPA to recognize the significant burden of toxics and pollution on impacted communities. The advisory committee recommended that Cal/EPA: (1) Use a precautionary approach: A precautionary approach to decision making means that regulations should prevent harm when there is credible evidence that harm is occurring, or is likely to occur—even when complete scientific evidence or proof is not available—in drafting and enforcing regulations. (2) Prioritize pollution prevention over pollution control: All too often communities of color have been left feeling sorry by pollution control—sorry for their lost health and quality of life. (3) Evaluate the cumulative impacts of toxics in an impacted community when making regulatory decisions. This process requires that the health effects of all sources of pollution be taken into consideration when determining the impact of pollution in individuals, communities, and the environment. The landmark environmental justice policies were adopted by Cal/EPA. <https://www.environmentalhealth.org/index.php/en/where-we-work/state-of-california/california-environmental-justice> (Last accessed on March 10, 2021).

meet the needs of the digester.[58] The costs to build and run a manure digester are rarely recovered, especially when taking into consideration both the construction and operating costs. One study revealed that the economic concentration of agricultural operations tend to remove a higher percentage of money from rural communities than when the industry is dominated by smaller farm operations, which tend to circulate money within the community.[59]

Without outside funding from a designee, operator, or developer, it simply does not make financial sense for most farms to build or operate a digester.[60] The capital costs for a digester include lift station pumps, mixing tanks, the digester tank itself, piping for gas and hot water, gas pumps, flow meters, safety features, generators, electrical wiring and controls as well as power transmission lines, design engineering, and on-site buildings for generators, maintenance, and operations.[61] In addition to direct financial considerations, there is considerable overhead generated by legal and management issues, such as insurance premiums, building permits, design and consulting fees, licensing and zoning, sales agreements with utilities to buy back electricity, and more.[62] With capital costs often exceeding $1 million, anaerobic or manure digesters are beyond the price range of most farmers in the United States.[63] The payback period (capital costs divided by annual net benefits) of this capital investment can be between 5 and 6 years.[64]

Grants and cost-share agreements from states, federal programs, and utility companies help fund the cost of manure digesters.[65] For example, in just under a 4-year period beginning in 2010, 12 Wisconsin dairy CAFOs received >13 million dollars in grants from the U.S. Department of Agriculture's Rural Energy for America Program.[66] Additional financial incentives have also been provided to these projects through the U.S. Department of Treasury's administrative of Section 1603 of the American Recovery and Reinvestment Tax Act of 2009,[67] among other programs.[68] California alone has funded >100 digester projects, spending nearly $200 million of its ambitious California Climate Investments dollars on digesters instead of using the money to help fund farmers through its Smart Agriculture Programs.[69] According to the California Climate Investments Annual Report (2020), $69.1 million dollars has been assigned for future dairy digester development and research.[70] Tax payer dollars should be used to fund sustainable farming practices that go directly to farmers instead of to major developers. Unfortunately, these digester projects are also helping to fund gas infrastructure and development, rather than sustainable farming practices, which would create jobs,

[58]The size of a conventional digester is equal to 15–20 times the daily waste volume produced, or more if the waste is diluted before digestion (Don D. Jones, John C. Nye, and Alvin C. Dale. ''Methane Generation from Livestock Waste.'' *Energy Management in Agriculture*. Department of Agricultural Engineering, Purdue University. <https://www.extension.purdue.edu/extmedia/AE/AE-105.html>. (Last accessed on March 10, 2021). The volume of waste that must be disposed of increases accordingly if dilution water is used. The EPA's ''minimum'' requirements reveal what large investment manure digesters are and how they do not reduce the waste on CAFOs, but instead incentivize the farmer to produce even more to *potentially* be successful in making any profit or breaking even from the digester. The U.S. EPA states that for farms to be potentially successful with anaerobic digestion, a minimum of 500 head of cattle, 2000 hogs with anaerobic lagoons or liquid slurry manure management systems, or 5000 hogs with deep pit manure management systems are suggested. (U.S. Environmental Protection Agency. ''Is Anaerobic Digestion Right for Your Farm?'' <https://www.epa.gov/agstar/anaerobic-digestion-right-your-farm>). This significantly limits their use, as more than 90% of dairy farms in the United States have fewer than 500 cows, accounting for 40% of all dairy cows in the country (Peter Lehner and Nathan A. Rosenberg. *Legal Pathways to Carbon-Neutral Agriculture*, 47 Envtl. L. Rep. facilitate carbon sequestering, and empower and rehabilitate rural and frontline communities.

The gas industry has an inherent incentive to convince farmers to invest in manure digesters. From their perspective, it is easier to transform an existing factory to produce and process biogas than to build a new one. Developers and energy executives have been selling the production of biogas as a solution to problems already existing on factory farms (too much manure, open lagoons, etc.), falsely motivating farmers to invest in ''composting[71]'' infrastructure that in actuality is much more complex and extensive, and is built to produce, process, and transport biogas, allowing the gas industry to profit from the dividends of the farmers' practically unpaid labor.

Unfortunately, some states are buying the industry's sales pitch about renewable natural gas and are allowing factory farms to receive carbon offset credits or compliance credits for installing manure-to-energy projects on farms. Carbon cap-and-trade programs allow industrial polluters to pay other pollution sources for their claimed pollution reductions.[72] For example, manure-to-energy projects that meet California's carbon offset protocols can be traded through its cap-and-trade program by approved national registries or through private contractors, or designees, who are registered with the state.[73] The polluting entity can then use the credits obtained from the trade to meet states' air pollution control standards. Negotiated agreements for the exchange of carbon credits are generally done in a private market, so it is difficult to know exactly how much money or other benefits manure digester projects receive.[74] Also, many factory farms that are receiving these credits are not in compliance with environmental and health regulations.[75] Critics such as the Institute for Agriculture and Trade Policy and the National Family Farm Coalition have argued that carbon markets are inherently inequitable, lock out most farmers, and could lead to more pollution, particularly in disadvantaged communities.[76] In short, the public is footing the bill for manure digesters,[77] whereas the CAFO industry profits by offsetting operation costs, selling the energy to utilities, and selling their claimed air pollution reductions to other polluters. Taxpayer dollars should be used to fund sustainable farming practices that go directly to farmers and environmental justice communities instead of to the pockets of major developers.[78]

(Last accessed on March 10, 2021).

[78]Manure to energy projects that meet California's carbon offset protocols can be traded by approved registries or through private contractors, or designees, that are registered in the state's Compliance Instrument Tracking System Service before these manure-to-energy projects are submitted. The California-based polluting entity can then use the credits obtained from the trade to meet the state's air pollution control standards. Negotiated agreements for the exchange of carbon credits are generally done in a private market. Thus, it is difficult to know exactly how much money or other benefits manure digester projects receive. However, the private company 3Degrees Group explains that digester projects are very expensive and carbon credits provide a very important stream of revenue to help make the projects economically viable <https://3degreesinc.com/resources/sunny-knoll-farm-digester/>. (Last accessed on March 10, 2021).What's important to understand, is that this program only benefits those that are able to comply with the rigorous guidelines of the California Air Resource Board's (''ARB'') Offset Protocols. Those that abide by these standards can generate offset credits that are facilitated by Offset Project Registries (''Registries'') <https://ww2.arb.ca.gov/our-work/programs/compliance-offset-program/offset-project-registries>. These Registries help facilitate the listing, reporting, and verification of offset projects developed, and issue Registry offset credits (''ROCs''). Id. But these ROCs cannot be used for compliance with the Cap-and-Trade Program, they need to be converted to ARB offset credits to be eligible for use in the Cap-and-Trade Program. After the issuance of ROCs, the ARB determines whether ARB offset credits should be issued for each offset project. If a project wants to deliver voluntary offsets, they may monitor, report, and verify greenhouse gas emission reductions under the Livestock Offset Protocol, but elect not to transition the resulting ROCs issued by the Registries to ARB offset credits, and are free to deliver the ROCs on the voluntary market. <https://ww2.arb.ca.gov/sites/default/files/classic/cc/capandtrade/protocols/livestock/livestock.2014.faq.pdf>. (Last accessed on March 10, 2021): 5. This complex system of compliance to even be eligible to receive carbon credits or participate in the carbon market is just another example of the powerful agriculture industry consolidating and dominating against those that are not part of the system. Funding and developing manure-to-energy projects does not benefit your average farmer because to actually profit from the project, you need to spend copious amounts of time and money toward being recognized by the ARB as an offset project, and even so, might not be granted the credits by the Registries to participate in the market. Those that opt in to allowing ARB recognized developers to front and fund the projects do not benefit from the cap-and-trade revenue and are stuck with operating costs.

Current national and state policies perpetuate environmental injustices and fail to support rural communities and sustainable farming practices

As of now, our national agriculture policies do not protect or incentivize sustainable farming practices that are necessary to build back national soil health and sequester carbon. Instead of subsidizing false solutions such as manure-to-energy projects, we must organize to reform our national and local-level farm bills and other government programs to invest and insure renewable, just, and equitable farming practices.

Some states are already taking the initiative to fight against the expansion of biogas. New York State just recently passed one of the country's most progressive climate-forward policies in its Climate Leadership and Community Protection Act (''CLCPA'').[79] The CLCPA ''prohibits waste-to-energy projects'' and ''biofuels used for energy or transportation purposes.[80]'' In essence, the state has banned the future development of manure-to-energy projects from its renewable energy platform. This kind of innovative lawmaking protects and prioritizes environmental justice communities, ensuring disadvantaged communities are not disproportionally burdened with more polluting infrastructure.

As we explained earlier, unlike New York, other states are propping up manure-to-energy projects as a gateway to regulatory ''compliance'' and profit through carbon cap-and-trade markets. For example, SRAP found Wisconsin CAFOs, which already struggle with pollution and other compliance issues, participate in and, therefore, benefit from the CA-ARB carbon trading program.[81] Regardless of the claimed air pollution reductions by CAFO manure digesters, we found numerous types of pollution events and regulatory problems caused by CAFOs participating in the program.[82] The CA-ARB carbon trading program does not take into account the severity of the environmental or health consequences of the regulatory violation.[83] CA-ARB invalidation verifiers should be checking for all violations of local, state, and federal laws that occur between initial waste collection and final disposal—not just specific dates of air-related noncompliance issues.[84] Strengthening regulations for factory farm operations and manure-to-energy projects is essential in protecting local communities from unnecessary health and economic burdens.

There are many ways that we can expand the programs currently in place to benefit struggling farmers and fenceline communities. Ensuring funding from existing federal conservation programs such as the Conservation Stewardship Program and Environmental Quality Incentives Program are directed toward truly sustainable farming practices, as well as expanding and creating local programs such as California's Healthy Soils Program Incentives, will help farmers and communities in numerous ways.[85] It is also imperative that we create new agriculture programs that lead with Indigenous knowledge, while creating equity and economic opportunities for Tribes and Indigenous communities. Shifting away from factory farming will create more jobs while bringing integrity, joy, and community back to farming.

The agribusiness industry's position that manure-to-energy projects help address climate change and CAFO waste problems needs to be more thoroughly studied and scrutinized. The reality experienced by those living in surrounding communities is that CAFOs rarely, if ever, actually deal with the pollution problems they create.[86] If nothing else, manure-to-energy projects have served as a facade to further a failed system that benefits the few at the expense of the public and the environment. Policymakers should be effectively enforcing existing environmental and public health regulations, as well as supporting and promoting more sustainable forms of livestock production and legitimate renewable energy programs.

RECOMMENDATIONS

Other policy suggestions include the following:

- There needs to be more openness and government transparency in permitting and other regulatory issues related to manure-to-energy projects.
- Governmental bodies need to stop providing financial incentives for the development of CAFO manure-to-energy technologies and instead focus funding on the promotion of sustainable agricultural practices.
- Subsidies that go to CAFOs must be eliminated so that traditional pasture-based animal agriculture and regenerative agriculture has a fair opportunity to compete and succeed in a free market.
- The federal government and states should establish, strengthen, and effectively enforce existing air and water pollution laws against CAFOs and stop subsidizing these facilities, particularly those that have caused pollution.
- States and local governments should provide citizens with more robust citizen suit provisions for enforcing environment regulations (similar to those provided under the federal Clean Water Act and Michigan's Environmental Protection Act). This way, the public would have greater ability to enforce environmental regulations when responsible agencies fail to act.

[81]SRAP. ''Trading Pollution: Wisconsin Industrial Dairies with Documented Regulatory Compliance Problems Benefit from California Greenhouse Gas Cap-and-Trade Program.'' Press Release, August 2020. <https://sraproject.org/2020/08/2016/>. (Last accessed on January 31, 2021).
[82]Ibid.
[83]Ibid.
[84]Ibid.
[85]''Are Carbon Markets for Farmers Worth the Hype?.'' <https://civileats.com/2020/09/24/are-carbon-markets-for-farmers-worth-the-hype/>. (Last accessed on March 10, 2021).
[86]SRAP. ''Trading Pollution: Wisconsin Industrial Dairies with Documented Regulatory Compliance Problems Benefit from California Greenhouse Gas Cap-and-Trade program,'' Press Release, August 2020. <https://sraproject.org/2020/08/2016/>. (Last accessed on January 31, 2021).

- Environmental protection and enforcement measures should be strengthened to reduce pollution, as opposed to using pay-to-pollute schemes.
- Congress could condition the receipt of federal subsidy funds in the agricultural sector on the implementation of truly sustainable farming and feedstock practices, and federal government should rescind support for manure biogas projects. Companies participating in the carbon market should have to demonstrate certification of sustainable operations before receiving any federal permits or other government approvals.[87]
- States should adopt or expand programs aimed at greenhouse gas emissions mitigation or sequestration from the forestry or agricultural sectors, such as[88] the following:
  - Create more local subsidy programs, such as California's Smart Agriculture Programs, that create value in land's carbon sink potential and shape cultivation techniques consistent with decarbonization objectives.
  - State governments should consider requiring farm owners to comply with basic climate-friendly practices, such as installing buffer strips next to streams, to receive tax benefits for agricultural activities or easements.[89]
    - The CA-ARB's program should take into consideration the type and magnitude of regulatory violations in addition to total periods of noncompliance when invalidating carbon credits. The current program that invalidates credits only for the time period in which the violation occurred is an inadequate deterrence for poor management.
    - The CA-ARB should meaningfully address input provided by its EJAC to ''[s]top investing in dirty energy'' and to eliminate subsidies and financing for ''waste-to-energy and other unsustainable technologies'' that impose negative impacts on environmental justice communities.
- The carbon credit market should be nationalized, instead of privatized, and credits should only be traded locally.
  - The CA-ARB should place geographic restrictions on trading and limit the amount of pollution ''offset'' credits that companies can use to comply with the program. This will help incentivize local emissions reductions and the annual statewide reduction of GHGs.
- Congress should require the Farm Service Agency and the Farm Credit System lending institutions to offer programs providing favorable credit to farmers and ranchers using truly sustainable and climate-friendly practices relating to all loans.
- States should look to New York State and its climate-forward policy in its Climate Leadership and Community Protection Act (''CLCPA'') and create more innovative laws that protect and prioritize environmental justice communities, ensuring disadvantaged communities are not disproportionately burdened with more polluting infrastructure.
- All states should look to New York's policy that disallows manure-to-energy projects in its renewable energy portfolio and follow suit.

CONCLUSION

Overall, manure-to-energy projects have the potential to be helpful for small farms (not CAFOs) if the biogas produced on the farm is reused only at that farm. When manure-to-energy projects are installed on factory farms, the processing of the methane produced for the power grid or for the transportation sector releases CO_2 and hazardous air pollutants, and requires the installation of gas pipelines and other infrastructure that leak tremendous volumes of methane. Biomethane production burdens and poisons local communities while degrading our planet's health and sustainability. Manure-to-energy projects are not a sustainable solution to the problems caused by CAFOs because they entrench an already polluting facility with more contamination mechanisms. Local, state, and national governmental entities need to stop promoting and incentivizing CAFO manure-to-energy projects at the expense of the environment and rural communities.

ACKNOWLEDGMENTS

We sincerely thank the Socially Responsible Agriculture Project (SRAP) and all of the internal staff, as well as external local community and organizational partners who contributed to this research. Many thanks go to Scott Dye, Audrey Clungeon, Terry Spence, Sherri Dugger, Diane Rosenberg, Christopher Hunt, and Dr. Christopher Grobbel. We also express our gratitude to Tyler Lobdel, Tarah Heinzen, Michele Merkel, and Krissy Kasserman of Food & Water Watch, and Brent Newell and Jessica Culpepper of Public Justice for their continued support and most thoughtful insights and input.

ABSTRACT
The social acceptance of biogas is often hampered by environmental and health concerns. In this study, the current knowledge about the impact of biogas technology is presented and discussed. The survey reports the emission rate estimates of the main greenhouse gases (GHG), namely CO_2, CH_4 and N_2O, according to several case studies conducted over the world. Direct emissions of gaseous pollutants are then discussed, with a focus on nitrogen oxides (NO_x); evidences of the importance of suitable biomass and digestate storages are also reported. The current knowledge on the environmental impact induced by final use of digestate is critically discussed, considering both soil fertility and nitrogen release into atmosphere and groundwater; several case studies are reported, showing the importance of NH_3 emissions with regards to secondary aerosol formation. The biogas upgrading to biomethane is also included in the study: with this regard, the methane slip in the off-gas can significantly reduce the environmental benefits.

Air quality; anaerobic digestion; biogas; digestate; renewable energy; secondary aerosol; waste management

Introduction

The environmental benefits of biogas technology are often highlighted, as a valid and sustainable alternative to fossil fuels.[1] Together with the reduction of greenhouse gas (GHG) emissions, biogas can enhance energy security, thanks to its high energetic potential.[2–4] As a renewable energy source, it allows exploiting agricultural and zootechnical byproducts and municipal wastes, with a lower impact on air quality when compared to combustion-based strategies for these biomasses.[5–7] Furthermore, while ashes from combustion find scarce agronomic applications,[8,9] the by-product of anaerobic digestion, i.e. digestate, looks as a reliable material for agricultural uses.[10] Another important advantage of biogas technology is its easy scalability, allowing exploiting the energetic potential of decentralized biomass sources.[11,12] Finally, biogas can be upgraded to biomethane, suitably used as a vehicle fuel, or injected into national natural gas grids,[13,14]

The energy potential of biogas is reported in Figure 1, based on data from the World Bioenergy Association.[15] For Europe, China and USA, data are detailed in terms of the following sources: manure, agriculture residues, energy crops, organic fraction of municipal solid waste (MSW), agro-industry waste and sewage sludge. For the total world biogas potential, data are only divided into waste (i.e. organic fraction of MSW, agro-industry waste and sewage sludge) and agricultural byproducts (i.e. manure, agriculture residues and energy crops).

In spite of the above cited advantages, social opposition is often observed towards biogas plants, generally based on concerns about environmental and health issues.[16] The frequency on which these opposition phenomena are observed depends on different factors, including the inclusion strategies and the considered country.[17,18] In order to overcome social and cultural barriers hampering a wider diffusion of biogas, the accurate and complete evaluation of the environmental impact of these processes remains an issue of high scientific and technical relevance. The aim of this work is to report an updated state of the art of current knowledge about the environmental impact of biogas and biomethane.

Greenhouse gas emissions

A main objective of biogas industry is the reduction of fossil fuel consumption, with the final goal of mitigating global warming. However, anaerobic digestion is associated to the production of several greenhouse gases, namely carbon dioxide, methane and nitrous oxide. As a consequence, dedicated measures should be taken in order to reduce these emissions. According to Hijazi,[19] the main measures to improve the global warming reduction potential of biogas plants are: to use a flare avoiding methane discharge, to cover tanks, to enhance the efficiency of combined heat and power (CHP) units, to improve the electric power utilisation strategy, to exploit as much thermal energy as possible, to avoid leakages. Similar conclusions were obtained by Buratti and co-workers[20] for the specific case study of cereal crops in Umbria, Italy. Biomethane chain exceeds the minimum value of GHG saving (35%) mainly due to the open storage of digestate; usual practices to improve GHG reduction (up to 68.9%) include using heat and electricity produced by the biogas CHP plant, and covering digestate storage tanks.

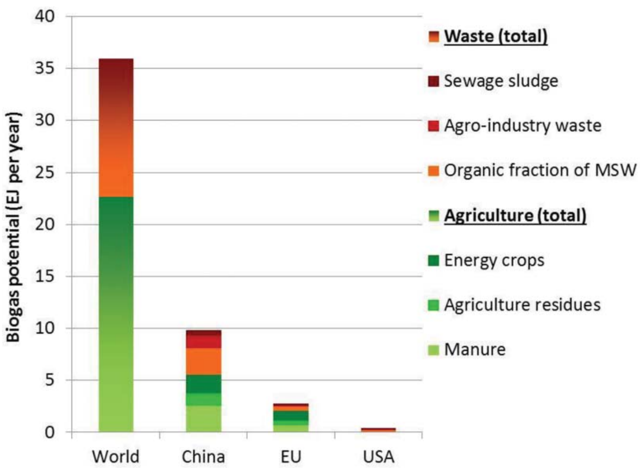

Figure 1. Energy potential of biogas.

The impact induced by biogas plants on global warming needs to be studied case by case. Bachmaier and co-workers[21] calculated the GHG impact of ten agricultural biogas plants. GHG emissions coming from electricity production in the investigated biogas plants ranged from −85 to 251 g CO_2-eq/kWh_{el}, and the GHG saving was 2.31 – 3.16 kWh_{fossil}/kWh_{el}. The results obtained also highlighted that reliable estimates of GHG emissions in the case of electricity production from biogas can be only made on the basis of individual monitoring data, for instance: reduction of direct methane emission and leakage, exploiting of heat obtained from cogeneration, amount and nature of input material, nitrous oxide emission (e.g. from energy crop cultivation) and digestate management. Battini and co-workers,[22] in a case study of an intensive dairy farm situated in the Po valley (Italy), calculated a GHG emission reduction due to anaerobic digestion ranging between −23.7% and −36.5%, depending on digestate management. In a Finnish case study,[23] the GHG release reduction was estimated equal to 177.0, 87.7 and 125.6 Mg of CO_2 eq. yr^{-1} for dairy cow, sow and pig farms, respectively. Optimizing all process parameters looks important with regard to final environmental impact: for instance, a specific case study on wastewater treatment showed that the process optimization could result into the emission abatement equal to 1,103 kg CO_2 eq/d for N_2O, 256 kg eq/d for CO_2 and 87 kg CO_2 eq/d for CH_4.[24]

Carbon dioxide emissions

Harmful compounds and air contaminants are introduced into the environment during biogas production and use through both combustion processes and diffusive emissions. Considering carbon dioxide, combustion of biogas leads to efficient methane oxidation and conversion to CO_2, with a rate of 83.6 kg per GJ (based on a biogas with 65% CH_4 and 35% CO_2[25]). Other releases of this contaminant are related to transport and storage of biomass, as well as digestate use. In the case of both biogas combustion and biomass/digestate emission, CO_2 is considered as biogenic and calculated neutral with regards to the impact on climate. Taking into account the reduction of fossil fuel, it can be demonstrated that biogas production leads globally to mitigation of anthropogenic greenhouse impact of the environment. Poeschl and co-workers[26] have investigated the CO_2 emissions associated to biogas production from several feedstocks, and the relative contribution of feedstock supply, biogas plant operation and infrastructure, biogas utilization and digestate management. According to this study, biogas use gives rise to a negative CO_2 balance because CO_2 caption results every time higher, in absolute values, than positive emissions from feedstock supply and biogas plant operation. As expected, biogas production from byproducts (e.g. from food residues, pomace, slaughter waste, cattle manure, etc.) is a more sustainable approach than energy crops utilization such as whole-wheat plant silage. Besides, digestate management provides significant contributions to total emission reduction in the case of specific feedstock such as municipal solid waste. A dedicated section of this study will below discuss the impact of digestate in full details, in paragraph 5.

Methane emissions

Methane released by biogas processes is not considered relevant for health issues: though exposure to hydrocarbon mixtures can have some adverse effects on humans,[27] no evidence exists of relevant interactions between methane and biologic systems.[28] However, methane is a greenhouse gas whose global warming power is estimated to be 28–36 times higher than CO_2 over 100 years: as such, it is the second major component among anthropogenic greenhouse chemicals.[29] Hence, in evaluating the impact of biogas industry on climate change, methane emissions are a point of primary importance. Methane can be released during biogas incomplete combustion; however a strong contribution to this contaminant comes out from diffusive emission related to biomass storage and digestate management. On the other hand, other biomass management strategies must be taken into account to abate emissions related to biogenic methane. In the above mentioned study of Poeschl and co-workers,[26] methane emissions were also discussed; in all investigated cases, the emission rates were below 5 g kg^{-1}. Considering cattle manure, important reductions in methane emission are related to digestate processing and handling, since this kind of biomass is characterized by high methane emission rate when spread in the field without any pre-treatment.

Nitrous oxide

Besides CO_2 and CH_4, nitrous oxide (N_2O) is another important GHG: Due to its high greenhouse effect potential, N_2O emissions from biogas production processes can result into a significant contribution to global warming budget.[30,31] The relative impact of nitrous oxide mostly depends on the chosen climate metrics: indeed, N_2O impact can even exceed those of CO_2 and CH_4, when the considered metric is Global Temperature change Potential with a time horizon of 100 years (namely GTP-100).[32]

Total GHG emission for energy production from biogas are generally calculated in a range between 0.10 and 0.40 kg CO2-eq/kWh_{el}, which is for instance 22–75% less than GHG emissions caused by the present energy mix in Germany.[33] The wide uncertainty about the estimates of global warming mitigation potential depends on N_2O emission rate assessment as well as on storage and use as a fertilizer of digestate, as discussed in paragraphs below.

Gaseous pollutants from biogas combustion

Along GHG reduction benefits, it must be considered that biogas combustion is associated to release of pollutants in the atmosphere; therefore, the correct assessment of these emissions is a key point in social acceptance of this technology. A summary of emission factors for the main gaseous pollutants are reported in Table 1.

Carbon monoxide (CO) is produced in all oxidation processes of carbon containing materials, and is an important by-product of incomplete combustion of biogas. Methane emission rates are 0.74 and 8.46 and g CO per Nm^{-3} CH_4 for flaring and CHP, respectively.[34] CO emissions related to energy production are estimated in a range between 80 and 265 mg CO MJ^{-1}, depending on the plant efficiency.[35]

Sulphur dioxide (SO_2) emissions from biogas plants manly depend on the desulphurization degree of the introduced biogas. The SO_2 emission rate of a CHP biogas plant is estimated to lie in the range 19.2–25 mg MJ^{-1}.[25] The UK National Society for Clean Air (NSCA) estimates an emission factor of 80 and 100 $g_{SO2}/tonn_{waste}$ for flaring and CHP, respectively.[36] The relatively high SO_2 concentrations in the proximity of biogas plants can depend on different reasons, e.g.: direct emission from biogas combustion, H_2S oxidation from diffusive emissions, and diesel truck exhausts.[37]

Emissions of NO_x are one of the most critical point with regard to environmental impact of biogas plants.[38] According to Kristensen and co-workers,[35] the NO_x emission level of biogas is, in general, higher than for natural gas engines: the averaged aggregated emission factor is 540 g NO_x GJ^{-1}, which is more than three times the rate from natural gas engines. When emission factor is reported to methane consumption, an emission factor of 0.63 and 11.6 g_{NOx}/Nm^3_{CH4} can be assumed for flaring and CHP, respectively.[34] The importance of controlling this pollutant is demonstrated by several case studies. For instance, Battini and co-workers[22] in the above mentioned case study of an intensive dairy farm situated in the Po valley (Italy) reported a low enhancement in acidification (5.5–6.1%), particulate matter emissions (0.7–1.4%) and eutrophication (+0.8%), while on the other hand a significant enhancement in photochemical ozone formation potential (41.6–42.3%) was calculated. In another case study, Carreras-Sospedra and co-workers[39] estimated a potential enhancement of up to 10% of NO_x emission in 2020 in California (US); nevertheless, their study included both biogas and biomass burning. Indeed, the lower emissions of methane from storage and the credits from substituted electricity are not enough to compensate the increase in NO_x emissions from the biogas combustion.

Biogas is a gaseous fuel rich in volatile organic compounds (VOCs), compared to natural gas: indeed, VOCs concentration normally ranges between 5 and 500 mg/Nm^3, and in some cases up to 1700 mg/Nm^3 were observed.[40,41] Generally, only non-methane volatile organic compounds (NMVOC) are considered in these studies. If combustion is assumed to reduce VOCs concentration of 99%,[42] VOCs emission from biogas combustion are in general lower, compared to liquid and solid biofuels. However, a specific critical issue can be highlighted for formaldehyde. In a case study conducted on anaerobic waste treatment plants in Barcelona (Spain), VOC emission factors was in the range 0.9 ± 0.3 g s^{-1}, contributing for 0.3–0.9% of total VOCs in the area. On the other hand, formaldehyde emission factors from biogas engines were found between 0.2 and 3.0 mg s^{-1}, resulting in a ~2% contribution to the total.[43] It is important to remark that a similar emission pattern is observed for natural gas: indeed, formaldehyde is a by-product of methane oxidation. Compared to natural gas, emissions of VOCs are 40% lower in biogas engines, while formaldehyde emissions are slightly lower and higher aldehydes (present in natural gas due to the presence of higher hydrocarbons) are almost absent.[35]

Noticeably, fuel-cycle emissions can be strongly influenced by the raw materials. For instance, CO_2, CO, NO_x, hydrocarbons and particles may differ by a factor of 3–4 between ley crops, straw, sugar beet byproducts, liquid manure, food industry waste and municipal solid waste. On the other hand, differences by a factor of up to 11 can be observed in SO_2 emissions, due to the high variability of H_2S and organic sulphur compounds in the produced biogas.[44]

Impact of feedstock and digestate storage and treatment

In the biogas combustion management, feedstock and digestate storage and treatments can be the most important processes to achieve the global warming benefits of biogas production processes. Indeed, the impact of a biogas plant on GHG emission is heavily influenced by feedstock storage: most of N_2O can be abated when a closed storage is used for manure and co-digestion feeding.[45]

Emissions from uncovered biomass storage have also been identified as the main ammonia source along the whole biogas production chain,[46] and closed storage is strongly advised.

In a specific French case study of anaerobic digestion and composting plant for municipal solid waste, Beylot and co-workers[38] have identified four conditions for process operation, which highly influence the impact of the whole plant; they are: (i) the features of degradation of the fermentable fraction; (ii) the collection efficiency of gas streams released by biological operations; (iii) the abatement effectiveness of collected pollutants; and (iv) NO_x emission rate from biogas combustion. The importance of digestate storage step has been highlighted by Battini and co-workers,[22] in the above mentioned case study of intensive dairy farm situated in the Po valley (Italy): GHG emission reduction due to AD, calculated as equal to −23.7%, can reach −36.5% when a gas-tight tank is used for digestate storage.

A proper design and management of feedstock and digestate storage units looks also important in order to mitigate the odour impact of the plant. Indeed, the two major sources of the olfactory annoyance are biomass storage production of biogas and digestate composting units.[47] Closed-operated hydrothermal hydrolysis has positive effects on overall fugitive odour control in plants; on the other hand, eventual fugitive emissions during high-temperature and seemingly open pre-treatments can be the principal source of odours.[48]

In conclusion, gas tight storage should always be advised, since the corresponding GHG and ammonia fugitive emissions are even more important those coming from fertilizers.[49] As mentioned above, avoiding leakages and using closed tanks are among the most important ways to reduce the global warming impact of biogas plants.[19]

Impact of digestate final use

The use of agricultural and zootechnical byproducts and MSW as soil improver and fertilizer is a sustainable approach, allowing to reduce the production, transport and use of synthetic chemicals: however, spreading untreated biomass on soils sometimes implies the release into the atmosphere of huge amounts of chemicals such as methane, nitrous oxide, ammonia, volatile hydrocarbons, etc. Anaerobic digestion of biomass followed by the use of digestate as biofertilizer is a common practice related to biogas production. In this paragraph, the current knowledge concerning the environmental impact of this practice is briefly discussed.

A recent study on this topic[50] concluded that direct effects of anaerobic digestion on long-term sustainability in terms of soil fertility and environmental impact at the field level are of minor relevance; indeed, the most relevant issue (with regard to both emissions to atmosphere and in soil fertility) is related to possible changes in cropping systems. According to this study, the main direct aftermaths of anaerobic digestion are short-term effects on soil microbial activity and changes in the soil microbial community. Considering soil quality, digestate is significantly more inert vs. atmospheric and biological agents than the biomass itself: this property results into a lower degradation rate of the organic matter. In fact, labile fractions of original biomass such as carbohydrates are rapidly degraded, causing the enrichment of more persistent molecules such as lignin and non-hydrolysable lipids.[51] In a specific case study on pig slurry anaerobic digestion, a high biological stability of biomasses was achieved, with a Potential Dynamic Respiration Index (PDRI) close to 1,000 mg O_2 kg VS^{-1} h^{-1}.[10]

With regard to nitrate leaching and release into the atmosphere of ammonia and nitrous oxide, the current state of knowledges needs to be improved: however, the impact is considered “negligible or at least ambiguous”.[50] The “ambiguity” of previous studies, as highlighted by this Author, is probably due to the different impact of digestate depending on the type of considered soil. For instance, Eickenscheidt and co-workers[52] investigated the emission of methane, nitrous oxide and ammonia from untreated manure and digestate applied on several soils: while methane emissions did not significantly change, high N_2O emissions were observed in the correspondence of high carbon loadings. A significative impact of soil moisture-soil mineral-N interactions on N_2O emissions was also observed by Senbayram and co-workers.[31]

Considering N_2O and CH_4, digestate can give rise to significant emission rates into the atmosphere: however, these emissions are generally lower than untreated biomass.[53] As for nitrous oxide, digested products are more recalcitrant than fresh slurry; thus, microbial degradation is slower, in which leads to relatively few anoxic microsites and poor N_2O emission compared to fresh slurry application.[54–56] Conversely, methane emissions from digestate are generally lower than those of original biomass, since the methanogenic potential is reduced: this is particularly relevant in the presence of reduced methane coming from manure[26,45] (Poeschl et al., 2012; Boulamanti et al., 2013). As for methane emission, an exception is known in the specific case of rice cultivation: indeed, adding digestate to paddy results into the methane emission rate enhancement from 16.9 to 29.9 g m^{-2},[57] whilst no significant effects are observed for N_2O.[57,58]

Based on the above-cited literature, N_2O and CH_4 emissions from digestate are not critical, while ammonia release and nitrate leaching are still a critical point. For instance, ammonia emissions from digestate higher than from original manure have been observed in several studies.[56,59,60] It was also reported that up to 30% of nitrogen can be lost by ammonia volatilization, due to the enhancement of soil pH.[59,60] Specifically, Matsunaka and co-workers[61] reported a 13% nitrogen volatilization as ammonia, when anaerobically digested cattle slurry was used as soil fertilizer for grassland. The practice of fertilizing soil with anaerobically digested materials increases soil concentration of NO_3^- (+30/40% compared to raw cattle slurry): this is associated to the four times more readily degradable organic C increased microbial biomass, depleting nitrogen and oxygen concentration in soil and resulting in the 10 times increase of CO_2 and N_2O emissions.[62] A proper management of digestate can mitigate its environmental impact: ammonia emission rates ranging from 1.6 to 30.4 were reported, depending on the adopted practice.[63]

With regards to pesticides, heavy metals and harmful microorganisms, the risk of food chain contamination is generally considered low,[64] but the soil burden of persistent organic pollutants (POPs) caused by the use of digestate as biofertilizer still needs to be fully assessed.[65] On the other hand, anaerobic digestion can have relevant effects on phytotoxicity of specific biomass: for instance, the phyto-toxic character of olive mill effluent is reduced after anaerobic digestion,[66] and the degradation of aflatoxin B1 from corn grain can be reached.[67] Finally, an odour reduction up to 82–88% can be obtained.[63]

In conclusion, the main critical issue in final use of digestate is nitrogen release into the environment, which can be reduced by applying the best practices for preserving soil quality. The management of nitrogen dosage is sometimes difficult because of the feedstock variability. It is also important to remark that fugitive emissions from digestate storage are generally more important than those released by its use into soil, as indicated above.[20,49]

Impact on particulate matter

With regards to particulate matter (PM), biogas combustion is not a significant emission source when compared to other fuels: emission factors of 0.238 and 0.232 g/Nm^3_{CH4} have been estimated for flaring and CHP, respectively.[34] However, secondary PM formation can occur, due to NO_x emissions from CHP and NH_3 volatilization from storage and digestate final use. Indeed, during secondary PM formation, the prominent roles of ammonia[68] and NO_x[69] are ascertained. As reported by Boulamanti and co-worker,[45] NO_x emissions are in general the principal source of secondary PM from biogas. As discussed above, closed storage can significantly abate ammonia emissions, resulting also into the global reduction of PM formation from this contaminant.

Impact of biogas upgrading to biomethane

Biomethane production is an efficient approach to increase the market share of biogas, resulting in a further reduction of fossil fuels. The equivalent CO_2 saving raises considerably if methane slip is limited to 0.05%,[70] while the process results no longer sustainable when methane losses reach 4%. Biomethane use as an alternative to gasoil is expected to improve local air quality, with regards to NO_x and particulate matter. As a consequence, biogas upgrading for vehicle fuelling purposes produces optimum benefits with respect to photochemical oxidant formation, marine eutrophication and ecotoxicity; on the other hand, scarce benefits are observed in terms of climate change compared to biogas combustion in CHP.[71]

Depending on several factors such as energy consumption, production and transport of materials used, produced waste and methane slip, the environmental impact of biomethane production depends on the upgrading technology adopted. In PSA, the eventual recovery of the off-gas plays a key role.[72,73] Starr and co-workers[74] reported that the most CO_2-efficient upgrading technology for MSW biogas is the BABIU (bottom ash upgrading) based on ash produced by municipal waste

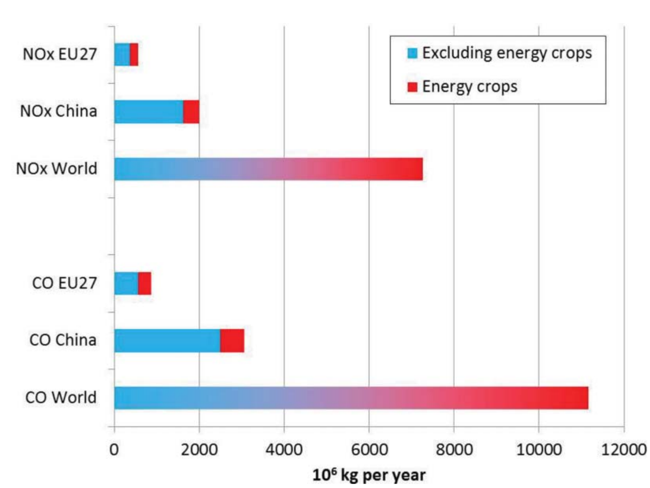

Figure 2. Emission potential of biogas plants for NO_x and CO.

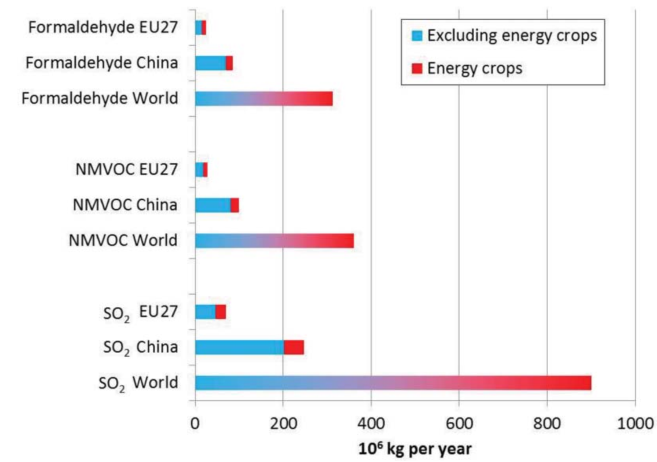

Figure 3. Emission potential of biogas plants for formaldehyde, NMVOC and SO_2.

incinerators. The condition required is that the incinerator lies within 125 km from the biogas upgrading plant. Considering water scrubbing in basic solutions, a lower impact can be achieved by replacing KOH with NaOH. Water from biogas upgrading plants can be recycled in the process or treated as wastewater, depending on chemical composition: the most common VOC in the wastewater of biogas upgrading plants are p-cymene, d-limonene and 2-butanone[75]; the maximum VOC content is observed in MSW treatment plants, reaching up to 238 mg/L, but no inhibition is observed when wastewaters are recycled in the plant.

Along its impact on climate, biomethane use as gasoil substitute of is expected to improve urban air quality, because emission factors of methane are up to 10 times lower than those of liquid fuels, considering PM, VOCs and polycyclic aromatic hydrocarbons.[76] Biomethane injection in the national grid may also reduce residential solid fuels consumption in some specific regions, with relevant benefits on indoor air quality and human health.[77]

Global emission potential

The potential emission associated to biogas plants is reported in Figure 2 (NO_x and CO) and in Figure 3 (for formaldehyde, NMVOC and SO_2). Data are obtained combining emission factors reported in Table 1[25] and energy potential reported in Figure 1. For Europe and China, the contribution of energy crops is reported separately, since their use is often disregarded due to its negative impact on land availability for food. In the case of the global potential, the relative contribution of energy crops is not available.

Conclusions

Biogas can significantly contribute to abate greenhouse gas emissions. However, attention must be payed towards undesired emissions of methane and nitrous oxide (N_2O). The emission budgets of the two compounds are scarcely related to direct release from biogas/biomethane combustion, whilst biomass storage and digestate management are the critical steps. Similar considerations apply to ammonia: to reduce its impact on secondary aerosol formation, efficient biomass and digestate storage should always be recommended. Among all the gaseous pollutants considered in direct emission from biogas combustion, nitrogen oxides (NO_x) level were worth of some concern in several case studies. On the other hand, volatile organic compounds do not seem to constitute a critical issue. Considering the aftermaths of digestate spreading on soil quality, further studies are needed in order to fully assess the long-term impact. In the medium-short term, digestate seems to be preferable compared to untreated biomass. The upgrading to biomethane can generally improve air quality and reduce GHG emissions; however methane losses in the off-gas can affect the sustainability of the whole process.

Acknowledgments

The study is part of the ISAAC project (Increasing Social Awareness and Acceptance of biogas and biomethane), funded by the European Commission within the Horizon 2020 programme under grant agreement no. 691875.

Abstract

Methane emissions from the U.S. oil and natural gas supply chain were estimated using ground-based, facility-scale measurements and validated with aircraft observations in areas accounting for ~30% of U.S. gas production. When scaled up nationally, our facility-based estimate of 2015 supply chain emissions is 13±2 Tg/y, equivalent to 2.3% of gross U.S. gas production. This value is ~60% higher than the U.S. EPA inventory estimate, likely because existing inventory methods miss emissions released during abnormal operating conditions. Methane emissions of this magnitude, per unit of natural gas consumed, produce radiative forcing over a 20-year time horizon comparable to the CO_2 from natural gas combustion. Significant emission reductions are feasible through rapid detection of the root causes of high emissions and deployment of less failure-prone systems.

One Sentence Summary:

A synthesis of recent measurements shows that methane emissions from the U.S. oil and natural gas supply chain exceed U.S. EPA estimates by ~60%.

Methane (CH_4) is a potent greenhouse gas, and CH_4 emissions from human activities since pre-industrial times are responsible for 0.97 W m^{-2} of radiative forcing, as compared to 1.7 W m^{-2} for carbon dioxide (CO_2) (1). CH_4 is removed from the atmosphere much more rapidly than CO_2, thus reducing CH_4 emissions can effectively reduce the near-term rate of warming (2). Sharp growth in U.S. oil and natural gas (O/NG) production beginning around 2005 (3) raised concerns about the climate impacts of increased natural gas use (4, 5). By 2012, disagreement among published estimates of CH_4 emissions from U.S. natural gas operations led to a broad consensus that additional data were needed to better characterize emission rates (4–7). A large body of field measurements made between 2012 and 2016 (Table S1) has dramatically improved understanding of the sources and magnitude of CH_4 emissions from the industry's operations. Brandt *et al.* summarized the early literature (8); other assessments incorporated elements of recent data (9–11). This work synthesizes recent studies to provide an improved overall assessment of emissions from the O/NG supply chain, which we define to include all operations associated with oil and natural gas production, processing and transport (Section S1.0) (12).

Measurements of O/NG CH_4 emissions can be classified as either top-down (TD) or bottom-up (BU). TD studies quantify ambient methane enhancements using aircraft, satellites or tower networks and infer aggregate emissions from all contributing sources across large geographies. TD estimates for nine O/NG production areas have been reported to date (Table S2). These areas are distributed across the U.S. (Fig. S1) and account for ~33% of natural gas, ~24% of oil production, and ~14% of all wells (13). Areas sampled in TD studies also span the range of hydrocarbon characteristics (predominantly gas, predominantly oil, or mixed), as well as a range of production characteristics such as well productivity and maturity. In contrast, BU studies generate regional, state, or national emission estimates by aggregating and extrapolating measured emissions from individual pieces of equipment, operations, or facilities, using measurements made directly at the emission point or, in the case of facilities, directly downwind.

Recent BU studies have been performed on equipment or facilities that are expected to represent the vast majority of emissions from the O/NG supply chain (Table S1). In this work we integrate the results of recent facility-scale BU studies to estimate CH_4 emissions from the U.S. O/NG supply chain, and then we validate the results using TD studies (Section S1). The probability distributions of our BU methodology are based on observed facility-level emissions, in contrast to the component-by-component approach used for conventional inventories. We thus capture enhancements produced by all sources within a facility, including the heavy tail of the distribution. When the BU estimate is developed in this manner, direct comparison of BU and TD estimates of CH_4 emissions in the nine basins for which TD measurements have been reported indicates agreement between methods, within estimated uncertainty ranges (Fig. 1).

Our national BU estimate of total CH_4 emissions in 2015 from the U.S. O/NG supply chain is 13 (+2.1/−1.6, 95% confidence interval) Tg CH_4/y (Table 1). This estimate of O/NG CH_4 emissions can also be expressed as a production-normalized emission rate of 2.3% (+0.4%/−0.3%) by normalizing by gross natural gas production (33 tcf/y, (13) with average CH_4 content of 90 vol%). Roughly 85% of national BU emissions are from production, gathering, and processing sources, which are concentrated in active O/NG production areas.

Our assessment does not update emissions from local distribution and end use of natural gas, due to insufficient information addressing this portion of the supply chain. However, recent studies suggest that local distribution emissions are significant, exceeding the current inventory estimate (14–16), and that end-user emissions might also be important. If these findings prove to be representative, overall emissions from the natural gas supply chain would increase relative to the value in Table 1 (Section S1.5).

Our BU method and TD measurements yield similar estimates of U.S. O/NG CH_4 emissions in 2015, and both are significantly higher than the corresponding estimate in the U.S. Environmental Protection Agency's Greenhouse Gas Inventory (EPA GHGI) (Table 1, Section S1.3) (17). Discrepancies between TD estimates and the EPA GHGI have been reported previously (8, 18). Our BU estimate is 63% higher than the EPA GHGI, largely due to a more than two-fold difference in the production segment (Table 1). The discrepancy in production sector emissions alone is ~4 Tg CH_4/y, an amount larger than the emissions from any other O/NG supply chain segment. Such a large difference cannot be attributed to expected uncertainty in either estimate: the extremal ends of the 95% confidence intervals for each estimate differ by 20% (i.e., ~12 Tg/y for the lower bound of our BU estimate can be compared to ~10 Tg/y for the upper bound of the EPA GHGI estimate).

We believe the reason for such large divergence is that sampling methods underlying conventional inventories systematically underestimate total emissions because they miss high emissions caused by abnormal operating conditions (e.g., malfunctions). Distributions of measured emissions from production sites in BU studies are invariably "tail-heavy", with

NIST Author Manuscript

NIST Author Manuscript

large emission rates measured at a small subset of sites at any single point in time (19–22). The difference between the EPA GHGI and BU estimates derived from facility-level measurements is explained if measurements used to develop GHGI emission factors under-sampled abnormal operating conditions encountered during the BU work. Component-based inventory estimates like the GHGI have been shown to underestimate facility-level emissions (23), probably because of the technical difficulty and safety and liability risks associated with measuring large emissions from, for example, venting tanks such as those observed in aerial surveys (24).

Abnormal conditions causing high CH_4 emissions have been observed in studies across the O/NG supply chain. An analysis of site-scale emission measurements in the Barnett Shale concluded that equipment behaving as designed could not explain the number of high-emitting production sites in the region (23). An extensive aerial infrared camera survey of ~8,000 production sites in seven U.S. O/NG basins found that ~4% of surveyed sites had one or more observable high emission-rate plumes (24) (detection threshold of ~3–10 kg CH_4/h was 2–7 times higher than mean production site emissions estimated in this work). Emissions released from liquid storage tank hatches and vents represented 90% of these sightings. It appears that abnormal operating conditions must be largely responsible, because the observation frequency was too high to be attributed to routine operations like condensate flashing or liquid unloadings alone (24). All other observations were due to anomalous venting from dehydrators, separators and flares. Notably, the two largest sources of aggregate emissions in the EPA GHGI – pneumatic controllers and equipment leaks – were never observed from these aerial surveys. Similarly, a national survey of gathering facilities found that emission rates were four times higher at the 20% of facilities where substantial tank venting emissions were observed, as compared to the 80% of facilities without such venting (25). In addition, very large emissions from leaking isolation valves at transmission and storage facilities were quantified using downwind measurement but could not be accurately (or safely) measured using on-site methods (26). There is an urgent need to complete equipment-based measurement campaigns that capture these large emission events, so that their causes are better understood.

Outdated component emission factors and temporal bias are unlikely to explain the difference between our facility-based BU estimate and the GHGI. First, an equipment-level inventory analogous to the EPA GHGI but updated with recent direct measurements of component emissions (Section S1.4) predicts total production emissions that are within ~10% of the EPA GHGI, although the contributions of individual source categories differ significantly (Table S3). Second, we consider unlikely an alternative hypothesis that systematically higher emissions during daytime sampling cause a high bias in TD methods (Section S1.6). Two other factors may lead to low bias in EPA GHGI and similar inventory estimates. Operator cooperation is required to obtain site access for emission measurements (8). Operators with lower-emitting sites are plausibly more likely to cooperate in such studies, and workers are likely to be more careful to avoid errors or fix problems when measurement teams are on site or about to arrive. The potential bias due to this “opt-in” study design is very challenging to determine. We therefore rely primarily on site-level, downwind measurement methods with limited or no operator forewarning to construct our BU estimate. Another possible source of bias is measurement error. It has been suggested

NIST Author Manuscript

NIST Author Manuscript

that malfunction of a measurement instrument widely used in the O/NG industry contributes to underestimated emissions in inventories (27); however, this cannot explain the >2× difference in production emissions (28).

The tail-heavy distribution for many O/NG CH_4 emission sources has important implications for mitigation since it suggests that most sources – whether they represent whole facilities or individual pieces of equipment – can have lower emissions when they operate as designed. We anticipate that significant emissions reductions could be achieved by deploying well-designed emission detection and repair systems that are capable of identifying abnormally operating facilities or equipment. For example, pneumatic controllers and equipment leaks are the largest emission sources in the O/NG production segment exclusive of missing emission sources (38% and 21%, respectively; Table S3) with malfunctioning controllers contributing 66% of total pneumatic controller emissions (Section S1.4) and equipment leaks 60% higher than the GHGI estimate.

Gathering operations, which transport unprocessed natural gas from production sites to processing plants or transmission pipelines, produce ~20% of total O/NG supply chain CH_4 emissions. Until the publication of recent measurements (29), these emissions were largely unaccounted by the EPA GHGI. Gas processing, transmission and storage together contribute another ~20% of total O/NG supply chain emissions, most of which come from ~2,500 processing and compression facilities.

Our estimate of emissions from the U.S. O/NG supply chain (13 Tg CH_4/y) compares to the EPA estimate of 18 Tg CH_4/y for all other anthropogenic CH_4 sources (17). Natural gas losses are a waste of a limited natural resource (~$2 billion/y), increase global levels of surface ozone pollution (30), and significantly erode the potential climate benefits of natural gas use. Indeed, our estimate of CH_4 emissions across the supply chain, per unit of gas consumed, results in roughly the same radiative forcing as does the CO_2 from combustion of natural gas over a 20-year time horizon (31% over 100 years). Moreover, the climate impact of 13 Tg CH_4/y over a 20-year time horizon roughly equals that from the annual CO_2 emissions from all U.S. coal-fired power plants operating in 2015 (31% of the impact over a 100-year time horizon) (Section S1.7).

We suggest that inventory methods would be improved by including the substantial volume of missing O/NG CH_4 emissions evident from the large body of scientific work now available and synthesized here. Such empirical adjustments based on observed data have been previously used in air quality management (31).

The large spatial and temporal variability in CH_4 emissions for similar equipment and facilities (due to equipment malfunction and other abnormal operating conditions) reinforces the conclusion that significant emission reductions are feasible. Key aspects of effective mitigation include pairing well-established technologies and best practices for routine emission sources with economically viable systems to rapidly detect the root causes of high emissions arising from abnormal conditions. The latter could involve combinations of current technologies such as on-site leak surveys by company personnel using optical gas imaging (32), deployment of passive sensors at individual facilities (33, 34) or mounted on ground-based work trucks (35), and *in situ* remote sensing approaches using tower networks, aircraft or satellites (36). Over time, the development of less failure-prone systems would be expected through repeated observation of and further research into common causes of abnormal emissions, followed by re-engineered design of individual components and processes.

Effects on Carbon and Nitrogen Emissions due to Swine Manure Removal for Biofuel Production

Kim H. Weaver,* Lowry A. Harper, and Sarah M. Brown

Methane (CH_4) and ammonia (NH_3) are emitted from swine-manure processing lagoons, contributing to global climate change and reducing air quality. Manure diverted to biofuel production is proposed as a means to reduce CH_4 emissions. At a swine confined animal feeding operation in the U.S. Central Great Basin, animal manure was diverted from 12 farms to a biofuel facility and converted to methanol. Ammonia emissions were determined using the De Visscher Model from measured data of dissolved lagoon ammoniacal N concentrations, pH, temperature, and wind speed at the lagoon sites. Other lagoon gas emissions were measured with subsurface gas collection devices and gas chromatography analysis. During 2 yr of study, CO_2 and CH_4 emissions from the primary lagoons decreased 11 and 12%, respectfully, as a result of the biofuel process, compared with concurrently measured control lagoon emissions. Ammonia emissions increased 47% compared with control lagoons. The reduction of CH_4 and increase in NH_3 emissions agrees with a short-term study measured at this location by Lagrangian inverse dispersion analysis. The increase in NH_3 emissions was primarily due to an increase in lagoon solution pH attributable to decreased methanogenesis. Also observed due to biofuel production was a 20% decrease in conversion of total ammoniacal N to N_2, a secondary process for the removal of N in anaerobic waste lagoons. The increase in NH_3 emissions can be partially attributed to the decrease in N_2 production by a proposed NH_4^+ conversion to N_2 mechanism. This mechanism predicts that a decrease in NH_4^+ conversion to N_2 increases ammoniacal N pH. Both effects increase NH_3 emissions. It is unknown whether the decrease in NH_4^+ conversion to N_2 is a direct or physical result of the decrease in methanogenesis. Procedures and practices intended to reduce emissions of one pollutant can have an unintended consequence on the emissions of another pollutant.

Confined animal feeding operations are economical from a production standpoint; however, concentrating a large number of animals in a relatively small geographical area increases the amount of feces and urine (manure) generated that must be managed by the producer. Manure is generally managed by anaerobic digestion and/or land application. In the digestion process, animal manure is pumped into large open retention ponds (lagoons) for microbial digestion. As the manure is digested, various gases, including methane (CH_4), carbon dioxide (CO_2), ammonia (NH_3), and dinitrogen (N_2), are released into the atmosphere. Methane, CO_2, and NH_3 have environmental consequences. Methane is a global climate change gas. Although CO_2 is normally considered a global climate change gas, CO_2 from agricultural sources is simply returning carbon (C) sequestered by agriculture to the environment. Nevertheless, agricultural CO_2 emissions are of interest because of their role in C cycling. Ammonia reacts with acidic gases in the atmosphere (mainly from fossil fuel combustion) to form ammonium (NH_4^+) aerosols. These aerosols affect air quality and are involved in wet and dry deposition, enriching N availability to cropping and natural ecosystems. Nitrogen may be beneficial in cropping systems, but in natural ecosystems deposited N may provide competitive advantage to nitrophyllic over nitrophobic plants.

Ammonia emissions were initially reported by the USDA to be about 60% of feed input (Hatfield et al., 1993). The USEPA estimates NH_3–N emissions to be 71% of the N discharged into the lagoon or about 53% of feed input (USEPA, 2004). The state of North Carolina estimates that NH_3–N emissions are 36% of feed input (Doorne et al., 2002). More recently, the USDA in the North Carolina and Georgia Coastal Plains (humid East) and in the U.S. Central Great Basin (arid West) (Harper and Sharpe, 1998; Harper et al., 2000, 2004, 2010) have shown that manure processing lagoons emit significantly less NH_3 than previously thought. Harper et al. (2004) found, in a highly measured swine production operation, that about 5.2% of the N going into the swine production operation as feed left the lagoon as NH_3, along with another 7.4% from housing and 2% from field application of waste effluent to nearby crops

(total of 14.6%). These emissions and other N components from a total N system's analysis (protein N output, crop N use, soil N denitrification to N_2 and nitrous oxide [N_2O] emissions, and lagoon NH_4^+ conversion to N_2 gas) accounted for 95% of the total feed N input to the system. Studies in the Central Great Basin (semiarid Utah) showed similar total NH_3 emissions of 15.2% of feed N but with a breakdown of 3.5 and 11.7% for housing and lagoon emissions, respectively (Harper, Weaver, and Flesch, unpublished data, 2002–2003).

Methane gas is particularly interesting not only because it has a radiative forcing about 25 times larger than CO_2 but also because it can be used as an energy source. Thus, capture of the energy-rich CH_4 gas greatly reduces the net radiative forcing of the lagoon gases emitted. To capture this escaping energy, the CH_4 can be collected from the manure-management lagoons or the manure may be collected from the production system and transported to a biofuel production facility where the organic materials are allowed to be microbially digested at an elevated temperature. The gases from this thermally accelerated digestion process are collected and scrubbed to remove CO_2 and other minority gases produced during the process. The purified CH_4 gas is converted onsite to methanol to be used in biodiesel for energy recovery.

In 2004, a biofuel treatment system was constructed at an existing facility in the semiarid U.S. Central Great Basin. The emissions from this farm system had previously been measured during 2000–2001 (Harper et al., 2006), so this was an ideal location to compare the effects of treatment for conversion of manure to biofuels (on gas emissions) with the previously measured gas emissions. In addition to this study, a concurrent short-term study was conducted onsite using different measurement technology (Harper et al., 2010). Thus, not only did we have an excellent location for the study of the effect of biofuel implementation, but we also were able to measure the effect on emissions by more than one technology with a short-duration and a relatively long-duration study.

There are complex interactions between C and N compounds during manure processing (Harper et al., 2000, 2004), and the conversion from a lagoon manure-management system to a biofuel system was anticipated to affect C and N emissions. Much of the N entering into manure management lagoons is converted to N_2 gas (Harper and Sharpe, 1998; Harper et al., 2000, 2001, 2004) by microbial and/or chemical conversion of NH_4^+ to N_2 (Van Cleemput, 1972, 1997, 1998). Although the exact mechanism of this process is not known, Van Cleemput (1998) suggested the term *chemical conversion of* NH_4^+ *to* N_2 be used to describe the process. Others have suggested the terms *chemical denitrification* and *chemo-denitrification*. We choose to describe this process as NH_4^+ conversion to N_2. The term *denitrification* is not used to avoid confusion with the denitrification process involving nitrate (NO_3^-) consumption, and *chemical* is also omitted because the exact process of this conversion is not known. Although little emissions research on the relationship between CH_4 and CO_2 has been published (Sharpe et al., 2001; McGinn et al., 2006) in confined animal feeding operations, Harper et al. (2000) found correlations between emissions of NH_3, CH_4, N_2O, and CO_2 from manure-processing lagoons, suggesting that manipulation of the manure-management system to reduce emissions of one constituent may affect the emissions of another. Harper et al. (2000) showed that, in a series of manure lagoons with a high rate of methanogenesis, there was a significant amount of NH_4^+ conversion to benign N_2 (molecular N) gas; however, when methanogenesis decreased, smaller emissions of N_2 occurred, and higher rates of N_2O were produced. They found that as the amount of NO_3^- and O_2 increased in the latter lagoon stages, even though smaller amounts of total gas flux were produced, the percentage of N_2 in the collected samples increased. The higher NO_3^- and O_2, along with lower NH_4^+, may have provided more suitable conditions for biological denitrification. Furthermore, there is no intermediate step producing N_2O in the NH_4^+ conversion to N_2, whereas in biological denitrification, N_2O is produced as an intermediate step (e.g., increasing concentrations of N_2O as O_2 and NO_3^- are evident). Harper et al. (unpublished data) found a similar relationship between methanogenesis and conversion of NH_4^+ to N_2 in a series of six geographically widely spaced swine operations in North Carolina. The purpose of our study was to evaluate the effects on C and N emissions from converting these farms to a biofuel production system.

Materials and Methods

From 2000 to 2003, CH_4 and NH_3 emissions were quantified from three 12,000-head swine finishing farms' manure processing lagoons in the U.S. Central Great Basin. Each farm consisted of three closely spaced and joined barns with adjacent primary and secondary manure processing lagoons (open-air). Each farm in the system had a 1.69-ha primary lagoon (8 m deep) where effluent from the control farm houses was transferred for processing. Each farm had a secondary lagoon for overflow from the primary lagoon if needed. The control farms' primary lagoons were organic rich with surface dissolved oxygen concentration less than 1% saturation. Due to the darkness of the liquid, no algae or surface bacterial layer was present. The secondary lagoons (0.59 ha) were similar in appearance, but the liquid was thicker due to evaporation. Evaporation and decomposition in both the biofuel and control farms maintained long-term manure equilibrium at the farm, and no manure removal was required.

In 2004, three of the previously measured farms, along with an additional nine finishing farms, were converted to a biofuel production system. This operation provided an excellent opportunity to test the effect of the biofuel production system on trace-gas emissions because the emissions from the biofuel farms could be compared with historical data from these same farms and with emissions from similar farms. At each of the biofuel farms, manure from the swine houses was first pumped to a small excavated collecting basin where organic material from the individual facilities is gravitationally concentrated. The organic-rich bottom layer was then pumped to the central biofuel production facility for further organic matter concentration. The final concentrated organic matter was then pumped to digesters for thermally accelerated anaerobic bacterial digestion resulting in biogas production. The CH_4–rich biogas produced in the digesters was then conveyed to a biomethanol conversion plant on site. The biomethanol produced at the site was transported to a refinery for conversion to biodiesel. All effluent from the concentrators and effluent from the digesters was then returned to the farms for further digestion and to maintain water levels at the manure-management effluent lagoons. Previous studies (2000–2003) from three farms at the production site (Farms 1, 2, and 3) were used as control data because they were converted to biofuel (treatment) production farms. Only a portion of the similar 12,000-head farms was converted to the biofuel manure treatment system within the swine farm complex. Three unconverted farms (Farms 4, 5, and 6) were studied intensively during our study and served as concurrent control farms.

The De Visscher model (De Visscher et al., 2002) was used to calculate NH_3 emissions from the lagoons. Ammonia emission from the De Visscher model (De Visscher et al., 2002) is described as a two-film model where NH_3 diffuses from the bulk liquid to the air–water interface through a thin boundary layer, each layer being characterized by a transfer coefficient. The model combines Henry's Law with the diffusion relationships and the mass-transfer coefficient in the boundary layer (derived from the relationship of the wind speed measured at a specified height). Because diffusion is concentration dependent, the higher the concentration of dissolved NH_3 in solution, the greater the diffusion rate. Dissolved NH_3 is dependent on the ammoniacal N concentration ($[NH_4^+ + NH_3]$) and the pH of the solution. The pH affects the concentration of dissolved NH_3 in a nonlinear relationship, where $[NH_3(aq)] = [NH_4^+ + NH_3] \times K_a/(10^{(-pH)} + K_a)$; K_a is the acid dissociation constant for NH_4^+. The model explained 70% of the variability compared with noninterference micrometeorological techniques using average daily NH_3 emissions. Average daily NH_3 emissions were calculated from average daily wind speed, lagoon temperature, pH, and dissolved ammoniacal N concentrations.

Water temperature, wind speed, pH, and $[NH_4^+ + NH_3]$ at the lagoons were measured for 13 mo. Wind speed data were collected using an anemometer (R.M. Young 03001-5, Campbell Scientific) whose output was recorded as 15-min averages. Water temperature data for emissions calculations were collected using one data logger per lagoon (HOBO Water Temp Pro, Onset Computer Corp.) attached to a buoy maintaining the logger at a depth of 5 to 7 cm. An additional data logger was placed at the bottom of each primary lagoon. One lagoon water sample was collected from the surface (0–4 cm) of each lagoon twice a month and then frozen for subsequent pH and $[NH_3 + NH_4^+]$ analysis. The pH and $NH_3 + NH_4^+$ measurements were performed on the thawed samples using an appropriate ion selective electrode (Accumet, Fisher Scientific). Water temperature and wind speed data were averaged to calculate daily average values. Although the actual measured pH and $[NH_3 + NH_4^+]$ values were used for emissions calculations on the days they were measured, days between consecutive measurements were represented by the average value of the measurements. For example, if the pH was 8.15 on 5 July and 8.25 on 19 July, a pH value of 8.15 would be used on 5 July, a pH value of 8.20 would be used from 6 July until 18 July, and a pH value of 8.25 would be used on 19 July for emissions calculations. The amount of feed N was determined using feed input data provided by the producer. Percent N in the feed was determined by Ward Laboratories.

The emissions of CH_4 and CO_2 gases were measured for approximately 24 mo. Methane and CO_2 gas emissions were determined by first measuring total biological gas emissions using gas collection devices (carboy method) to capture the evolved gases below the lagoon surface, with subsequent analysis by gas chromatography (GC). The gas collection devices were constructed from 5-gal plastic carboys with the bottoms removed (Harper et al., 2000, 2004). The carboys were tethered to boat anchors with 8 to 9 m of rope to the bottom of the lagoon, and each remained upright by ballast secured to the bottom of the carboy and a buoy secured to the top. The carboys were filled with water and allowed to sink below the water surface. The gases produced from decomposition of the animal manure displaced the water in the carboy, causing it to rise to the surface. Each carboy was graduated with liter lines to measure how much gas was in the carboy. Carboy volume was measured as frequently as twice a week in the summer and as infrequently as twice a month in the winter when gas production was low. Six carboys were placed uniformly in each primary manure treatment lagoon. The volumetric gas emission rates (adjusted for vapor pressure) were converted to kmol gas to compensate for the variation in gas composition along with change in lagoon temperature throughout the year. The kmol of gas were calculated using the monthly average surface temperatures of the lagoon (to estimate gas temperature), the average atmospheric pressure (83.6 kPa) corresponding to the elevation of the farms, and the ideal gas law.

The composition of the gases was determined by GC. Valves were placed in three carboys in each lagoon to allow for the transfer of the biological gases to SUMMA canisters (B.R.C. Rasmussen) for GC analysis. Gas samples were collected in the SUMMA canisters as frequently as every 2 to 3 wk in the summer to every 4 to 8 wk in the winter. Earlier tests using an inert gas (i.e., helium) in the containers provided a measure of potential atmospheric N_2 contamination in the collection and transfer processes and showed contamination to be less than 2% (Harper et al., 2004). Collected gases were analyzed using an Agilent 5390 gas chromatograph with a Supelco PLOT-5 column and a thermal conductivity detector. The configuration of the gas chromatograph allows for the determination of the composition of the major components present in the gas samples. The composition of the collected gases and the total gas emission rates were then used to calculate the emission of each gas.

Statistical Analysis

Most of the results of the emission measurements were analyzed using the independent two-sample *t* test assuming equal variances. All *p* values reported in the paper correspond to this *t* test. Because some interesting trends in average monthly emissions were seen, we examined the monthly means as paired data. The traditional paired *t* test and repeated measures ANOVA cannot be used because the monthly means are not normally distributed. Instead, we used a nonparametric test, the one-tailed Wilcoxon signed-rank test. Results of this analysis are simply reported as significant or not significant at the 95% confidence level.

Results and Discussion

Ammonia Emissions

Table 1 details the monthly average NH_3 emissions from each primary lagoon of the study. Ammonia emission parameters were measured from 1 July 2004 to 31 July 2005. Thus, July emissions were determined twice. The results from July 2004 and July 2005 were used to calculate an average July emissions rate, which, with all the month's emission averages, was used to calculate an annual emission rate. Annual average NH_3–N emissions from the biofuel farms primary lagoons were 18.8 kg NH_3–N d^{-1} $lagoon^{-1}$ larger ($p < 0.001$) than emissions from the control farms. We recognize that many units are used in expressing emissions and emission factors. For clarity, emissions expressed in other units have been omitted and are summarized in Table 2. All primary lagoons are equal (1.69 ha) and all secondary farms are equal (0.59 ha) in this study. Emissions per lagoon are used to evaluate the effect of the biofuel treatment system. In all but 1 mo, the control farm emissions were less than the biofuel farm NH_3 emissions. In 5 out of the 13 months, NH_3 emissions were significantly larger ($p < 0.05$) from the biofuel farms than from the control farms. In the month when emissions from the control farms were higher, the difference was very small (<1%).

The increase in NH_3–N emissions can be explained by a change in chemistry in the lagoons. Although $[NH_4^+ + NH_3]$ was not found to be higher in the biofuel lagoons (Fig. 1A), the average yearly pH of the biofuel farms was higher ($p < 0.01$). The pH (Fig. 1B) of the lagoons determines the form of ammoniacal N. Ammonia emissions are directly dependent on the concentration of dissolved NH_3 ($[NH_3(aq)]$), not on $[NH_4^+ + NH_3]$. Because NH_3 is a soluble gas, it exists in significant concentrations dissolved in the liquid and as a gas over the liquid. At equilibrium, the vapor pressure of this gas is directly proportional to ($[NH_3(aq)]$). The difference in $[NH_3(aq)]$ is shown in Fig. 1C, where the average monthly $[NH_4^+ + NH_3]$ for each lagoon and the average monthly pH for each lagoon are used to calculate the monthly $[NH_3(aq)]$ for each farm, which is used to calculate the average dissolved $[NH_3]$ for each farm system. On a year-to-year basis, the $[NH_3(aq)]$ was 31% larger ($p < 0.001$) in the biofuel farms' primary lagoons compared with the control lagoons.

The NH_3–N emissions were determined in three different studies at this production site. The farms were studied in 2000–2001 (Harper et al., 2006), in 2002–2003, and in the present study. The average yearly NH_3–N emissions from the primary lagoons of each farm are summarized in Table 3. The control farm results from 2000–2001 were from an earlier study (Harper et al., 2006) in which the published yearly emissions were divided by 365, and the results from 2002–2003 are from a previously unpublished study. The 2004–2005 control and the biofuel results are from the present study. The average control farm NH_3 emission of the three studies was 52.7 ± 1.8 kg NH_3–N d^{-1} $lagoon^{-1}$, which is significantly lower than emissions from the biofuel-treated lagoons (71.5 ± 1.6 kg NH_3–N d^{-1} $lagoon^{-1}$). Thus, the biofuel farms' NH_3–N primary lagoon emissions were 36% ($p < 0.001$) larger than the control lagoons. The close agreement of control NH_3 emissions between the three studies demonstrates a consistency between annual emissions, which is due not only to similar annual effluent characteristics ($[NH_4^+ + NH_3]$ and pH) but also to similar effluent temperature and wind speed. For example, the average annual wind speeds (July–July) for 2002–2003 and 2004–2005 were 2.76 and 2.79 m s^{-1}, respectively.

Emissions from secondary lagoons for 2004–2005 are summarized in Table 4. In this treatment system, the secondary lagoons are used as overflow reservoirs to capture any extra liquid from primary lagoons and to provide a larger surface area for evaporation. There is little microbial digestion (no bubbles observed at surface of lagoons) in these lagoons; thus, there would be little direct effect on NH_3 emissions anticipated due to reduced methanogenesis and conversion of ammoniacal N to N_2 gas (Harper et al., 2000, 2004). However, any changes in pH and $[NH_4^+ + NH_3]$ seen in the primary lagoons would also be carried over to the secondary lagoons. In the initial months of the study, some of the biofuel farms' secondary lagoons were empty due to water being diverted to the biofuel digester basin. Thus, emissions in the biofuel farms' secondary lagoons could not be measured at the biofuel farms during July, August, and September 2004. Between October and July, the biofuel farm secondary lagoons emitted 9.9 kg NH_3–N d^{-1} $lagoon^{-1}$ more (115%; $p < 0.01$) than those of the control farms. Omission of the first 3 mo is valid because the biofuel data are incomplete for this time period and the biofuel system had not completely affected the secondary farms until after this time. The 10-mo averages for the biofuel

† Lagoon dimensions are 1.69 ha each. Emissions were calculated from the De Visscher Model (De Visscher et al., 2002) using pH and ammoniacal N concentration, lagoon temperature, and wind speed.

and control secondary lagoons (18.5 and 8.6 kg NH_3–N d^{-1} $lagoon^{-1}$, respectively) are reasonable estimates of annual NH_3 emissions and are used for further comparisons. Average annual [NH_4^++NH_3] was higher in the biofuel secondary lagoons (240%; $p < 0.01$), but the pH was lower (0.18 pH units; $p > 0.05$). When these two factors are combined, the [NH_3 (aq)] was calculated to be 74% larger ($p < 0.001$) in the biofuel farm secondary lagoons. When NH_3 emissions from both secondary and primary lagoons are added, total lagoon emissions from the biofuel farms are 90.0 ± 1.8 kg NH_3–N d^{-1} farm-$lagoon^{-1}$, which is 47% larger than the 61.3 ± 3.0 kg NH_3–N d^{-1} farm-$lagoons^{-1}$ from the control farms.

Methane and Carbon Dioxide Emissions

Although NH_3 emissions increased at the biofuel farms relative to the control farms, CH_4 and CO_2 emissions decreased. Because the purposes of the biofuel facility were energy capture (manure conversion to methanol) and the subsequent reduction of CH_4 emissions, the reduction of C emissions was expected. Figure 2 summarizes average total biological gas emissions (total gas collected in the carboys) per farm type. Total biological gas emissions are expressed in kmol to compensate for changes in gas composition and temperature throughout the year. There was a slight difference between farm systems because the biofuel farm biogas emissions were 7% less the first year (2004–2005) and 13% less the second year (2005–2006) ($p > 0.05$). Although these differences were not statistically significant on an annual basis using standard deviations of the average yearly emissions from each farm ($p > 0.05$), a definite trend exists. The question is whether this trend is significant. During the first year of the study when the biofuel system had just been initiated, the biofuel farm biological gas emissions were larger or equal to control

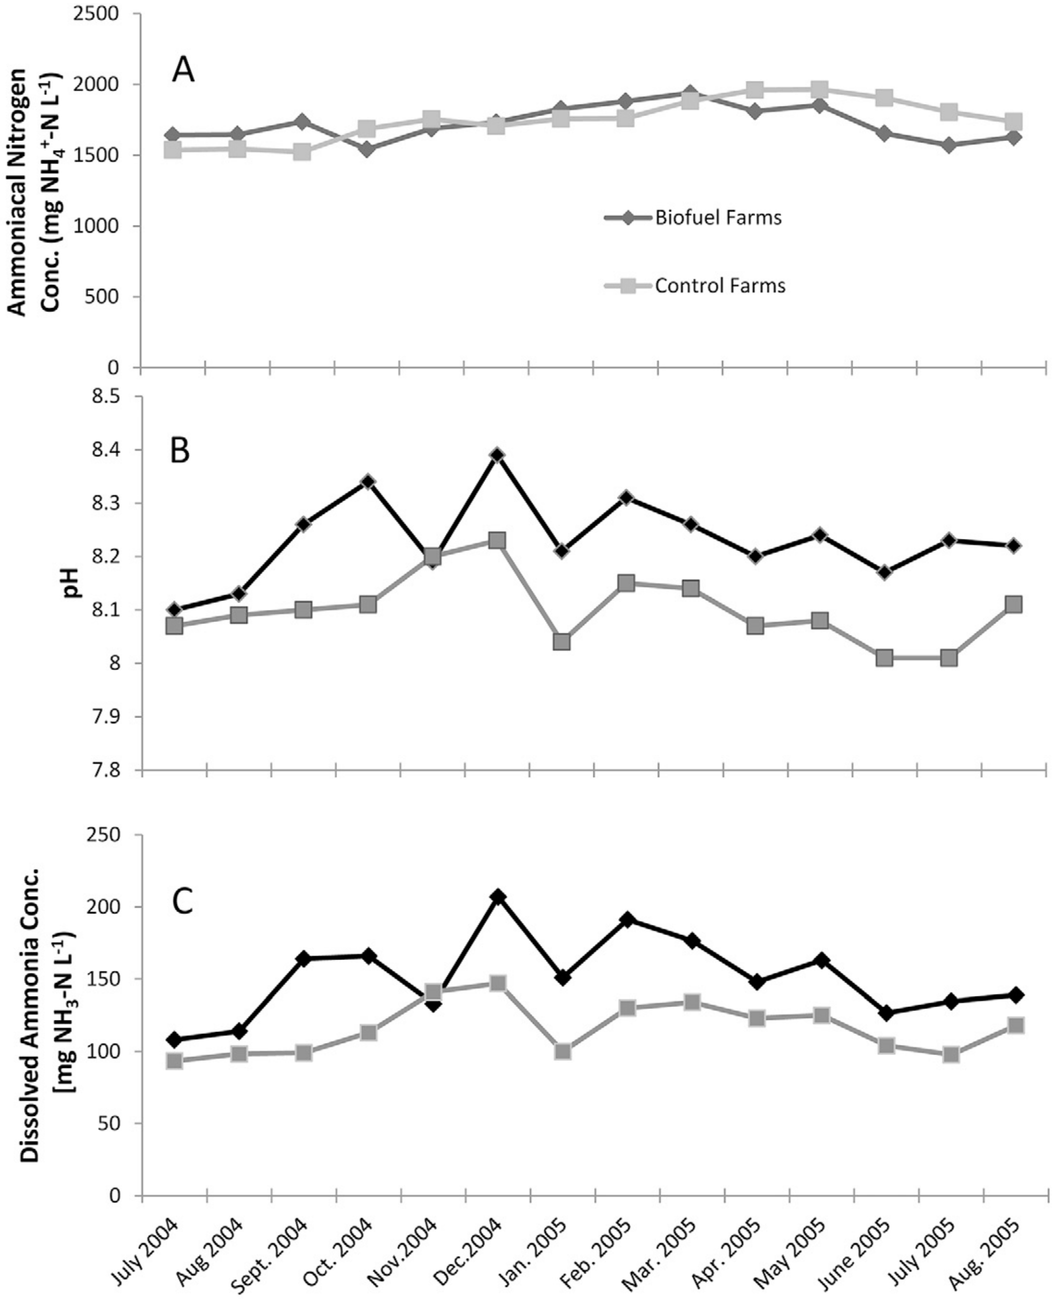

Fig. 1. The effect of concentration (A) and pH (B) of dissolved ammoniacal N on dissolved ammonia of effluent of primary lagoons at depth of 5 to 7 cm. The dissolved ammonia concentration (C) was calculated using the pH and ammoniacal N concentration and the acid dissociation constant for NH_4^+.

emissions during the first 5 mo. During the remaining 7 mo, the biofuel farms emissions were larger only during October. Again, during the second year, biofuel farm biogas emissions were larger only during the months of September and October. When these monthly means are evaluated by the Wilcoxon signed-rank test, the biofuel farms produced less biogas than the control farms after October of 2004 at the 95% confidence level. When the months before October 2004 were included in the analysis, no statistical significance was seen at the same confidence level.

Larger biofuel farm biological gas emissions in September and October may be explained by the following hypothesis where the biofuel facility is constantly returning warmer water, consequently affecting the gas production in the fall. This is important because microbes tend to operate in a very narrow temperature range and bacteria that operate in the lagoons would be a different thermal group of bacteria than those of the biofuel facility. The anaerobic bacteria are divided into three thermal groups: psychrophiles (<20°C), mesophiles (25–40°C), and thermophiles (>40°C) (Conrad et al., 2009; Donoso-Bravo et al., 2009; van Lier et al., 1997). Microbes operating in the biofuel facility have very little activity in colder temperatures where only psychrophilic methanogens would grow. During the summer months temperatures exceed 20°C, and the mesophiles would be expected to have diminished growth rates (van Lier et al., 1997). As the summer ends, both lagoons would cool, and at first mesophilic microbes from the biofuel facility would enhance methanogenesis by increasing the population and diversity of microbes. As the lagoon temperatures further cool, these mesophilic microbes would become dormant and would not affect biogas production. van Lier et al. (1997) found mesophiles to remain active at low metabolic rates even after 8 mo of psychrophilic conditions. It is speculated that there would be a time when the additional C loading of the control lagoons would be offset by the effect of the increased microbe population. The temperature readings at the bottom of the primary lagoons of the biofuel lagoons tended to be warmer in the winter, but the temperatures were not statistically different (p > 0.05). A warming effect from the return of effluent to the biofuel lagoons is not likely due to heat removed in the surface pipes during transmission. Instead, we think an introduction of the mesophilic microbes may have had an effect on gas production.

Gas chromatography was used to measure the percent composition of gases collected from the lagoon sampling carboys to determine the daily composition of each gas emitted. Only CH_4, CO_2, and N_2 were detected. No N_2O was seen in the GC chromatograms; therefore, there were no N_2O emissions. This phenomenon has been seen in earlier work (Harper et al., 2000, 2004) in anaerobic lagoons where little or no N_2O was seen in similar gas collection devices or from emissions observed by tunable diode lasers over the lagoons. Concentrations of N_2O over the lagoons were found (Harper et al., 2000) to be lower than background N_2O levels, indicating that N_2O was consumed from the atmosphere. The data from GC analysis of all of gas samples collected in any 2-wk period was averaged, and this average composition was mathematically fit to a sixth-order polynomial curve. The polynomial fit was used to estimate daily percent composition of each gas for the sampling time period. The percent composition of each gas was calculated from the average GC data of all of the farms because the large variance in the data and the occasionally limited number of samples during some periods prevented calculation of statistically significant individual control and biofuel averages. The validity of pooling the data was tested by curve fitting the gas composition data from the control and biofuel farms independently. The standard error of each fit was used as the 95% confidence interval. Because the confidence intervals overlapped almost completely, we could not say that the gas compositions of the biofuel and control farms were significantly different, and it was proper to combine the data. A sine curve was also fit to the combined data. The polynomial fit could not be used to extrapolate outside of the data points. However, the periodic sine curve takes into account the cyclic nature of the data due to the seasonal variation and

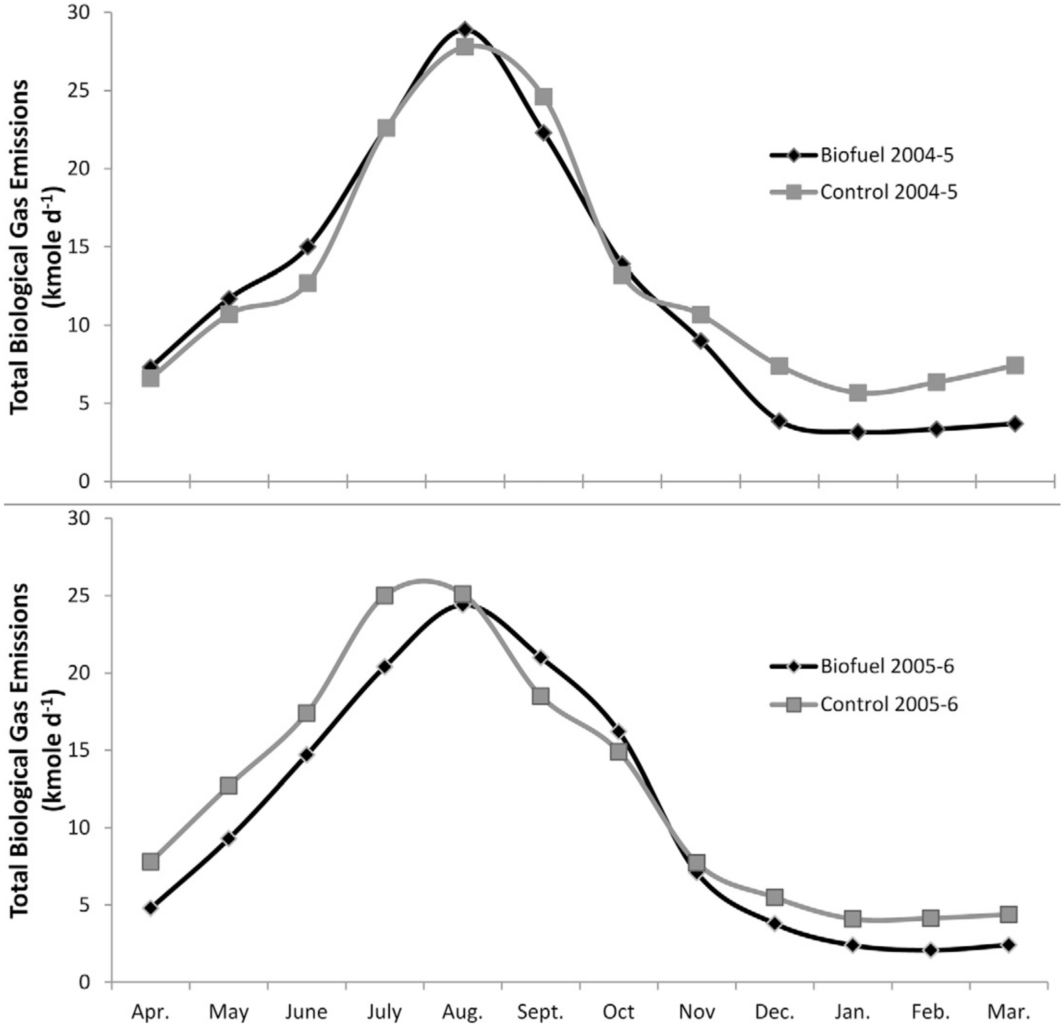

Fig. 2. Total biological gas production of the primary lagoons for each month.

extrapolates the data very well. Therefore, the sine curve was used to estimate gas compositions for the final 40 d of the study. The percent composition for each gas from the fits of the data from all farms was used to represent the daily composition of each gas for subsequent calculations. Figure 3 shows the fit of the average data along with the standard deviation demonstrating the uncertainty of the measurements.

Figure 3 shows a seasonal trend in the gas composition. Maximum CO_2 and CH_4 compositions (as a percent of total gas emissions) occurred in the summer months, whereas maximum N_2 composition occurred in the late winter. There are several possibilities that explain this variation in gas composition. Because the sampling interval of the carboys was much longer in the winter before collection for GC analysis, several processes must be considered. First, there is the possibility that the CH_4 and CO_2 in the carboys and not N_2 are being dissolved back into the effluent. This is highly unlikely because these lagoon waters are saturated with the gases from the constant emission of gases from the bottom. Second, there is a possibility that the gases that are saturated in the effluent from the atmospheric partial pressure, namely N_2, will transfer into the carboys. This is also not likely because carboys filled with helium did not show appreciable contamination with atmospheric N_2 in earlier experiments (Harper et al., 2004) and gas-solution calculations showed insignificant N_2 transport from the gas in solution to gas in the carboys (Harper, 2005; A. De Visscher and L.A. Harper, unpublished data). The individual steps of anaerobic microbial digestion involve different microbes that have been shown to be affected differently by temperature (Conrad et al., 2009; Fey and Conrad, 2000). We infer that if NH_4^+ conversion to N_2 occurs by another chemical or biological process that is affected by temperature differently, the percent composition of gases would not remain the same throughout the year. For example, if the NH_4^+ conversion to N_2 takes place via pychrophilic organisms, the production of N_2 would not coincide with the mesophilic methanogenesis that occurs in the summer. Instead, methanogenesis would tend to produce more CO_2 and CH_4 via mesophilic methanogens relative to N_2 in the summer and less in the winter.

The monthly gas emissions (Table 5) were calculated for each farm using the total biological gas emission of each farm type multiplied by the average fractional composition of each gas of all farms. The monthly average of each farm was then used to calculate the monthly biofuel and control average emissions. Monthly standard deviations ranged from 7 to 52% of the monthly means (data not shown).

Examination of CH_4 emissions shows important trends (Table 5), where CH_4 was generally lower. Methane emissions were lower the second year for both types of farms. Average CH_4

emissions from the biofuel farms were 118.6 ± 1.9 and 103.1 ± 19.7 kg CH_4–C d^{-1} $lagoon^{-1}$ for the first and second years, respectively. Average emissions from the control farms were 123.5 ± 11.4 for the first year and 117.1 ± 11.1 kg CH_4–C d^{-1} $lagoon^{-1}$ for the second year. During both years, the control emissions were higher than the biofuel farms, but in each case, the differences were not significant ($p > 0.05$). Although the difference in CH_4 emissions was not significant on an annual basis, the average monthly biofuel farms emissions were consistently lower after September of the first year. Monthly biofuel average emissions were generally lower after October of the first year (September and October of the second year were exceptions to this trend). Evaluation by the Wilcoxon signed-rank test showed that the biofuel farms produced less CH_4 than the control farms after October 2004 at the 95% confidence level.

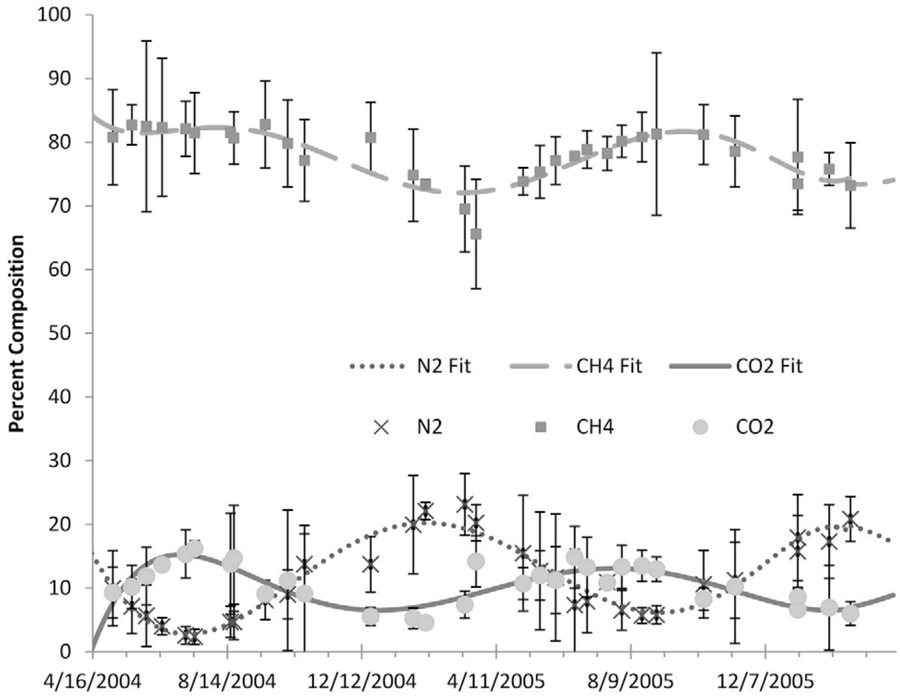

Fig. 3. Comparison of biological gas composition. Markers indicate average composition of gas samples collected by SUMMA canister and analyzed by gas chromatography for a given 2-wk period. Error bars are SDs of these averages. The curves are the best fit of the data.

This difference in CH_4 emissions between farm systems is best explained by an overall decrease in biological gas production (less decomposition and methanogenesis), which has been previously discussed. As total biogas production decreases, each individual gas within the biological gas decreases. The biofuel farm CO_2 emissions (Table 5) were also found to be lower than the control farms, but, similar to CH_4, there was no difference between farm systems or between yearly averages for the first and second years of the study ($p > 0.05$). Average CO_2 emissions from the biofuel farms were 16.6 ± 0.1 the first year and 15.2 ± 2.9 kg CO_2–C d^{-1} $lagoon^{-1}$ the second year, and for the control farms the averages were 16.7 ± 1.9 and 17.2 ± 1.5 kg CO_2–C d^{-1} $lagoon^{-1}$ for the first and second years of the study, respectively. The same month-to-month statistically significant trend was seen for CO_2 and CH_4 emissions: Monthly biofuel CO_2 emissions were lower after October of first year with the exception of September and October of the second year. As was the case with biogas, when

§ The lagoon size of each lagoon in the study is 1.69 ha. The emission of each gas was calculated from the measured daily average of biogas collected from SUMMA canisters and the daily percent composition of each gas measured from gas chromatography.

¶ The SD from the mean of the annual emissions of the three farms from each farm type.

the trend in the monthly means was evaluated by the Wilcoxon signed-rank test, the biofuel farms produced less CO_2 than the control farms after October of the first year at the 95% confidence level. When the months before October of the first year were included in the analysis, no statistical significance was seen at the same confidence level. Biofuel CO_2 emissions decreased in the biofuel system as the study progressed.

The trend in CH_4 and CO_2 leads us to ask whether the biofuel conversion process stabilized such that the study characterized the emissions of a normally operating biofuel/methanol facility. We believe that the change in the production of biogas beginning in September or October of the first year is an excellent indication that the system was ending in its startup phase. The fact that the biofuel farms produced more gas the first 5 mo and then produced less thereafter leads us to believe that the emission trends seen in the 2 yr of the study would not have reversed but instead would have maintained or increased with time.

Reduction of the individual biogas emissions is attributed to the reduction of C loading in the primary lagoons. A general annual decrease in available organic matter (sludge layer) from that accumulated at the bottom of the lagoons during winter months was observed (Weaver and Harper, unpublished data) as methanogenesis increased each summer due to higher lagoon temperatures. Measurements of organic matter between systems may be difficult because these differences are expected to be less than those observed between winter and summer sludge levels. Because earlier attempts to quantify C loading and the sludge layer were very difficult due to the large variability in the data, these measurements were not made in this study. However, it is not unreasonable to expect a similar phenomenon to occur in the biofuel facility. In this facility, the operating temperature (35°C) is at least 11 to 18°C more than measured temperatures in the bottom of the lagoons. Therefore, because methanogenesis increases with temperature (Hill et al., 2001), the net (biofuel facility + lagoon) methanogenesis should be higher than that observed in the control farm lagoons. We hypothesize that this would result in a decrease in the amount of organic matter entering the lagoons, thus creating a new baseline concentration of organic matter in the lagoon. During the first year, only a small decrease in CH_4 production was observed due to the residual manure decomposition. This process predicts the amount of manure stored in the bottom of the lagoons to decrease and lower CH_4 production. Carbon dioxide emissions result from the same microbial processes, and, likewise, CO_2 emissions decreased due to depletion of residual C in the lagoons. The decrease in NH_4^+ conversion to N_2 agrees with earlier studies where a decrease in methanogenesis resulted in less NH_4^+ conversion to N_2 (Harper et al., 2000).

Dinitrogen Gas Emissions

Another gas found in the carboys was N_2 gas (Table 6). Dinitrogen gas emissions from the biofuel farms were 27.5 ± 0.9 and 28.8 ± 6.8 kg N_2–N d^{-1} $lagoon^{-1}$ the first and second years and for the control farms were 32.7 ± 2.2 and 35.0 ± 2.8 kg N_2–N d^{-1} $lagoon^{-1}$ for the first and second years, respectively. Dinitrogen emissions were significantly lower at the biofuel farms for the first (7.1 kg N_2–N d^{-1} $lagoon^{-1}$; 16%; $p < 0.05$) and second years (6.0 kg N_2–N d^{-1} $lagoon^{-1}$; 20%; $p < 0.01$). The trend that had been seen for CH_4, CO_2, and total biogas production was seen where monthly N_2 production was lower in the biofuel lagoons after October of the first year (except for September and October of the second year). When the monthly means are evaluated by the Wilcoxon signed-rank test, the biofuel farms produced less N_2 than the control farms after October of the first year at the 95% confidence level. When the months before October of the first year (when CO_2 production was greater) were included in the analysis, no statistical significance was seen at the same confidence level.

Comparison to a Concurrent Study

Individual biological gas species' emissions (CH_4 and CO_2) decreased throughout the course of the study. Methane emissions were reduced 4.0% ($p > 0.05$) the first year and 12.0% ($p > 0.05$) the second year due to diminishing available organic matter in the lagoons for decomposition (removed for biofuel production). Likewise, CO_2 emissions were reduced 0.6% ($p > 0.05$) and 11.6% ($p < 0.05$) the first and second years of the study, respectively. The reduction in N_2 gas emissions in the biofuel lagoons was associated with reduced methanogenesis. It is possible that the thermodynamics of the system and Gibbs free energy for NH_4^+ conversion to N_2 (Van Cleemput, 1972) suggest that spontaneous conversion of NH_4^+ to N_2 may occur. With reduced NH_4^+ conversion to N_2, NH_3 emissions would be expected to increase. During the same period, primary lagoon NH_3 emissions increased 36% ($p < 0.001$), whereas N_2 production during the first and second years of the study decreased 16% ($p < 0.05$) and 20% ($p > 0.05$).

The decrease in CH_4 emissions and the increase in NH_3 emissions agrees with a concurrent study at the same location when NH_3 and CH_4 emissions were measured intensely during brief periods of high emissions (summer) and low emissions (winter). In this concurrent study (Harper et al., 2010), whole-farm (including barns and lagoons) emissions were measured

§ The lagoon size of each lagoon in the study is 1.69 ha. The emission of N_2 gas was calculated from the measured daily average of biogas collected from Summa canisters and the daily percent composition of each gas measured from gas chromatography.

¶ The SD from the mean of the annual emissions of the three farms from each farm type.

by the inverse Lagrangian stochastic analysis (bLS) technique (Flesch et al., 2004, 2005, 2007; McGinn et al., 2006; Harper et al., 2009). In the study using the bLS technique, the whole-farm CH_4 emissions decreased 47% (830 kg CH_4–C farm^{-1} d^{-1}) compared with control farms, whereas NH_3 emissions increased by 46% (144 kg NH_3–N d^{-1} farm^{-1}, 28.4% of feed N). In our study, CH_4 primary lagoon emissions decreased 12%, and NH_3 primary plus secondary lagoon emissions increased 47%.

To better compare differences in emission measurements between the two studies, emissions were calculated using the De Visscher model for the same brief time periods (winter and summer) of the bLS study for the secondary and primary lagoons. The winter and summer emissions were then averaged to calculate a yearly emissions rate for the lagoons as was done in the bLS study. Using this calculation procedure, the biofuel farms' total NH_3 emissions from the primary and secondary lagoons were 58% larger than those from the control farms (97.7 vs. 62.1 kg N-NH_3 d^{-1} farm-lagoons^{-1}). Similarly, larger emissions' differences were also seen for CH_4. Biofuel CH_4 emissions measured by the carboy method during the bLS time period were 23.3% less (95.8 vs. 124.9 kg CH_4–C lagoon^{-1} d^{-1}) than control lagoon emissions. This is a considerably larger difference compared with 12% smaller CH_4 emissions determined for the second year of the study. As differences in emissions were larger during the bLS study period due to the limited measuring time period, care should be used when representing annual emissions with short-term studies.

Although the NH_3 emissions' relative difference between farm systems is similar between bLS and the De Visscher methods during the bLS study period (46 and 58%, respectively), carboy-measured CH_4 emissions' relative decrease (23%) was less than half of that (47%) measured by the bLS method. The comparison of differences is compounded by the fact that the bLS determines emissions from both the lagoons plus barns combined (whole-farm measurement). Although bLS emission measurements for CH_4 and NH_3 are considerably larger than corresponding values measured by the carboy and De Visscher methods, both studies demonstrate an observed decrease in CH_4 emissions corresponding with an increase in NH_3 emissions.

The Effect of pH on Lagoon Emissions

Along with producing energy from manure, normally a waste commodity, a decrease in global warming gas emissions was one of the original intentions for biofuel production. There was a decrease in total CH_4 emissions, which resulted from reduction in lagoon C loading in the farm lagoons due to diverted organic matter being converted to biofuel. The relationship between NH_4^+ conversion to N_2 and methanogenesis predicted that a decrease in methanogenesis (smaller CH_4 and CO_2 emissions) would result in a decrease in the amount of [NH_4^++NH_3] converted to N_2 and an increase in [NH_4^++NH_3], causing a potential for NH_3 emissions. However, the decrease of 6.2 kg N_2–N d^{-1} lagoon^{-1} emissions from [NH_4^++NH_3] conversion is much smaller than the increase of 18.8 kg NH_3–N d^{-1} lagoon^{-1} emissions and cannot be explained simply by a decrease in denitrification.

The difference between the relative increase in denitrification (emission of N_2) and increase in NH_3 emissions can be explained by the change in pH observed in the lagoons. Ammonia emissions are controlled by four factors: effluent temperature, wind speed (turbulence at the solution/air interface), effluent pH, and [NH_4^++NH_3] (Harper, 2005). Any process that affects these four factors will affect NH_3 emissions. Dissolved ammoniacal N exists in two forms: the nonionic form (NH_3), which is volatile, and the ionic form (NH_4^+), which is not volatile. The ratio of these two forms is controlled by the relationship [NH_3]/[NH_4^+] = $10^{(pH-pKa)}$. Therefore, a small increase in pH greatly increases the NH_3/NH_4^+ratio at the pH range observed in the lagoons. As the concentration of dissolved NH_3 increases, the partial pressure of NH_3 increases according to Henry's Law, thus increasing NH_3 emissions.

The importance of pH is demonstrated in Fig. 1B, with lagoon pH being higher in the biofuel lagoons. Examination of the data in Fig. 1A shows that the N concentrations are very similar, suggesting no difference in NH_3 emissions; however, slight differences in pH affect NH_3 emissions considerably more than differences in [NH_4^++NH_3]. For example, a 0.3 pH unit difference in two lagoons with the same ammoniacal N concentration would result in a nearly a twofold difference in aqueous [NH_3] and subsequently a twofold difference in NH_3 emissions from the more alkaline lagoon. To have the equivalent effect, the [NH_4^++NH_3] would have to double. Thus, a small change in pH can have a large effect on emissions.

Although methanogenesis rates control CO_2 and CH_4 emissions and influence conversion to N_2, methanogenesis only indirectly affects NH_3 emissions by affecting the lagoon solution pH. Methanogenic microbial communities consist of various guilds of microorganisms that perform various functions (Conrad et al., 2009; McInerney and Bryant, 1981; Zehnder, 1978; Zinder, 1993). Many products of methanogenesis are acidic. The first step in the microbial degradation of manure involves conversion of complex organic matter to fatty acids, alcohols, and CO_2 (also acidic). The fatty acids and alcohols are converted to acetic acid, which is converted to CO_2 and CH_4 (Abbanat et al., 1989). These products would interact with the buffering system of the lagoons and lower the pH. Conversely, a decrease in methanogenesis would therefore result in increased solution pH. Because all the lagoons in this study were similar due to identical feeding operations, the buffer capacities, which were not measured, should be equal, and pH effects would be due to changes in methanogenesis rather than differences in buffer capacity between treatment systems. The effect of methanogenesis on pH has already been seen in another study, where pH and temperature depth profile measurements of the lagoons were conducted (Weaver and Harper, unpublished data). The pH was considerably lower (>0.3 pH units) at the bottom (deepest 1–2 m) of the lagoons where the manure solids accumulate as sludge and methanogenesis is largest. However, all of the bioreactors' methanogenesis acidic products, except for CO_2, are returned to the primary lagoons. Furthermore, the primary lagoons are saturated with CO_2, so, whether the bioreactors are present or not, most CO_2 produced in the lagoons is released into the atmosphere. Therefore, whether the methanogenesis occurs in the bioreactor or the primary lagoons, the pH effect should be same. Could another process also be affecting pH?

Although other factors may exist in the biofuel process that increase pH, a decrease in NH_4^+ conversion to N_2 could also affect pH as well as increase [NH_4^++NH_3]. Harper et al. (2004) theoretically demonstrated that NH_4^+ conversion to N_2, under low dissolved oxygen conditions (partial pressure O_2 = 10 kPa to 1 × 10^{-13} kPa), is thermodynamically ($\Delta G \approx -1249$ to

−992 kJ mol^{-1}) favorable for the following reaction under typical lagoon conditions where dissolved oxygen concentrations are too low to be measured by a dissolved oxygen meter:

$$4(1-a)NH_3\,(aq) + 4aNH_3(aq) + 3O_2(g) \rightarrow 2N_2(g) + 6H_2O(l) + 4(1-a)\,H^+\,(aq) \qquad [1]$$

According to this proposed reaction, if NH_4^+ is oxidized, H^+ is produced, thereby lowering the pH. If NH_3 is oxidized, the acid base equilibrium of NH_4^+ is shifted to produce more NH_3, which produces more H^+.

$$NH_4^+(aq) \leftrightarrow NH_3(aq) + H^+\,(aq) \qquad [2]$$

Consequently, a decrease in conversion to N_2 by the proposed mechanism would tend to increase the pH. Additionally, because N_2 production only occurs in the presence of methanogenesis (Harper et al., 2000), a decrease in methanogenesis would increase the [NH_4^++NH_3]. Therefore, a decrease in NH_4^+ conversion to N_2 would not only increase NH_3 emissions by producing more available NH_4^+(aq) and NH_3(aq), but, more importantly, it would raise the pH, increasing the [NH_3(aq)] and thus the NH_3 emissions (Fig. 1).

The implementation of the biofuel system demonstrated immediate small decreases in CO_2 and CH_4 lagoon emissions after the first year of the study. These C emissions were decreased even further (11–12%) after the second year of the study due to the diversion of manure for conversion to biofuel. The implementation of the biofuel system also resulted in a decrease in N_2 gas emissions, which we attribute to a decrease in the conversion of NH_4^+ to N_2. The lagoon solution pH also increased corresponding to the decrease in conversion to N_2 and the decrease in methanogenesis. This pH increase resulted in an increase (47%) in lagoon NH_3 emissions. Further studies are necessary to determine if the effect is seen at other biofuel facilities at different locations and using different systems. This study shows the unintended consequences of how an effort to reduce one emissions' process (greenhouse gas emissions) affects the amount of another process (air quality gas emissions). This should be considered when making changes to any management system because the benefits of any biofuel system should be weighed against any detriment that may occur.

Acknowledgments

The authors thank USDA project technical assistants M.A. Thorton and J.E. Scarbrough and SUU undergraduate assistants C. Holyoak and K.M. Shumway (deceased) who made this work possible. This project was funded by the USDA-ARS Global Climate Change Program, Smithfield Foods, and a faculty development grant from SUU. Special thanks are also extended to the host swine producers and their hospitality during the study.

Quarterly Progress Report
April to June 2019

Submitted via email on July 30, 2019

In accordance with Appendix H of the Consent Decree, Premium Standard Farms, LLC, Murphy-Brown of Missouri LLC and KC2 Realty, hereafter collectively referred to as "PSFMBM" or "the Companies", provide this Quarterly Progress Report for the Second Quarter of 2019. Please be made aware that Premium Standard Farms has changed its name to Murphy-Brown of Missouri LLC.

Under the Consent Decree, each quarterly progress report shall contain the following information: (1) a brief description of the actions taken by the Defendants towards achieving compliance with this Consent Decree during the reporting period, including actions related to compliance with the requirements set forth in Appendices A through G; (2) a summary of the results of any testing conducted pursuant to Appendices B, C, and F during the reporting period; (3) an identification of all instances of noncompliance with the performance standards set forth in Appendix D and any other failures known to the Defendants to comply with the requirements of this Consent Decree during the reporting period, the reasons for such failures to comply, and actions already taken or planned to be taken to correct such failures to comply; and (4) a brief description of the actions that the Defendants anticipate taking towards achieving compliance with this Consent Decree during the next quarter, including any possible delays or other problems that may affect compliance with the Consent Decree and the Defendants' anticipated actions to resolve such delays or problems.

I. Actions Toward Achieving Compliance with Consent Decree Including Appendices

This section will provide a brief description of the actions taken by the Companies towards achieving compliance with this Consent Decree during the reporting period, including actions related to compliance with the requirements set forth in Appendices A through G. This section will also provide a summary of the results of any testing conducted pursuant to Appendices B, C, and F during the reporting period.

A. Appendix A – Technology Alternatives

Somerset, Locust Ridge and Hedgewood Projects

All required technologies have been installed and are operational at the Locust Ridge and Somerset farms, including the AND system and scraper systems at all required barn sites. Both farms have been repopulated and are currently operating as Class IA farms on a daily basis.

Quarterly Progress Report
April to June 2019

The AND system has not been installed on the Hedgewood farm and it remains a Class IB operation. This farm has and continues to maintain compliance with the 50 percent nitrogen reduction standard.

The total storage volume available at Hedgewood on June 28, 2019 was 10,969,889 gallons.

During this quarter, we land applied 3,073,651 gallons of effluent at the Hedgewood farm.

During this quarter, the AND systems at Somerset and Locust Ridge returned to normal operation.

The total storage volume available at Somerset on June 28, 2019 was 36,210,176 gallons. During this quarter, we land applied 22,719,260 gallons of effluent at the Somerset farm.

The total storage volume available at Locust Ridge on June 28, 2019 was 26,820,828 gallons. During this quarter, we land applied 1,557,256 gallons of effluent at the Locust Ridge farm.

Green Hills and South Meadows Projects

During this quarter, the AND systems returned to normal operation.

The total storage volume available at Green Hills on June 28, 2019 was 29,540,978 gallons. During this quarter, we land applied 7,245,900 gallons of effluent at the Green Hills farm.

The scraper systems at Green Hills were installed and operational on the following dates: Green Hills 10, October 10, 2011; Green Hills 11, November 1, 2011.

The total storage volume available at South Meadows on June 28, 2019 was 20,778,203 gallons. During this quarter, we land applied 7,823,727 gallons of effluent at the South Meadows farm.

All primary lagoons at South Meadows have impermeable covers installed.

The scraper systems at South Meadows were installed and operational at all sites in March, 2011.

During this quarter, the lagoon cover at South Meadows 3 experienced damage. A majority of the cover is still in working order, but we plan replace the cover in the upcoming months.

Homan and Ruckman Projects

During this quarter, the AND systems returned to normal operation.

The total storage volume available at Homan on June 28, 2019 was 67,628,126 gallons. During this quarter, we land applied 20,311,486 gallons of effluent at the Homan farm.

Quarterly Progress Report
April to June 2019

The scraper systems at Homan were installed and operational on the following dates: Homan 17, February, 11, 2011; Homan 18, February 2, 2011; Homan 19, June 28, 2011; Homan 20, January 28, 2011; Homan 21, May 20, 2011; Homan 22, June 3, 2011 and Homan 23, February 18, 2011.

The total storage volume available at Ruckman on June 28, 2019 was 60,916,781 gallons. During this quarter, we land applied 20,414,231 gallons of effluent at the Ruckman farm.

During the second quarter of 2017, a storm destroyed the lagoon cover at site 11. Installation of the new cover at site 11 was completed during the second quarter of 2018.

The scraper systems at Ruckman were installed and operational in all 70 barns in April, 2011.

Badger/Wolf / Brantley Project

During this quarter, the AND systems returned to normal operation.

The total storage volume available at Badger/Wolf/Brantley on June 28, 2019 was 43,650,154 gallons. During this quarter, we land applied 36,567,076 gallons of effluent at the Badger/Wolf/Brantley farm.

Terre Haute Project

During this quarter, the AND systems returned to normal operation.

The total storage volume available at Terre Haute on June 28, 2019 was 37,090,262 gallons. During this quarter, we land applied 49,263,999 gallons of effluent at the Terre Haute farm.

Scraper installation at Terre Haute was completed on December 24, 2011. This consisted of scrapers being installed in all farrowing, breeding and gestation barns for sites 1, 2, 5, 6, 7, 11, 13, 14 and all barns at Cooley Mega and Terre Haute Mega.

Valley View Project

During this quarter, the AND systems returned to normal operation.

All primary lagoons have impermeable covers installed.

The total storage volume available at Valley View on June 28, 2019 was 58,436,447 gallons. During this quarter, we land applied 16,385,545 gallons of effluent at the Valley View farm.

Whitetail Project

During this quarter, the AND systems returned to normal operation.

The total storage volume available at Whitetail on June 28, 2019 was 23,216,329 gallons. During this quarter, we land applied 15,772,471 gallons of effluent at the Whitetail farm.

All the Whitetail sites (72 barns) were installed with scraper systems by December 31, 2010.

In an effort to minimize the impact of storm water on our irrigation basins and the AND system at Whitetail, PSFMBM began the installation of a high density polyethylene cover on site 1 lagoon in late 2010. The cover installation process was completed during the first quarter of 2011. This system has a storm water collection system in place as well as a gas collection system. During the fall of 2011, PSFMBM began the installation of an additional impermeable cover on the Whitetail site 5 lagoon. The cover installation was completed during the third quarter of 2012.

B. Appendix B – Lagoon Integrity Testing

On March 5, 2007, EPA sent a letter to PSFMBM requesting quarterly monitoring for a period of one year at monitoring wells near the Terre Haute 11 and Ruckman 15 lagoons. A report summarizing data from the first two quarters of sampling was submitted to EPA on October 19, 2007. The fourth quarter of sampling was completed during December 2007. A summary report on all four quarters has been sent to EPA. PSFMBM received a letter from EPA on January 19, 2010 requesting additional testing of monitoring wells. The test wells were drilled at our Scott/Colby and Whitetail farms. Sampling at the farms has been completed and we submitted the final report for the Scott/Colby farm to EPA and CLEAN during the first quarter of 2012. EPA responded with an approval letter for the Scott/Colby report in the second quarter of 2012. The report for the Whitetail lagoon integrity testing results was submitted during the third quarter of 2012. In late 2013, PSFMBM received a letter from EPA that approved the Whitetail lagoon integrity test results.

C. Appendix C – Testing Criteria for Technology Alternatives

All data indicates the Whitetail, Terre Haute, Badger/Wolf/Brantley, Homan, Ruckman, Green Hills, South Meadows, Valley View, Somerset and Locust Ridge AND systems are operating as designed and meeting the treatment goals.

Appendix D – Performance Standards

During this quarter, the Badger/Wolf, Whitetail, Terre Haute, Homan, Ruckman, Green Hills, South Meadows, Valley View, Somerset and Locust Ridge AND systems returned to normal operation.

D. Appendix E – Best Management Practices

During this quarter, PSFMBM had no releases that required reporting to MDNR.

E. Appendix F – Air Emissions Monitoring

On November 17, 2004, PSFMBM mailed to EPA the *Air Emissions Monitoring Completion Report* pursuant to Appendix H, paragraph II.A.(8) of the Consent Decree. PSFMBM revised the Report in response to EPA's September 2, 2011 comments and submitted the revised report to EPA on September 26, 2011. EPA subsequently approved the report.

During the fourth quarter of 2012, PSFMBM submitted the post-technology monitoring report dated October 18, 2012 for the Whitetail Farm to EPA for review; that report was entitled *Post-technology Emissions Measures of a Covered Anaerobic Lagoon and Nitrification/Denitrification Treatment Cells at the Whitetail Farm* (Whitetail Report). EPA disapproved the report by letter dated December 16, 2013. PSFMBM's January 31, 2014 response explained that the disapproval was based on incomplete information (which was provided in the response) and expressed a desire to resolve the disapproval without invoking dispute resolution. Since then, PSFMBM, EPA and CLEAN have been engaged in discussions to resolve this and other issues through amendments to the Consent Decree. In October, 2016, Murphy-Brown of Missouri, LLC, as successor-in-interest, filed a notice of dispute with the federal court (WD Mo.) pursuant to Section XV (Dispute Resolution) of the Consent Decree. That notice of dispute concerns the requirement in Subsection II.A of Appendix F to the Consent Decree and EPA's December 16, 2013 disapproval of the Whitetail Report. At the request of the United States, MBM agreed to extend the dispute resolution informal negotiation period to February 21, 2017. PSFMBM received EPA's response letter on February 21, 2017.

Although not required by the Consent Decree, PSFMBM submitted to EPA a Quality Assurance Project Plan (QAPP) for calculating emissions from the Hedgewood, Locust Ridge and Somerset Farms during the fourth quarter of 2012 in the mistaken belief that EPA wished to see emissions calculations from these down-sized farms. After EPA disapproved the QAPP by letter dated December 16, 2013, however, PSFMBM withdrew the QAPP by letter dated January 31, 2014. PSFMBM has decided to replace the CPF system at the Valley View Farm with the AND system, and therefore, will not be conducting post-technology emissions monitoring on the CPF system.

F. Appendix G – Supplemental Environmental Projects

On December 15, 2003, PSFMBM and ContiGroup Companies submitted via electronic mail to EPA the final *Report on Evaluation of Oil Sprinkling SEP* pursuant to Appendix H, paragraph II.A.(5) of the Consent Decree. There were no Supplemental Environmental Project-related activities during this reporting period.

II. Noncompliance with Performance Standards and Other Requirements of Decree

This section will identify all instances of noncompliance with the performance standards set forth in Appendix D and any other failures known to the Defendants to comply with the requirements of this Consent Decree during the reporting period, the reasons for such failures to comply, and actions already taken or planned to be taken to correct such failures to comply.

PSFMBM is not aware of any failures to comply with the requirements of the Consent Decree during this reporting period.

III. Planned Actions to Comply With Decree and Potential Delays/Problems

This section provides a brief description of the actions that PSFMBM anticipates taking towards achieving compliance with this Consent Decree during the next quarter, including any possible delays or other problems that may affect compliance with the Consent Decree and PSFMBM's anticipated actions to resolve such delays or problems.

At this time, PSFMBM does not anticipate any delays or other issues that may affect compliance with the Consent Decree.

CERTIFICATION STATEMENT

To the best of my knowledge, after thorough investigation, I certify that the information contained in or accompanying this submission is true, accurate and complete. I am aware that there are significant penalties for submitting false information, including the possibility of fine and imprisonment for knowing violations.

Received: February 10, 2015 *Accepted in revised form: May 18, 2015*

Abstract

As a major swine-producing state, North Carolina (United States) has adopted incentives for energy recovery from swine waste and environmental performance standards for new swine facilities. However, there are no treatment performance requirements for existing farms; therefore, management of swine waste in open lagoons with spray irrigation for disposal is nearly universal in North Carolina. Emissions of nitrogen to the atmosphere and the landscape from large industrial swine farms have led to concerns over the impact on environmental quality and human health. Accordingly, there has been increasing interest in developing alternate treatment methods for swine waste, including methods that allow for energy recovery. To evaluate the technical feasibility and limitations of coupling biological nitrogen removal with anaerobic digestion of swine waste for energy recovery, we operated a pilot nitrification/denitrification system at an 8,000-head finishing farm already practicing full-scale anaerobic digestion in covered lagoons with methane capture. Of primary interest was the extent to which alkalinity and biodegradable chemical oxygen demand (COD) in the digested waste could meet the stoichiometric requirements for oxidation of ammonium-N (AN) and denitrification, respectively. The system removed 98% of the influent AN and 83% of influent total nitrogen. Approximately 75% of influent total COD was oxidized, mostly as electron equivalents for denitrification. Alkalinity in digested waste may not meet the alkalinity demand from nitrification, depending on the extent of denitrification. Stripping of ammonia into the gas phase was negligible, but 8.2% of the ammonium-N removed was converted to nitrous oxide-N.

Key words: ammonia; nitrification; nitrogen removal; swine waste

Introduction

Anthropogenic inputs of fixed nitrogen to the environment, particularly from intensive agriculture, have led to substantial pollution of both air and water globally (Schlesinger, 2009). In the United States, North Carolina is currently home to 8.5 million swine (NCDACS, 2013), most of which are raised in industrial-scale facilities. Waste from swine farms in North Carolina is typically stored in large uncovered lagoons and periodically applied to sprayfields to fertilize crops (NCDENR). The scale of waste generation results in more nitrogen than can be assimilated at agronomic rates in the entire region of swine production (NCDENR).

High concentrations of ammonium in swine waste lead to emissions of ammonia to the atmosphere (Aneja *et al.*, 2009), which can cause significant concentrations of ammonia in air at nearby communities (Wilson and Serre, 2007) as well as transport and subsequent deposition over longer distances (Dennis *et al.*, 2010). Volatilized ammonia has been linked to respiratory problems among exposed populations, including swine farm workers (Dosman *et al.*, 2004) and those living or attending school near the farms (Merchant *et al.*, 2005; Mirabelli *et al.*, 2006). Furthermore, ammonia reacts in the atmosphere to form fine particles that can cause respiratory disease (McCulloch *et al.*, 1998). In addition to ammonia, uncovered lagoons are sources of methane emission (Sharpe and Harper, 1999), with corresponding implications for climate change (Aneja *et al.*, 2009; Miller *et al.*, 2013).

In an effort to mitigate the environmental and human health impacts of emissions from industrial-scale swine farms, the North Carolina legislature enacted the 2007 Swine Farm Environmental Performance Standards Act (NC General Assembly, 2007b). This legislation banned the construction of new swine farms that employ open anaerobic lagoons and sprayfields as the primary methods of waste treatment and disposal (as crop fertilizer), respectively;

*Member of AEESP.

instead, new farms must employ technologies that meet environmental performance standards (NC General Assembly, 2007b; NCDENR, 2009). The standards require substantial reductions in emissions of various pollutants to soil, groundwater, surface water, and air, including emissions of ammonia. The 2007 NC Renewable and Energy Efficiency Portfolio Standard Act also established a target for statewide energy production from swine waste, and it created a pilot program that authorized higher rates of payment for electricity generated from anaerobic digestion and methane capture systems on swine farms (NC General Assembly, 2007a). However, the incentives for energy production are not coupled to requirements to meet environmental performance standards. In addition, there are no environmental performance standards for existing swine farms, so that the state of practice for waste management continues to be storage and treatment in open lagoons with spray irrigation on nearby cropland for disposal.

We conducted a pilot study to evaluate the technical and economic feasibility of coupling conventional biological nitrogen removal (nitrification and denitrification) with anaerobic digestion for methane capture and energy recovery at a swine farm. The study was conducted at one of the few swine farms in North Carolina practicing full-scale anaerobic digestion of waste in covered lagoons with a methane capture system. Of particular interest was an analysis of stoichiometric issues relevant to nitrogen conversions in waste from which a substantial fraction of organic matter would have been removed by anaerobic digestion, including the availability of electron donors for denitrification, oxygen consumption, and net alkalinity demand of combined nitrification and denitrification. Production of nitrous oxide (N_2O) was also quantified. Details of the economic analysis are available elsewhere (Bunk, 2012).

Several previous studies have been conducted on combined anaerobic digestion and nitrification/denitrification of swine waste at much smaller scales than used in this study (Obaja *et al.*; Poo *et al.*; Deng *et al.*; Dosta *et al.*; Anceno *et al.*; Rajagopal *et al.*). To our knowledge, this is the first study to incorporate the modified Ludzack-Ettinger (MLE) concept for nitrogen removal (Grady *et al.*, 2011), although without external solids separation or recycle of settled biomass. In the MLE process, influent wastewater enters a denitrification reactor, which is followed by a nitrification reactor; internal recirculation between the reactors allows the oxidized nitrogen produced in the nitrification reactor to be denitrified in the denitrification reactor at the expense of electron donors in the influent. We also note that because there are no effluent concentration standards for waste treatment at existing swine farms in North Carolina (nor federal-level standards in the United States), the objectives of treatment and performance characterization are not the same as for treated wastewaters that are discharged to surface waters.

Materials and Methods

Study design and general characteristics

The pilot-scale nitrogen removal system was installed in a trailer located at the edge of a covered lagoon at Butler Farms in Lillington, NC (Supplementary Fig. S1 in Supplementary Data). Butler Farms is an 8,000-head grow/finishing farm with 10 barns, each housing an approximately equal number of animals. The lagoon that served as the source of influent for this study was the larger of two at the farm, receiving waste from six of the barns. The lagoon is not mixed, has a maximum volume of 2.5×10^7 L, and a maximum depth of 3.3 m. As is typical for swine farms in North Carolina, waste is flushed from the barns with liquid from the lagoons. Periodically, the lagoon liquid is sprayed onto on-site fields in accordance with State agronomic regulations. The lagoon cover and methane collection system were installed ~2 years before this study was initiated.

Influent to the pilot system was pumped continuously from the lagoon through an opening in the lagoon cover at the opposite end of the lagoon from the barn discharge, from a depth of 1 m below the liquid surface. The lagoon liquid was pumped to a flow-through sealed tank in the trailer, from which the influent to the pilot system was pumped through a peristaltic pump. The remainder of the lagoon liquid flow was recirculated to the lagoon through a second opening in the cover, ~4.5 m from the intake.

The on-site trailer accommodated the reactors (Supplementary Fig. S2), pumping equipment, and associated instrumentation as described below, computer for system monitoring and control, and an area for analytical equipment (analytical balance, drying oven, chemical oxygen demand [COD] digester, filtration apparatus, titration apparatus, and benchtop pH meter; Supplementary Fig. S2). It was heated and air-conditioned to maintain a consistent inside temperature; over the course of the study, the temperature in the trailer was 23.2°C ± 3.2°C (n = 288).

Chemical characteristics of the lagoon liquid for the entire duration of continuous system operation are summarized in Table 1.

Pilot system overview

As noted above, the nitrogen removal system incorporated the MLE concept in two bioreactors in series without external solids separation. Influent (lagoon liquid) was pumped to the denitrification reactor. Denitrified liquid was pumped to the nitrification reactor, to which pure oxygen was supplied as the oxygen source. Mixed liquor was internally recycled by

Table 1. Lagoon Liquid Characteristics Over Project Duration (September 10, 2010–May 27, 2011)

Parameter	*Mean ± S.D.* (n)	*Range*
NH_4^+-N (mg/L)	2,310 ± 280 (101)	1,770–2,670
Total N (mg/L)	2,750 ± 230 (85)	2,120–3,740
TDN (mg/L)	2,610 ± 180 (81)	2,060–2,980
Total COD (mg/L)	7,550 ± 2,240 (38)	1,770–10,200
Soluble COD (mg/L)	5,370 ± 1,820 (37)	1,390–7,740
TSS (mg/L)	1,580 ± 260 (27)	1,180–2,180
VSS/TSS (—)	0.40 ± 0.04 (15)	0.34–0.51
pH	7.71 ± 0.23 (27)	7.28–8.12
Total alkalinity (mg $CaCO_3$/L)	12,200 ± 420 (27)	11,200–13,100
Bicarbonate alkalinity (mg $CaCO_3$/L)	10,600 ± 460 (27)	9,840–11,300

COD, chemical oxygen demand; TDN, total dissolved nitrogen; TSS, total suspended solids.

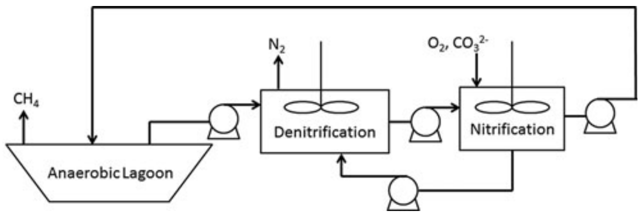

FIG. 1. Schematic of pilot-scale nitrogen removal system; not to scale.

pumping between the nitrification and denitrification reactors at a recycle ratio of 2.5 (recycle flow rate/system influent flow rate). Effluent from the nitrification reactor was pumped to the lagoon for discharge. A simplified process flow diagram is provided in Figure 1.

Hydraulic retention times (HRT) were $\sim$33 days for the nitrification reactor and $\sim$9 days for the denitrification reactor, based on the system influent flow and mean volume of each reactor. The pilot system was operated continuously from September 10, 2010, through May 27, 2011. Over the first 5 months, there were several issues with equipment failure and other operational problems that led to reactor upsets, usually manifested as nitrite accumulation in the nitrification reactor. Therefore, reactor operating and performance data are reported only for the period after which the final operating conditions were established (final 107 days; referred to below as the performance reporting period). Since the influent characteristics are important for stoichiometric analysis and did not depend on reactor performance, as noted above, the lagoon liquid properties are reported for the entire period of continuous operation in Table 1.

Reactor design

Reactors were 5,000 L (nitrification) and 1,000 L (denitrification) high-density polyethylene tanks. Operating volumes were $\sim$2,000 L and 500 L, respectively. The reactors were totally enclosed except for ports for pump tubing, and off-gas; each reactor was operated with a gauge headspace pressure $\sim$0.5 kPa. To prevent reactor short circuiting, liquid pumped into a reactor was discharged above the liquid surface and the intakes for liquid pumped from the reactor were located near the bottom of the tank. Mixing in the denitrification reactor was provided by an internal recirculation line with intake and discharge located at opposite ends of the tank. Mixing in the nitrification reactor was provided by a submersible pump located at the bottom near one end of the tank, whose discharge was directed to the opposite end of the tank. Each reactor was assumed to be completely mixed, so that the effluent composition from each reactor was the same as its contents.

Pure oxygen was provided to the nitrification reactor through a fine-bubble diffuser (Western Outdoor Aquatics, Inc., Frederick, CO) and through a mass flow controller (Omega, Stamford, CT); pure oxygen was used rather than air because of logistical constraints on the frequency of exchange of gas cylinders in the field. The pH in the nitrification reactor was adjusted by pumping a concentrated sodium carbonate solution into the reactor in response to continuous pH measurement using a proportional digital controller (Hannah Instruments, Woonsocket, RI), with pH 6.8 as the minimum set point. The majority of sodium carbonate required for pH control was consumed over the first few months of system operation, with relatively little consumed over the performance reporting period. Liquid volume in each reactor was measured by comparing the liquid level to a calibrated scale on the exterior of the tank; the volume in each reactor was recorded daily.

All pumping into and out of each reactor was with dedicated peristaltic pumps (MasterFlex computerized drive with Easy-Load II head and high-performance precision Norprene L/S 36 tubing; Cole-Parmer, Vernon Hill, IL). Each pump was operated continuously with adjustment as needed to maintain the desired volume in each reactor. The pump drives were controlled with software (WinLIN; Cole-Parmer) installed on a personal computer. Pump flow rates were periodically calibrated by timed delivery into a graduated cylinder.

Startup

The nitrification reactor was filled to the desired volume with tap water and $\sim$200 L of return activated sludge from the Orange Water and Sewer Authority wastewater treatment plant (Chapel Hill, NC), which performs nitrification and biological phosphorus removal. The denitrification reactor was filled to the desired volume with lagoon liquid. The system was operated in batch mode with internal recycle between the nitrification and denitrification reactors for 12 days, and then the internal recycle between reactors was turned off to allow strictly batch operation in the nitrification reactor for 4 weeks. Continuous operation was initiated after this period of batch operation.

Instrumented measurements

The temperature of the lagoon liquid was measured continuously with a probe submerged in the lagoon near the intake for the pilot system influent. The temperature and pH of mixed liquor in the denitrification reactor were monitored continuously with probes mounted in the internal recirculation line used for mixing. Temperature, pH, and dissolved oxygen (DO) of mixed liquor in the nitrification reactor were monitored continuously with probes similarly mounted in an internal recirculation line. Temperature probes were calibrated against an electronic thermometer (Cole-Parmer) that had been calibrated against a mercury thermometer whose calibration was traceable to the US National Institute of Standards and Technology; room-temperature deionized water was the calibration medium. The mass flow controller for oxygen delivery was calibrated using a Gilibrator automated bubble meter (Sensidyne, St. Petersburg, FL). Calibration of the DO and pH probes was checked weekly according to the manufacturer's instructions. For reporting purposes, temperature, pH, and DO were recorded manually daily.

Sample collection

Lagoon liquid was collected from the sealed tank inside the trailer used as the source of reactor influent. Samples from each reactor were obtained from a port located on the respective internal recirculation line. Grab samples of lagoon liquid, denitrification effluent, and nitrification effluent were collected at least twice weekly, but not all samples were analyzed for every parameter. Samples were immediately filtered through glass fiber filters (Whatman GF/B or GF/C) on-site using a filtration apparatus dedicated to each sampling location. COD, total suspended solids (TSS), and alkalinity were measured on-site. Otherwise, filtered and unfiltered samples were frozen in an on-site freezer and transported weekly to the laboratory at the University of North Carolina, Chapel Hill campus, for further analysis. Off-gas from the nitrification reactor and headspace gas from the denitrification reactor were collected weekly over the performance reporting period and stored in air-tight syringes for transport to the campus laboratory.

Analytical methods

Filtered samples were analyzed for ammonium, nitrite, and nitrate according to standard methods 4500-NH_3F, 4500-NO_2^-B, and 4500-NO_3^-F, respectively (Eaton *et al.*, 1999). Each of the duplicate dilutions (100×–5,000× as needed) was measured in duplicate. Ammonium chloride, sodium nitrite, and potassium nitrate were used to prepare standard curves. Concentrations are reported in mg N/L. In preliminary analyses of lagoon liquid, neither nitrite nor nitrate was detected (data not shown).

Total nitrogen (TN) and total dissolved nitrogen (TDN) were analyzed on unfiltered and filtered samples, respectively, using a Shimadzu (Columbia, MD) total organic carbon analyzer with TN attachment. Duplicate dilutions (500×–2,000× as needed) were each measured in duplicate or triplicate; triplicates were analyzed when the difference between duplicate measurements was >2%. Disodium ethylenediaminetetraacetic acid was used to prepare standard curves for TN and TDN analyses.

Total COD (tCOD) and soluble COD (sCOD) were determined using CHEMetrics (Midland, VA) COD digestion vials (20–1,500 ppm range) on unfiltered and filtered samples, respectively, in duplicate. Samples were diluted 10× directly in the COD vials. Sodium acetate was used as the standard, on the assumption that the majority of sCOD in the anaerobically digested lagoon liquid comprised volatile fatty acids.

Alkalinity was measured using standard method 2320B (Eaton *et al.*, 1999). Fresh sulfuric acid solution was prepared as needed, and samples were titrated to pH 4.3 as a measure of total alkalinity. The volume of acid required to reach pH 5.8 was recorded and used to calculate bicarbonate alkalinity. Acid equivalents required to reach the respective pH endpoints were converted to alkalinity in mg $CaCO_3$/L. TSS were measured using standard method 2540D (Eaton *et al.*, 1999).

Nitrous oxide was measured on a Shimadzu 14A gas chromatograph (GC) with an electron capture detector and 90% argon/10% methane as carrier gas. Methane (CH_4) was measured on a Shimadzu 8AIF GC with a flame ionization detector and ultra-high-purity (UHP) N_2 as carrier gas. Carbon dioxide (CO_2) was measured with a Shimadzu 8AIT GC with a thermal conductivity detector and UHP He as carrier gas. Gas-phase ammonia was captured in 0.2% (w/v) boric acid and measured as aqueous ammonium.

Data analysis

Cumulative mass loading and mass discharge were calculated by multiplying the concentration of a constituent by the net pumping rate into or out of a reactor, respectively. Pumping rates were recorded daily; concentration data were linearly interpolated between measured values. Cumulative mass loading and discharge across the system were used to calculate the removal efficiency over the performance reporting period.

Oxygen consumption in the nitrification reactor was assumed to equal the oxygen required to oxidize ammonium to nitrite and nitrate plus the net change in total COD across the reactor. The proportion of oxygen required for oxidation of ammonium to nitrite versus nitrate was based on the ratio of nitrite and nitrate in the nitrification reactor effluent and the known stoichiometry of nitrification reactions (3.43 g O_2/g NH_4^+-N for ammonium oxidation to nitrite and 4.57 g O_2/g NH_4^+-N for ammonium oxidation to nitrate).

Cumulative off-gas flow from each reactor was combined with the mean gas-phase concentration of N_2O to estimate the yield of N_2O relative to ammonium-N removal (cumulative mass of N_2O-N production/cumulative mass of AN consumption) over the performance reporting period. The off-gas flow from the nitrification reactor was estimated based on the known mass of O_2 addition (converted to molar units based on the mean temperature in the trailer and the ideal gas law), mass of oxygen consumed, and the volumetric composition of measured gases (CO_2, CH_4, N_2O, and NH_3), with the balance assumed to be O_2. The off-gas flow from the denitrification reactor was based on the mass of nitrogenous gases (N_2, N_2O, and NH_3) produced and the measured gas composition, assuming the unmeasured balance to be N_2; the cumulative mass production of nitrogenous gases was estimated from the net change of TN across the system minus the N_2O-N released from the nitrification reactor.

Results

Characteristics of the lagoon liquid over the entire project period are summarized in Table 1. The most variable influent parameter was COD, which resulted from the variability of temperature in the lagoon (Fig. 2). Since the lagoon was not heated, the temperature of the lagoon liquid varied seasonally in accordance with the ambient temperature. Gas production

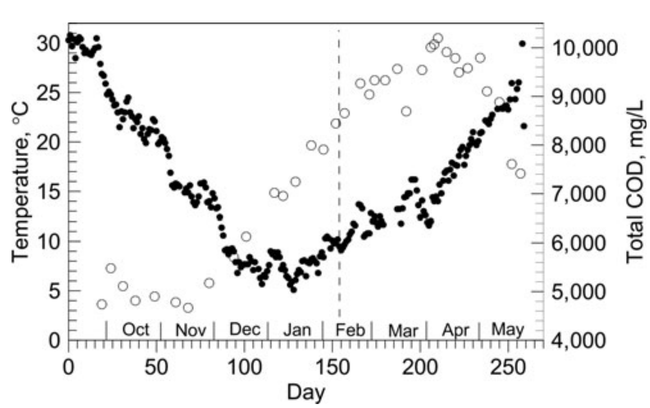

FIG. 2. Lagoon liquid temperature (*filled symbols*) and total chemical oxygen demand (COD) concentration (*open symbols*) over the duration of the project (day 0 was September 10, 2010). The *dashed vertical line* indicates the beginning of the performance reporting period as defined in the text (February 10–May 27, 2011).

in the lagoon declines with decreasing temperature in the winter months (Supplementary Fig. S3), with a corresponding decrease in anaerobic consumption of COD and increasing COD concentration in the lagoon (Fig. 2). COD concentrations in the lagoon liquid did not begin to decline from the peak until the lagoon temperature reached ~15°C (Fig. 2).

The majority (95%) of TN in the lagoon liquid was dissolved, with ammonium-N accounting for 89% of the TDN (Table 1). The majority of TSS appear to be inert, as the mean VSS/TSS ratio was only 0.4.

System performance

Data on nitrogen species, COD, and other characteristics of the influent and each reactor over the performance reporting period are summarized in Table 2. Based on cumulative mass loading and discharge over this period (Table 3), the system achieved 98% removal of NH_4^+-N, 83% removal of total N, and 75% removal of total COD. Cumulative mass loading and discharge of TN and NH_4^+-N are plotted in Supplementary Figure S4. Nearly all of the effluent nitrogen other than N_2O could be accounted for as nitrite and/or nitrate (Tables 2 and 3).

It is not possible to quantify organic N in the reactors because the data for TN and TDN in the nitrification reactor (or system effluent; Tables 2 and 3) are less than the sum of the inorganic N species. In addition, the apparent total N removal across the system (Table 3) is equivalent to the NH_4^+-N removal alone. We believe these discrepancies are likely a result of the instrumental method used for TN and TDN analysis, which relies on catalytic thermal conversion of N species; at the high dilution required for our samples, even small inefficiencies in conversion would be magnified and manifested as lower-than-expected concentrations.

Consumption of COD

There was no measurable removal of total COD across the nitrification reactor (Fig. 3), suggesting that virtually all the total COD removal across the system occurred in the denitrification reactor. Accordingly, the system effluent COD appears to comprise mostly nonbiodegradable or very slowly biodegradable COD (i.e., ~25% of the influent tCOD was nonbiodegradable over the retention times used in this study). Based on the cumulative mass data in Table 3, assuming that the TN removed was oxidized to nitrite and nitrate in proportion to the masses discharged (65.7% NO_2^--N), and assuming COD consumption by NO_2^--N equal to 60% of that of NO_3^--N, the total COD removed was 3.8 g COD/g NO_3^--N equivalent.

Table 3. Cumulative Mass Loading and Discharge Across the System Over Performance Reporting Period (February 10–May 27, 2011)

Parameter	*Loading (kg)*	*Discharge (kg)*	*Removal (%)*
NH_4^+-N	14.9	0.4	97.5
Total N	17.7	3.1	82.7
TDN	16.9	3.2	81.4
NO_2^--N	NA	2.3	NA
NO_3^--N	NA	1.2	NA
N_2O-N	NA	1.2	NA
Total COD	55.2	13.9	74.7
Soluble COD	38.8	10.6	72.7

Data are rounded to one decimal place.

Gas-phase measurements

Data on the composition of the gas phase in each reactor over the performance reporting period are summarized in Table 4. For stoichiometric analysis, the most important of these gases was N_2O. Based on the cumulative mass production of N_2O and the mass removal of ammonium across the system (Table 3), 8.2% of the oxidized NH_4^+-N was converted to N_2O-N. Since the concentration of N_2O in the off-gas from the denitrification reactor was much lower than that from the nitrification reactor (Table 4), as well as the fact that there was a much greater flow of gas (primarily oxygen) through the nitrification reactor, the contribution of N_2O from denitrification was negligible (3.3% of the total N_2O produced).

With concentrations of off-gas ammonia in the ppmv range (Table 4), volatilization of ammonia was negligible (~0.01% of the ammonium removal across the system).

Table 2. Influent and Reactor Characteristics Over Performance Reporting Period (February 10–May 27, 2011)

Parameter	*Influent*	*Denitrification*	*Nitrification*[a]
NH_4^+-N (mg/L)	2,370 ± 140 (2,070–2,670; 41)	651 ± 86 (499–858; 42)	78 ± 53 (1–199; 42)
NO_2^--N (mg/L)	NA	32 ± 43 (ND–140; 42)	484 ± 217 (3–779; 42)
NO_3^--N (mg/L)	NA	71 ± 75 (ND–249; 42)	288 ± 234 (66–1,190; 42)
Total N (mg/L)	2,820 ± 135 (2,510–3,200; 41)	836 ± 158 (609–1,250; 41)	681 ± 191 (439–1,080; 41)
TDN (mg/L)	2,690 ± 150 (2,340–2,980; 37)	794 ± 165 (565–1,180; 37)	682 ± 191 (450–1,090; 40)
Total COD (mg/L)	9,270 ± 742 (7,410–10,200; 20)	3,080 ± 210 (2,600–3,580; 31)	3,180 ± 460 (2,620–4,680; 32)

DO, dissolved oxygen; NA, not applicable; ND, not detected.

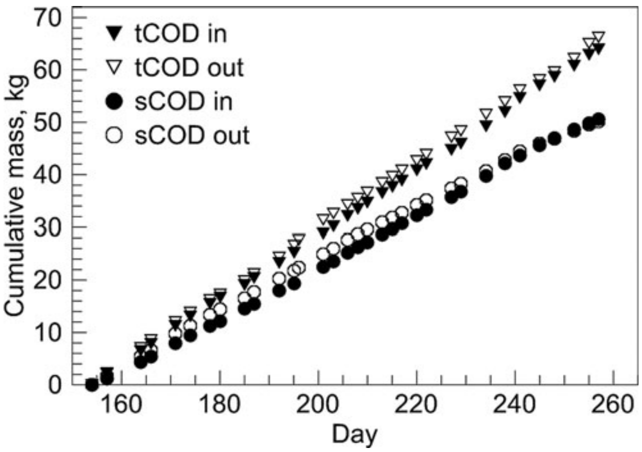

FIG. 3. Cumulative COD loading and discharge across nitrification reactor over performance reporting period (February 10–May 27, 2011); day numbering is relative to the start of the overall project.

Methane in the headspace of the denitrification reactor is assumed to represent volatilization of dissolved methane present in the influent (lagoon liquid).

Discussion

Swine waste is high strength with respect to both biodegradable organic matter and ammonium-N nitrogen. It is, therefore, a candidate for anaerobic digestion with energy recovery as well as a significant source of nitrogen pollution to the environment. Most earlier work on coupling anaerobic digestion with biological nitrogen removal has included some combination of at least partial oxidation of ammonium with nitrogen removal by denitrification or anaerobic ammonium oxidation (ANAMMOX), although various schemes have been proposed. These include bypassing a fraction of the raw waste around the anaerobic digester to provide more electron donors for denitrification (Obaja *et al.*, 2004; Deng *et al.*, 2008; Anceno *et al.*, 2009; Rajagopal *et al.*, 2011); recycling nitrified effluent to the anaerobic digester, which therefore would be responsible for both denitrification and methanogenesis in the same reactor (Bernet *et al.*, 2000; Bortone, 2009; Rajagopal *et al.*, 2011); nitritation and ANAMMOX for nitrogen removal from anaerobically digested waste (Hwang *et al.*, 2006; Karakashev *et al.*, 2008; Yamamoto *et al.*, 2008; Zhang *et al.*, 2012); and the concept evaluated in the present study, anaerobic digestion of the complete waste stream followed by nitrification/denitrification (Poo *et al.*, 2004; Deng *et al.*, 2008; Dosta *et al.*, 2008; Rajagopal *et al.*, 2011).

The previous studies, in which either nitritation/ANAMMOX or nitrification/denitrification were evaluated on anaerobically digested swine waste, have been conducted at a small laboratory scale. In the study by Rajagopal *et al.* (2011), both the anaerobic digestion and nitrogen removal processes were operated at a small pilot scale ($\sim$120 L). None of the studies on nitrification/denitrification utilized the MLE configuration and, in some cases, a supplemental carbon source was added to maximize denitrification (Poo *et al.*, 2004; Dosta *et al.*, 2008; Zhang *et al.*, 2012). Therefore, none of the previous studies on nitrogen removal from anaerobically digested swine waste is comparable to the present study.

Denitrification

Employing nitrification/denitrification on waste that has already been subjected to anaerobic digestion maximizes the amount of organic matter available for conversion to methane, while minimizing the amount of oxygen required for subsequent aerobic treatment. A drawback to this approach, however, is that the residual organic matter from anaerobic digestion might be insufficient to meet the electron donor demand for denitrification, thereby limiting the extent of nitrogen removal. Nitrate has the capacity to remove 2.86 g COD per g NO_3^--N (more if biomass growth is accounted for). Using mean data for the entire project (Table 1), the total COD in the lagoon liquid would not have met the demand for denitrification if all the TN was converted to nitrate. As noted above, the residual COD in the lagoon varies seasonally in response to the extent of gas production in the lagoon, so that the extent of denitrification in a biological nitrogen removal system can be expected to vary seasonally as well.

In principle, the total COD in the lagoon liquid over the performance reporting period (Tables 2 and 3) should have been sufficient to completely remove nitrate if all the TN in the lagoon liquid was converted to NO_3^--N. However, only 88% TN removal was achieved. The COD concentration in the denitrification reactor was high (Table 2), suggesting that residual COD not used for denitrification may not have been readily biodegradable. This is supported by the observations that there was little difference in the COD concentrations between the denitrification and nitrification reactors (Table 2) and that there was no removal of sCOD across the nitrification reactor (Fig. 3), which suggests that most of the residual COD was not aerobically degradable either. The bioavailability of residual COD in anaerobically digested swine waste has been demonstrated to depend on the solids retention time of the digester (Kinyua *et al.*, 2014).

As noted above, previous studies have explored either bypassing a fraction of the raw waste around the anaerobic digester or recycling nitrified effluent to the anaerobic digester to provide the necessary electron equivalents for

TABLE 4. REACTOR OFF-GAS COMPOSITION OVER PERFORMANCE REPORTING PERIOD (FEBRUARY 10–MAY 27, 2011)

Gas	*Denitrification reactor*	*Nitrification reactor*
CO_2 (%)	8.9 ± 2.7 (5.2–15.1; 13)	37.2 ± 8.9 (16.9–49.8; 13)
CH_4 (%)	2.2 ± 0.8 (1.5–4.1; 14)	0.02 ± 0.05 (0.01–0.20; 14)
N_2O (%)	0.13 ± 0.20 (0.01–0.67; 14)	0.78 ± 0.19 (0.43–1.11; 14)
NH_3 (ppmv)	38 ± 21 (2–82; 11)	5.0 ± 4.3 (<1–15; 11)

Data are mean ± S.D. (range; *n*).

denitrification. Both approaches would reduce the amount of methane that could be generated from the waste. In addition, adding raw waste directly to the nitrogen removal process can substantially increase the oxygen consumption associated with the aerobic component of the process (Deng *et al.*, 2008). Another proposed strategy, which simultaneously would decrease oxygen consumption, is to partially oxidize ammonium to nitrite (nitritation), relying on the produced nitrite for denitrification (Dosta *et al.*, 2008; Rajagopal *et al.*, 2011); the electron donor demand from denitrification with nitrite (1.71 g COD/g NO_2^--N) is less than that with nitrate. Although not intentional, in this study, nearly two-thirds of the oxidized nitrogen in the effluent from the nitrification reactor (system effluent) was in the form of nitrite (Table 2).

Unlike municipal wastewater treatment, in which there may be upper limits on TN discharged to receiving water, there are no such limitations on nonpoint nitrogen sources from agricultural waste management in the United States. Nevertheless, extensive removal of ammonium-N by nitrification and even partial denitrification of the oxidized nitrogen would still have a substantial impact on human health and on reducing nitrogen loads to the environment, respectively. These factors should be taken into account when evaluating the impact and limitations of coupling anaerobic digestion with nitrogen removal from swine waste.

Ammonium oxidation

Throughout the study, nitrite tended to accumulate in the nitrification reactor in lieu of complete oxidation of ammonium to nitrate, even during most of the performance reporting period (Table 2). Accumulation of nitrite typically is observed under oxygen-limiting conditions, which is the principal means of promoting nitritation over complete ammonium oxidation to nitrate (Lackner *et al.*, 2014). However, DO was not limiting in the present study (Table 2), suggesting that other mechanisms were responsible for limiting nitrite oxidation. It is likely that populations of nitrite-oxidizing bacteria (NOB) were slower to recover from process upsets that occurred before the performance reporting period; as seen in Supplementary Figure S5, effluent nitrite concentrations declined steadily over time, with a substantial decrease over the last few weeks of the study. Inhibition of NOB by nitrite or free nitrous acid (Anthonisen *et al.*, 1976; Vadivelu *et al.*, 2006; Park *et al.*, 2010; Zhou *et al.*, 2011; Wang *et al.*, 2014) or by free ammonia (Anthonisen *et al.*, 1976; Park *et al.*, 2010) could explain such slow recovery. Free nitrous acid can be inhibitory in the sub-mg/L range, and free ammonia can be inhibitory in the low mg/L or even sub-mg/L range (Anthonisen *et al.*, 1976; Park *et al.*, 2010). At the mean pH and temperature of the nitrification reactor (Table 2), free nitrous acid concentrations would have ranged from about 0.02 to 0.17 mg/L (0.11 mg/L at the mean NO_2^--N concentration) and free ammonia from about 0.05 to 0.81 mg/L (0.43 mg/L at the mean NH_4^+-N concentration); the higher concentrations in these ranges could have inhibited growth of NOB (Park *et al.*, 2010). It is also possible that characteristics of the anaerobically digested swine waste adversely affected NOB.

Although ammonium removal was excellent, the mean effluent concentration over the performance reporting period (Table 2) was higher than might be expected at steady state for the retention time of the nitrification reactor. Like nitrite, ammonium concentrations in the effluent declined steadily over time (Supplementary Fig. S5); it is possible that, therefore, relatively slow recovery of AOB during the performance reporting period also could have been a result of inhibition from free nitrous acid and/or free ammonia (Anthonisen *et al.*, 1976; Park *et al.*, 2010).

It was necessary to add supplemental alkalinity (as carbonate) to the anaerobically digested lagoon effluent to maintain pH > 6.8 in the nitrification reactor. Most of the added alkalinity was required earlier in the project before stable reactor operation was achieved, so that the total carbonate requirement during the performance reporting period was not quantifiable.

Oxidation of ammonium to either nitrite or nitrate consumes 7.1 g alkalinity as $CaCO_3$ per g NH_4^+-N oxidized. Based on the lagoon liquid characteristics over the duration of the project (Table 1), the total alkalinity would be far less than required for oxidation of all the TN. However, denitrification from nitrate produces alkalinity to an extent that is nearly half of the alkalinity consumed from ammonium oxidation per unit nitrogen (Grady *et al.*, 2011), so that there would be sufficient alkalinity in the lagoon liquid for complete oxidation of TN followed by denitrification of the nitrate produced. However, as noted above, the extent of denitrification would vary seasonally and also depends on the biodegradability of the residual COD after anaerobic digestion. Therefore, the need for additional alkalinity to maintain pH for nitrification can be expected to vary seasonally. Depending on how much alkalinity is required, this can represent a significant operating cost in a full-scale system (Bunk, 2012). Providing alkalinity is one rationale for enhancing denitrification by adding undigested raw waste to the nitrification/denitrification process (Deng *et al.*, 2008).

A strategy that would simultaneously reduce the alkalinity demand, oxygen demand, and electron donor demand for nitrogen from anaerobically digested swine waste is to combine nitritation of a fraction of the ammonium with ANAMMOX to remove the remainder of the ammonium (Hwang *et al.*, 2006; Karakashev *et al.*, 2008; Yamamoto *et al.*, 2008; Zhang *et al.*, 2012). Nitritation/ANAMMOX treatment of the anaerobically digested swine waste evaluated in this study is described in a companion article (Staunton and Aitken, 2015).

Nitrous oxide production

The yield of N_2O-N per unit NH_4^+-N oxidized (8.2%) obtained in this study is within the range reported in the literature for biological nitrogen removal systems (Ni *et al.*, 2011), although it is higher than the range observed in a survey of municipal wastewater treatment plants in the United States (Ahn *et al.*, 2010). Production of N_2O tends to be higher in systems operated for nitritation rather than complete nitrification of ammonium to nitrate (Yang *et al.*, 2009; Ahn *et al.*, 2011) and has generally been associated with low DO conditions (Aboobakar *et al.*, 2013; Peng *et al.*, 2014; Pijuan *et al.*, 2014). Ammonium oxidation to nitrite exceeded the complete oxidation to nitrate in this study, but the mean DO concentration in the nitrification reactor was generally quite high (Table 2). Ahn *et al.* (2010) have suggested that a combination of high nitrite and high DO can also lead to increased rates of N_2O production in nitrifying systems. As noted above, it is also possible that the characteristics of swine waste may inherently influence the activity of NOB and/or N_2O production during ammonium oxidation.

Nearly all the N_2O produced in this study was attributable to the nitrification process, rather than denitrification. A similar observation was made in a previous study on nitrification/denitrification of anaerobically digested swine waste (Rajagopal and Béline, 2011), although the yield of N_2O per unit TN removed was much lower than in the present study.

Scale-up issues

There are currently no U.S. federal or North Carolina concentration standards for on-farm disposal of waste (treated or otherwise) from existing industrial-scale animal operations. Accordingly, issues relevant to scale up of any contemplated treatment scheme cannot be extrapolated from standard practice for discharge of municipal or industrial wastewater to receiving waters. Treated effluent from the coupling of nitrogen removal to anaerobic digestion for energy recovery, as considered in this study, would simply be used to flush barns to remove fresh waste and/or to irrigate fields at the farm. Under such a scenario, solids removal from the effluent would not be a priority. Furthermore, operation of a nitrification/denitrification system in an activated sludge format (with solids separation and biomass recycle) would add a level of operational complexity that could be a disincentive for the typical farmer to adopt the technology. At existing industrial-scale farms, there would be plenty of capacity to modify existing uncovered lagoons to accommodate both anaerobic digestion and the two-reactor nitrogen removal system, without biomass recycle as evaluated in this study. For example, at Butler Farms, the combined capacity of its two lagoons is over 40 million liters; for the volume of waste generated at Butler Farms, the combined HRT of the nitrification/denitrification system that we evaluated would require less than 2% of the existing lagoon capacity.

Summary

Nitrification/denitrification is capable of achieving high extents of ammonium removal from anaerobically digested swine waste. The extent to which TN can be removed depends on the biodegradable organic matter in the digested waste that is available for denitrification; the available organic matter, in turn, can depend on the extent of gas production during the anaerobic digestion process, which can vary seasonally. In the pilot system operated in this study, the majority of biodegradable influent organic matter was consumed in the denitrification step. The extent of denitrification will also influence the stoichiometry of net alkalinity consumption across the system; the lower the extent of denitrification, the more likely that supplemental alkalinity would be required to maintain neutral pH in the nitrification reactor. Production of N_2O from the nitrification/denitrification process can be significant, offsetting some of the greenhouse-gas benefit from anaerobic digestion with methane capture for energy recovery.

Acknowledgments

Financial support for this project was provided by Carolina Public Health Solutions (Gillings School of Global Public Health, University of North Carolina at Chapel Hill). We thank John McNeill for operating the pilot system and for performing several of the chemical and physical analyses. We also thank Tom Butler and other personnel at Butler Farms for providing access to the site, their hospitality, and their logistical assistance throughout the project.

ATTACHMENT 56

Loyd Ray Farms, Inc.
Innovative Animal Waste Management System
Permit No. AWI990031
Permit Compliance Semi-Annual Report

July 1, 2018 – December 31, 2018 Semi-Annual Reporting Period

Submitted January 31, 2019

Submitted on Behalf of:
Loyd Ray Farms, Inc.
2049 Center Rd.
Boonville, NC 27011

This Semi-Annual Compliance Report provides an overview of the manner in which the subject facility, Loyd Ray Farms, has maintained compliance with the conditions of the Innovative Animal Waste Management System permit for the reporting period from July 1, 2018 through December 31, 2018. During this reporting period, the system was operated in accordance with the Innovative Swine Waste Treatment System and subject to the requirements thereof.

Overview of System

The animal waste treatment system installed at Loyd Ray Farms is designed to meet the Environmental Performance Standards set forth by North Carolina law for new and expanded swine facilities through the use of nitrification/denitrification and further treatment. This report confirms on a semi-annual basis that the innovative waste management system is in compliance with NC Department of Environmental Quality and its divisions, to insure that the utilization of the anaerobic digester technology to turn raw animal waste into biogas for the purpose of reducing greenhouse gas emissions minimizes the overall environmental impact of the swine farm, and explains the occurrences of operations, and testing requirements over the six month period, to monitor the

MB018692

system, as it continues to produce renewable energy, generate carbon offsets, and reduce odor on the farm. The report is designed to not only show a synopsis of the maintenance activities on the farm, but also to supply the analysis of the system's performance and further describe the results of the monitoring and testing activities.

In addition to addressing compliance with the conditions of the permit, the following summaries provide an overview of the system operations including graphs of systems performance, the Microturbine performance, and biogas levels (pages 2-5), and lists all sampling and reporting requirements per the Innovative Animal Waste Management System Permit No. AW1990031 (pages 16-18). For each requirement, this report records on-site monitoring that occurred, with a brief explanation for each farm site visit (pages 6-16) for this reporting period. Additionally, detailed site visits recording maintenance and repairs completed during the second half of 2018, from July 1 through December 31, 2018 are also included in this report. In summary, From July 1, 2018 through December 31, 2018, all processes that comprise the innovative swine waste treatment system were fundamentally operational, and electricity generation was capable for the greater percentage of the reporting period, except for several weeks in September and October, which required the system to undergo repairs which are specified in more detail later in this report. Overall, except for a few disruptions for minor repairs, the system performed well from operational, power generation, greenhouse gas emission reduction and environmental performance perspectives. The maintenance activities were a little more accelerated as the system is getting older, and as the farm staff was unable to maintain a regular flushing schedule. Additional observations of system performance are exhibited in the operator log attached to this report. (Appendix A)

During this compliance period, ambient air analyses were accomplished on September 25th, 2018, and December 19th, 2018, details of the monitoring events have been added to this report (pages 20-22). The air emissions from water surfaces were found to be in compliance and much lower than the permit allows and show that the system is performing according to expectations.

This report was completed on behalf of Loyd Ray Farms, Inc., by Cavanaugh & Associates, P.A., under the direction of the Duke Carbon Offsets Initiative (DCOI). Please contact Matthew Arsenault at 919-613-7466 (Matthew.Arsenault@duke.edu) with any questions. A copy of this report will be provided to Loyd Ray Farms, Inc., and will be maintained on-site with the other permit compliance documentation.

Environmental Treatment System

Figure 1. below, **Environmental Treatment System Uptime**, depicts the operation of the aeration system that performs the nitrification function for the monitoring period. The environmental treatment system performed well and remained consistent for most of the year with the exception of a few weeks in September 2018. A few required Operations and Maintenance activities over the months of September and October will be explained in more detail in the Site Observation logs. Once corrected, the environmental treatment system returned to normal operations, and continues to generate electricity derived from hog manure and wastes.

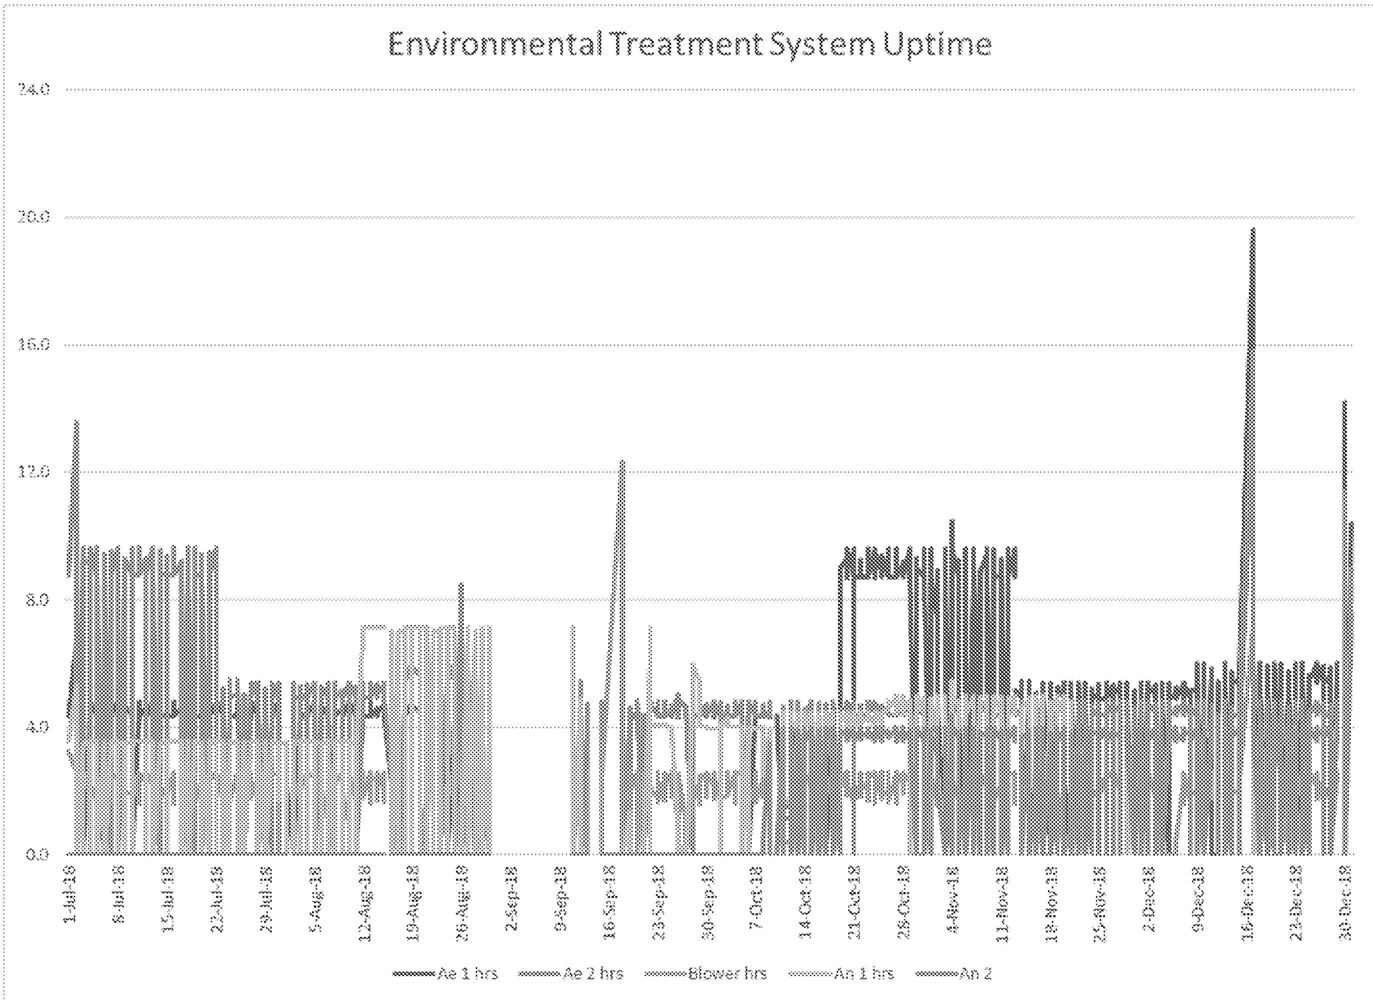

Figure 1. Environmental Treatment System Generator Uptime 7-1-2018 through 12-31-2018

The information in the daily log sheets correlates directly with the graph above, an electrical shutdown occurred during the first two weeks of September, which required replacing some parts to get the environmental system and the SCADA system back operational. Another complication during that time was a clogged digester mixing pump. After troubleshooting the problem, the operations staff was able to open the valves, back flush the system, rectify the bilge pump, and get the system operational again. Many areas in North Carolina received historical flooding in September, and Loyd Ray Farms received an unusually heavy amount of rain. However, the digester and operations remained intact and were not particularly affected by the storms nor rainfall. During the electrical outage that occurred around September 16th the flare was kept burning via gravity feed of the biogas continuously until we could get the system back online, as evidenced in Figure 1. Another atypical occurrence was October 8th, when the system required a repair of the digester pump. A spike in blower hours also occurred in December, when installation of like replacement fans and like replacement circuit boards in the Phase converter were required to properly cool down the system. Once corrected, the environmental treatment system returned to normal operations. Both aerobic and anaerobic performance during the compliance months are recorded in the **Environmental System Uptime** graph above. The anaerobic mixing system uptime was 71% for the reporting period, while the aeration system uptime was reported as 70%.

Figure 2. below depicts the **Microturbine Output in kilowatt hours** (kWh) during the compliance period. Biogas flow is also monitored and recorded for the system. The biogas may only be disposed of through use by the microturbine and flare, controlled release through venting, or leaks from the system, which cannot be measured.

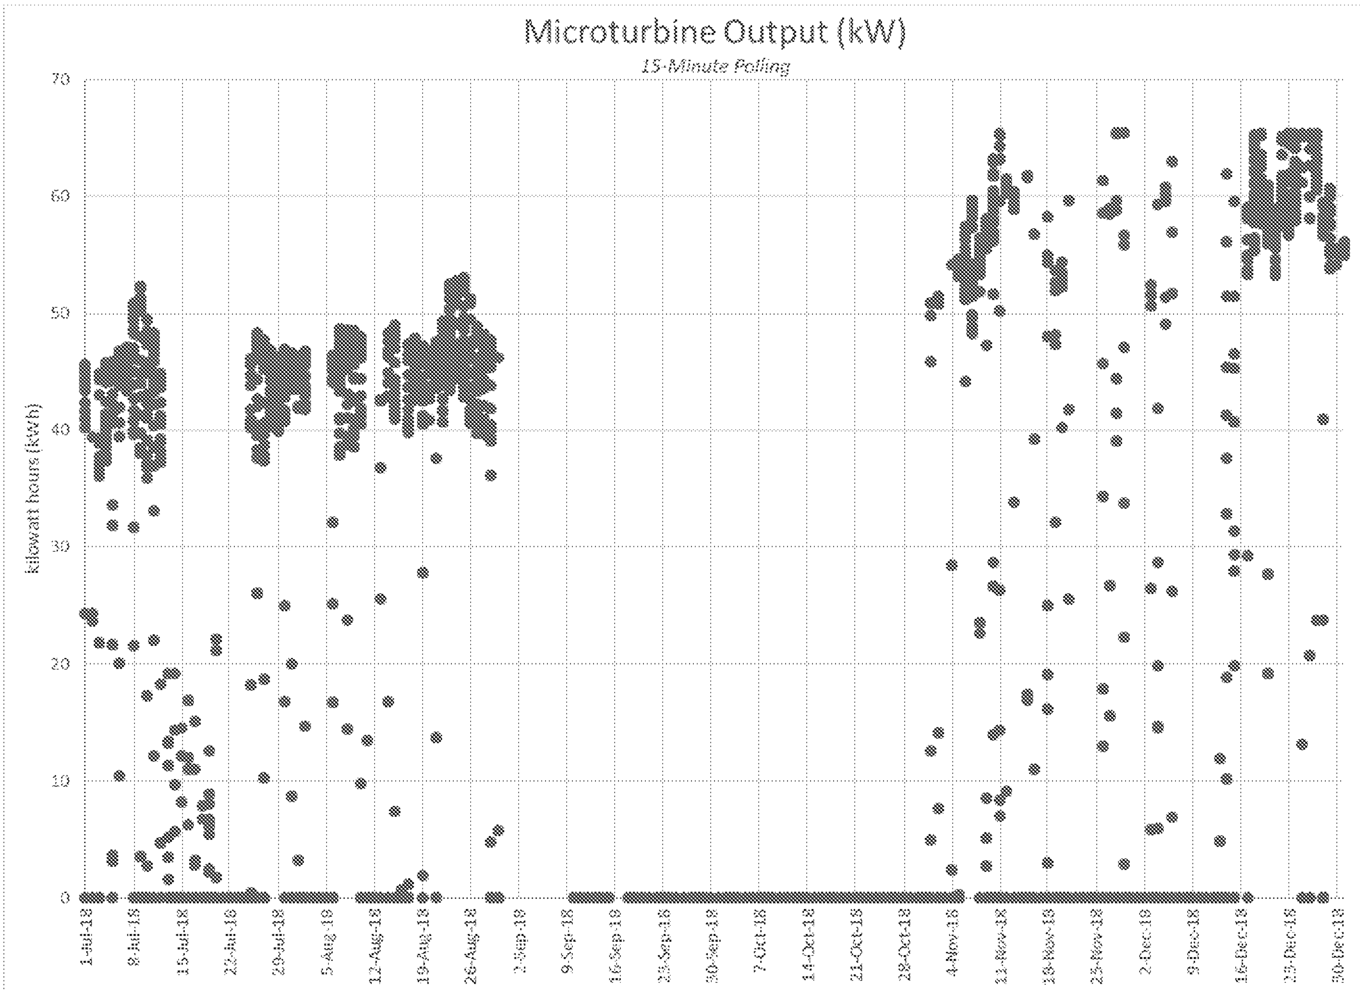

Figure 2. Microturbine Output per Kilowatt Hour (KWh) July 1, 2018- December 31, 2018

Figure 3., **Measured Biogas Flow and Flare Use,** which follows, depicts the dataset relative to the measured biogas flow and flare usage, which utilizes the same dataset for the duration of the compliance period. The measured gas flow directly correlates to Figure 2, the microturbine output above, both reflect the system consistency, except for the downtime in the months of September and October of the reporting period. Once the required maintenance activities were accomplished, and the system returned to operational, the performance was normalized.

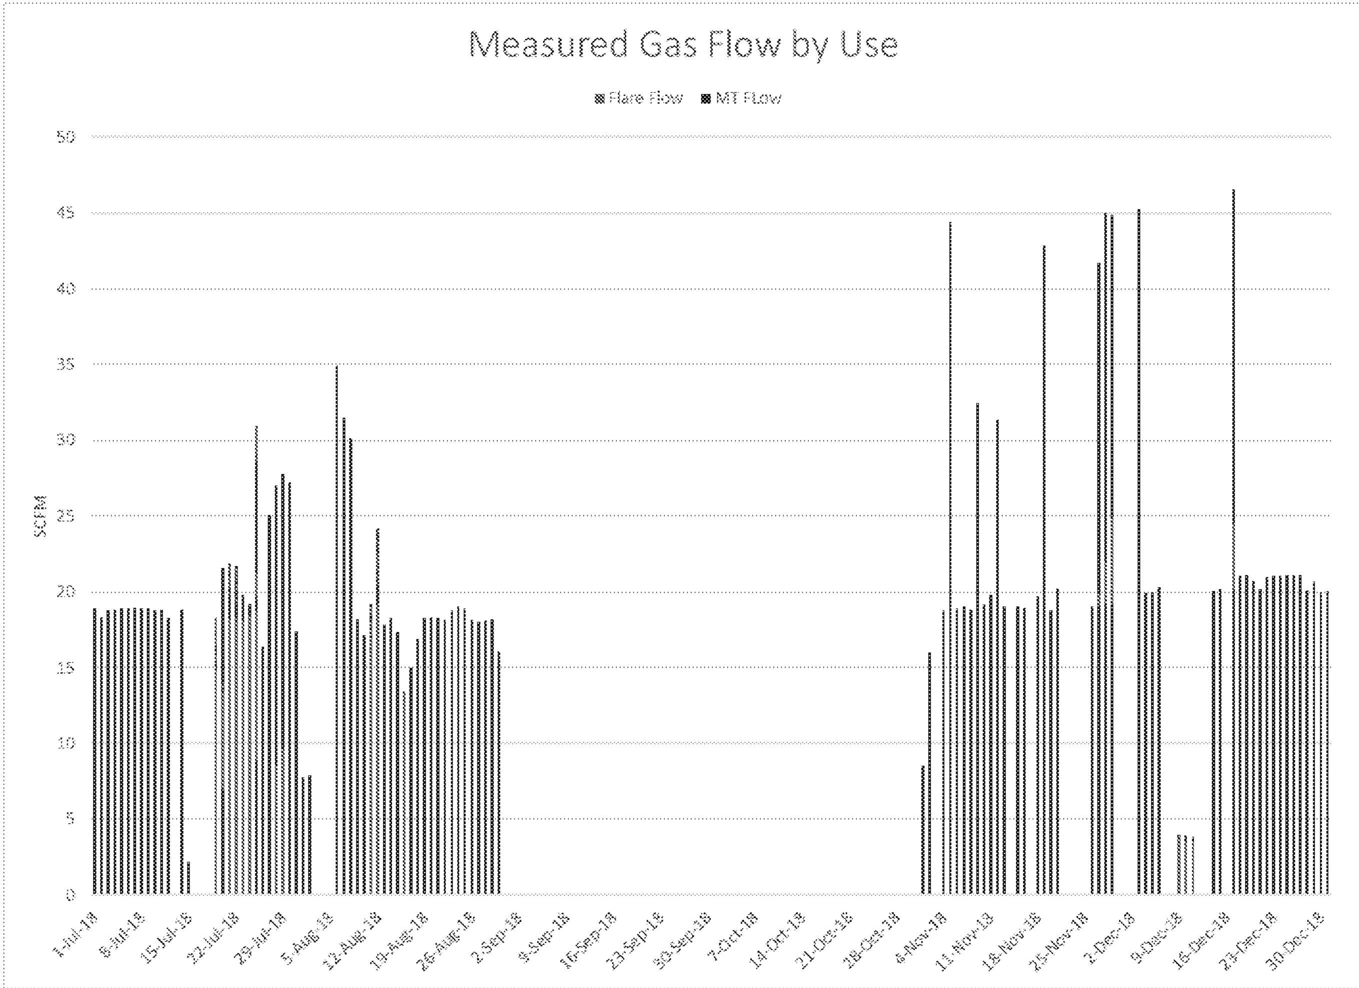

Figure 3. Measured Biogas Flow and Flare Use (July 1, 2018-December 31, 2018)

The above graph illustrates the measured biogas usage for the system. Flare usage, as indicated by measured flow to the flare meter, for the reporting period may also be surmised from the graph. It should be noted that days that indicate zero flow may sometimes indicate a disruption with the data acquisition system. As described previously, system operations had periodic downtime(s) in September and October, which correlates directly with the microturbine output above. After system repairs replacing like parts during these months, the microturbine output was improved and remained high for the months of November and December. The hog barns were also full during those months, compared with only half full in the early months of this report, which may help to explain the increase in electricity generation (kWh's).

The volume of gas is measured in Standard cubic feet per minute (SCFM). During normal operations, July through the beginning of September, the system was fairly consistent in the 18-19 SCFM range, with a little better flow in the months of November through December months averaging between 19 and 21 SCFM, with a few intermittent spikes on days of very high gas flow reaching up to 45 SCFM.

Overview of System Maintenance and Repairs

Overall, the operating biogas system and the environmental treatment system performed well, and remained under compliance. All maintenance exceptions appear in the log below, as maintained and recorded physically in the **Loyd Ray Farms Inspection and Operation Log Sheets**. While remote monitoring occurs on a daily basis, those activities are not normally captured in the report. We will note here only occurrences which required a site visit to resolve, or how the technicians would troubleshoot any problems that arose. If a system alert precipitated a site visit, we have indicated how the monitoring team went about troubleshooting the problem, and logged the experience required to make the corrections. Oftentimes, Cavanaugh's team was able to resolve the issue, but if a representative from either Unison, the biogas skid provider, or another service technician, such as an electrician, was required for further assessment or repairs, we have also noted the dates of their presence, how they troubleshooted the problem, and if replacement, new or rebuilt parts were required. Please note that the system required a little more frequent servicing as some of the parts in this pioneering system commissioned in 2011 are approaching their expected service life, but most of the service activities are viewed as normal Operations and Maintenance (O&M), and in all instances, no system parts were added to normal operations.

In summary, most of the maintenance activities during this period were gas conditioning skid shutdowns, which required on-site inspections or manual restarts. Please note that at the beginning of this semi-annual report only five of the nine barns were filled with hogs, which affected the biogas produced. Some severe weather occurrences, such as heavy rains required surface water pumping, oftentimes necessitating a reset of the system. While one occurrence, at first was diagnosed to be a bad transformer, but after further investigation, it turned out to be a converter issue. The electrical service technician determined the converter could be rebuilt. Considering the significant rainfall in the state following Hurricanes Michael and Florence, the storms themselves did not particularly disrupt the routine flow of biogas, but sometimes required more frequent pumping of surface water. On occasion, back-flushing of the system was required, along with other remedies to unclog the digester pump, if the bilge pump failed. During the months of November and December, when all the barns were completely full, gas was flowing steadily, and the rate at which the biogas was accumulated and stored beneath the HDPE cover exceeded the capacity of the microturbine, and the flare was used to augment biogas use. A necessary improvement was the installation of a new camera to replace the older model, to enhance images, and provide a clearer picture for remote observances and monitoring. It should also be noted that since this system's installation in 2011, many improvements in technology and instrumentation have developed.

The summary of the detailed operations log of on-site activities and monitoring for the period of July 1, 2018 through December 31, 2019 is presented as follows:

Date	Observation
7-2-2018	Monitored system remotely
7-25-2018	Site Visit to meet with Alex Gusnes of E-finity. We serviced the Microturbine (MT) and replaced air filter and the faulty fan we had been running. We found a faulty Rosemount meter which was registering incorrectly going to the MT. Also pumped surface water and did a site inspection.
7-27-2018	After remote monitoring, did a site visit. Pumped surface water and did a walk around site check. Turned flare on with 10 CMF going to flare.
7-30-2018	After remote monitoring, did site visit. Pumped surface water and performed site check. Flare off the balloon is getting low, as 5 of the 9 hog farms are empty. I installed a temporary

	cover for gas MH and dug a small ditch to help divert water away from the MH. Most operations automatic, with the exception of flush pumps by hand.
7-31-2018	Remote system monitoring during storms and heavy rainfall.
8-1-2018	Remote system monitoring, then site visit to inspect and review storm damage. After 6 inches of rain, worked all day with all entities to try and restore system back to normal operations. Monitored operations after storm damage trying to keep it running
8-2-2018	Remote system monitoring, then site visit to review storm damage. After 6 inches of rain, worked all day with all entities to try and restore system back to normal operations. Monitored operations after storm damage trying to keep operations running in stable mode.
8-3-2018	Monitored system remotely, checking to make sure post storm operations are normal.
8-6-2018	Monitored system remotely, then site visit to try and start the system. The gas balloon is growing, I started the flare, and pumped surface water and nursed the system to run. It failed twice due to heat, the outside temperature was in the 90's today.
8-7-2018	Monitored system remotely, then site visit to restart and monitor the operations. I shut the Flare off, as the balloon reach the level needed to shed rain. Pumped surface water and nursed the system to run. Communicated with reps at Unison and E-finity. A technician from E-finity is scheduled to be here on Thursday.
8-11-2018	Monitored system remotely, then site visit to do a restart after skid shut down because the MT would not start remotely. I ran a test and found that the MT failed to restart automatically after a skid shut down, so I started the flare. I will do a follow-up email with Nick at Unison.
8-13-2018	Site visit to do a restart of system with E-finity. We had a good start up, but now a skid warning for 33/342 reheat temp at 2:45 p.m. Will do a follow up email to Nick at Unison.
8-14-2018	Site visit to do a restart of system with E-finity. After the heat up at 2:45 p.m. yesterday, the skid was restarted, but the MT would not start, so I shut it down. I have restarted the skid today and will get E-finity to unblock the MT, and re-start it. Did a walk around inspected the system and started the auto pump for surface water.
8-16-2018	Monitored system remotely, Site inspection. Started the surface water pump. During the night, the Flare would not start. I turned on the mail at the MT, and it ran fine. I took influent, digester and effluent samples.
8-19-2018	Monitored system remotely, we had a shut-down today (Sunday). This was due to the outside temperature, after it cooled, I accomplished a successful restart of both the skid and the MT.
8-20-2018	Walk around inspection and site visit, operations are working normally.
8-21-2018	Monitoring system remotely, experienced a couple of shut downs, but was able to restart remotely.
8-22-2018	Monitoring system remotely, experienced a couple of shut downs, but was able to get back on line remotely.

8-23-2018	Site visit to meet with Matt Arsenault, Alex Gusner of Duke University, and Sarah Lanier (a student there). We took samples from the Lagoon Basin and Digester and also gas samples. I performed a site inspection and restarted the automatic pump and another non-automatic pump to handle surface water on the cover. System operations are normal.
8-27-2018	Site visit to do an On-site inspection, system and ground check. I worked on the camera with little success, system operating normally.
8-29-2018	After remote monitoring, did a site visit, tried to adjust the camera, system operations are running normally.
8-30-2018	System monitored remotely, then Site visit to do a system and ground check. Found the Unison system down. I tried to hard boot it, with no success. Unison is scheduled to be here on 9-10-2018, and I will call Unison to discuss.
9-5-2018	Remote monitoring this week.
9-10-2018	Site Visit. Met Marty Kass of Unison there to do service work. Flare is burning gravity gas. We found out we had no power. I called Salem Electric to do an emergency visit. They think the transformer is bad, and are checking on a source for a replacement one.
9-11-2018	We are still without power. Marty Kass of Unison, and Keith and Bryan from ProPump were on site, and I asked them to assess the no-electricity situation. They found the phase converter was bad, which showed like a bad transformer. They took down the two-phase converters and will ship them off to be rebuilt. They are also troubleshooting to change the flush pump from 3-phase to single phase, and are working to rebuild the IT. Marty Kass of Unison could not finish his service, and went to another job close by.
9-12-2018	ProPump returned with the converter rig for the flush pump and wired it inside the building to the pump with Kevin's help. We were able to get it back online and were able to flush.
9-13-2018	Flare is burning gravity gas. Kevin and Marvin worked to unclog the digester pump, but it is still clogged.
9-14-2018	Flare is burning gravity gas. Site visit to monitor operations and to prep for upcoming Tropical Storm Florence, which may be a hurricane.
9-15-2018	Monitored system remotely, flare is burning gravity gas.
9-15-2018	Monitored system remotely, then site visit to check system and water levels, flare is burning gravity gas.
9-16-2018	Remote monitoring, Flare is burning gravity gas, Site visit to check system and water levels.
9-17-2018	Remote monitoring, Flare is burning gravity gas
9-18-2018	After remote monitoring, went to Site to do a system and ground check. Found digester pump still clogged, tried to back flush system, but was not able to get valves open. The balloon is growing so I vented for one hour. The auto bilge pump failed, so I pumped surface water with two pumps for two hours.
9-22-2018	Remote monitoring, then site visit to check gas levels. Still flaring, but only had to vent once.
9-23-2018	Monitored system remotely, No Site visit today. System is still flaring, but not venting, only once.

9-24-2028	Monitored system remotely, No Site visit today. System is still flaring, but not venting, only once.
9-25-2018	Site visit to do a system and ground check, and found the digester pump still clogged, tried to backflush to see if I could unclog. I am still flaring but vented only once. The auto bilge pump failed so I pumped surface water with two pumps for the entire visit.
9-26-2018	Site visit to do a system and ground check, and found the digester pump still clogged, tried to backflush to see if I could unclog. I am still flaring but vented only once. The auto bilge pump failed so I pumped surface water with two pumps for the entire visit.
9-27-2018	Site visit to do a system and ground check, and found the digester pump still clogged, tried to backflush to see if I could break it free. I finally got the Digester pump to work, and plan to let it run all night to get it cleaned out. Still flaring the gas, vented only once. The auto bilge pump still failing, so I pumped surface water with two pumps for the entire visit.
9-28-2018	Site visit to do a system and ground check. Found the digester pump still working, so I moved it to the auto cycle. Pumped surface water during the site visit, vented at 2 ports for two hours.
10-1-2018	Site visit for system and ground check. Found digester pump still working, so I kept it on the auto cycle. Pumped surface water during the site visit.
10-2-2018	Site visit for a system and ground check. Operations are normal and the digester pump, remains on auto cycle. Pumped surface water. Conducted a tour of Duke University students and professors who came to observe operations.
10-3-2018	Site visit for a system and ground check. Digester pump still operating correctly, remains on auto cycle. Pumped excess surface water during the site visit.
10-4-2018	Monitored system remotely, no Site visit today.
10-5-2018	Site Visit to do a system and ground check and found our digester pump still working so I kept it on the auto cycle. Pumped surface water during site visit. Vented at two ports for 2 hours
10-6 & 10-7	Monitored system remotely without incidence.
10-8-2018	Site Visit to do a system and ground check and found digester pump still working so I kept it on the auto cycle. Pumped surface water during site visit. Met with Josh Amon to get the repaired Digester Pump installed. We worked on getting pumps unclogged, we are going to try to run as long as possible but not leave them unattended for a while, as sometimes they clog up and no fluid is being pumped.
10-9-2018	Site Visit for system and ground check, digester pump still working. Pumped surface water during site visit. I changed the timers and after the Digester pump restarted with a prime, I am going to try it through the evening.
10-10-2018	Site Visit to do a system and ground check and found our digester pump still working. Pumped surface water during site visit. I changed the timers and after the Digester pump restarted with a prime I am going to try it through another evening.
10-11-2018	Pumped surface water during site visit. I changed the timers and after the Digester pump restarted with a prime I am going to try it through another evening. Heavy rains from

	Michael with some flooding in the ditch. Mr. Bryant not happy with the ditch. Lost power for an hour or so all back running and seeing breaks in the clouds
10-12-2018	Pumped surface water during site visit. I changed the timers and after the Digester pump restarted with a prime I am going to try it through another evening. The Flare continues to run on gravity gas flow of 8-10 CFM I needed to vent today at two ports for 2.5 hours
10-14-2018	Monitored system remotely, particularly the flare.
10-15-2018	Site Visit to do a system and ground check and found our digester pump still working. Pumped surface water during site visit. The timers are working well with the restart of the Digester pumps. I am going to leave them as they are for now. The Flare continues to run on gravity gas flow of 8-10 CFM. No venting since Friday 10-12-2018.
10-17-2018	Pumped surface water during site visit. The timers are working well with the restart of the Digester pumps. I am going to leave them as they are for now. The Flare continues to run on gravity gas flow of 8-10 CFM. No venting since Friday 10-12-2018.
10-18-2018	Remote monitoring
10-19-2018	Pumped surface water during site visit. The timers are working well with the restart of the Digester pumps. I am going to leave them as they are for now. I worked on Drainage some. The Flare continues to run on gravity gas flow of 8-10 CFM. No venting since Friday 10-12-2018.
10-21-2018	The Flare continues to run on gravity gas flow of 8-10 CFM. No venting since Friday 10-12-2018.
10-22-2018	Site Visit to do a system and ground check and found our digester pump still working. Timers continue to work well, worked on drainage more. No venting since Friday 10-12-2018.
10-23-2018	Site Visit, no changes since yesterday.
10-24-2018	Site Visit, Pumped surface water during site visit. The timers are working well with the restart of the Digester pumps. The Flare continues to run on gravity gas flow of 8-10 CFM. No venting since Friday 10-12-2018.
10-25-2018	Site Visit, no change since yesterday.
10-26-2018	Site Visit needed to check system the team viewer was not working dependably we need to install cameras ASAP to save on visits. Timers still operating correctly to restart pumps. No venting since 10-12-2018.
10-28-2018	Monitored system remotely.
10-29-2018	The Flare continues to run on gravity gas flow of 8-10 CFM. No venting since Friday 10-12-2018. Technicians from ProPump were on site installing the Phase converters and setting up for the wiring changeover of Flush Pump from 1 Phase back to 3 Phase
10-30-2018	ProPump was on site installing the Phase converters and setting up for the wiring changeover of Flush Pump from 1 Phase back to 3 Phase, Kevin Harward joined us to assist. We put boat in Basin for the wiring change on the Flush Pump.
10-31-2018	Site visit, Kevin Harward came to the farm to install a power part on the Unison system. We attempted to start the system, but the chiller had a failure and would not start. We are trying to get help resolving the problem. ProPump will probably need to come back and help with

MB018701

	the SCADA. Kevin and I moved the hose to push some of the digester sludge water to the Lagoon
11-1-2018	Site visit to accomplish a manual restart after an overnight failure, then working with folks from ProPump, trying to get SCADA to communicate with the Unison skid. The MT and skid were running again and no flare. Talked to ProPump via phone to set up for the SCADA repair.
11-3-2018	Steve Cavanaugh made a Site visit to start the conditioner. The MT failed after several tries it shut down.
11-4-2018	Site visit to start conditioner and MT. I found conditioner running but the MT not running and SCADA not recording properly. The MT failed after several tries it shut down. I then did a hard boot and it has been running since 11:05 AM. The MT is producing 59.6 output 54.9 on 18.3 CFM. I will monitor and keep records of output until SCADA can be fixed.
11-5-2018	Bryan from ProPump came to farm to work on SCADA, I was able to talk him through a restart. He had to drain the water from the gas pump on the south end of the skid and then the skid would start. I made a site visit to meet with Bryan. We were able to get the Skid and SCADA communicating and we are now running full bore. We have a lot of gas and I plan to stay as long as possible running both flare wide open; and the MT wide open burning about 50 CFM. I shut the Flare off at 4:30 PM
11-7-2018	I turned the flare off before I left on Monday and monitored remotely all-day Tuesday. Site visit today, the gas is still up, and the MT has been running since Monday.
11-8-2018	Site visit today, had a power blip that shut off team viewer, when I got to the site there were no alarms and the computer was back up the skid was just sitting there and not running, and the MT was in standby mode. Started the skid and when it was ready and sending to the MT; the MT would not start it was on, but not starting. I had to shut-off the breaker as before and when I turned it back on the MT started automatically. The gas volume is still up, and I will return tomorrow, and we may need to flare. Eight of the 9 hog houses are full of animals, loaded one out just now leaving the 8. The MT has been running since Monday,
11-9-2018	Site visit today, we have been running up until around 12:33PM we had a skid fault of high condensate at 741. I reset and restarted skid and the MT came on as it is supposed to at 2:00 PM. I started the flare to run while I am on site as the gas volume is still up. I did a walk around and up on the cover all is well. I installed a replacement fridge today. I received a new camera and will try and install it next week.
11-10-2018	Remote monitoring all day; we had three shutdowns and then late we had a MT fault. No site visit

11-11-2018	Site visit to restart the MT, as remote monitoring indicated a fault on the screen and the breaker had tripped. I had cut the skid off when the MT was in fault, so I restarted it, reset the breaker and opened the Flare valve. Everything restarted as it should have.
11-12-2018	Site visit to restart the MT I found a fault showing on the screen and the breaker had tripped. I had cut the skid off when the MT was in fault, so I restarted it, reset the breaker and opened the Flare valve. Everything restarted as it should have. This is the same as yesterday. I started the Gravity-flow Flare and it is running 10+ CFM, even though it does not seem to register on SCADA
11-13-2018	Remote monitoring, shutdown today, will do a site visit tomorrow.
11-14-2018	On Site Visit, I started the Gravity Flow Flare and it is running 10+ CFM even though it does not seem to register on SCADA and I am glad because we had a shut down on Tuesday.
11-15-2018	Site visit to restart system it refused to restart, but after 3 tries, I finally got the system restarted.
11-16-2018	Site Visit, due to shut-downs this week. I started the Gravity Flow Flare and it is running 10+ CFM even though it does not seem to register on SCADA and I am glad because we had a shut down on Tuesday and Wednesday and another during the evening on Thursday. Site visit to restart system and I found that the skid is not communicating with the SCADA and I am unable to start and stop or monitor skid data. I was able to re-start the skid and the flare continues to burn on gravity as above. The MT started as it should, and is running fine. I will monitor but if we shut down then it will be Sunday before I can manually restart. We need to burn all the gas that we can, the volume is high.
11-18-2018	During the evening on Thursday and again after site visit on Friday we had shut-downs. Monitored off and on Saturday, Flare burned at 10+CFM all the time. We need to burn all the gas that we can the volume is high. Site visit to try and restart system I had to do a hard boot of the Skid and the MT before I could get the System to run properly. When I did the hard boot on the Skid the communication with SCADA came back?? We are up and running again.
11-19-2018	Site visit to try and restart system Kevin restarted and was able to re-establish the communication Skid to SCADA by resetting at the panel several times. The MT started as it should at 12:52 PM. We started the flare through the conditioner and opened 2 vents at 1:45 PM. We had a shutdown at 3:16 PM and a quick restart. We shut the vents off at 3:45 venting for 2 hours. I cut the flare off coming through the Skid and restarted the Gravity Flow Flare and it is running 10+ CFM.

11-20-2018	Kevin and Marvin did a Site visit and took quarterly water samples. Had to reset the communications on the Unison panel as it shut down yesterday, acting like power is lost on the panel or something is going bad. Able to restart Skid and MT at 10:30a.m. Contacted Unison to let them know the issues hopefully get it fixed and or schedule a site visit soon. Think we have 2 bad level switches on the skid, they keep tripping-off and on, for 5- 30 seconds, once they are on for 30 seconds, the alarm is tripped, one is a high-level switch and is causing a shut down, again will let Unison know. We installed the new camera and set it up on team viewer. We did a walk around and up on top to check for leaks
11-21-2018	We did a site visit to restart same problem shutdown for condensate that is not there and faults out, so we cannot restart remotely but have to go to site to manually restart. Gravity Flare is burning at 10+ CFM
11-22-2018	Monitored system remotely most of week, trying to burn all the gas we can while the volume is high.
11-26-2018	Had to reset the communications on the Unison panel which shut down yesterday, acting like power is lost on the panel or something is going bad, was able to restart Skid and MT at 4:00PM. I emailed Unison to try to troubleshoot site issues and requested a site visit hopefully to get it fixed as soon as possible. Think we have 2 bad level switches on the skid, they keep tripping off. We did a site visit to restart, without success. The same problem occurred; shutdown for condensate that is not there, and the system short circuits, or faults out, disrupting the normal flow of the system, so we cannot restart remotely but must visit the site manually to restart. Gravity Flare is burning at 10+ CFM Started venting at two vents at 4:05 PM and closed them at 5:05 PM. By the time I got home at 8 it shut down.
11-27-2018	Monitored all during the night to see if flare was continuing to burn at 10 CFM. Site visit today to restart the system. I shut off the Gravity Flare at 11:00 AM and opened the valve and flared with gas through the skid at feed=28.4 and flow = 21.4 CFM. The skid is running with the fault light showing on SCADA, but the MT and skid are running full. Every shut down, or system failure, is requiring an on-site visit. At 2:00 PM I went back to Gravity Flare at 10+ CFM. The skid and MT have been running 4 hours. The red fault light is still showing on SCADA, but the system is running, and it will continue to fault out. We need to burn gas and make KWs. System shutdown at 3:10p.m. Flare continued to burn at 10+ CFM.
11-28-2018	Monitored all during the night to see if flare was continuing to burn at 10 CFM. Site visit today to restart the system. I shut off the Gravity Flare at 2:38p.m. and opened the valve and flared with gas through the skid at feed=30.4 and flow = 25.4 CFM. The skid is running with the fault light showing on SCADA, but the MT and skid are running full. At 2:00p.m., I shut

MB018704

	the system down and did a hard boot and this time the fault light on SCADA picture of the skid went off and the Unison screen started registering data. At 2:08 p.m., we are running full bore. Back to Gravity Flare at 10+ CFM. The skid and MT have been running 4 hours. The red fault light is still showing on SCADA, but the system is running, and after troubleshooting I discovered we need to burn gas and make KWs. System shutdown at 3:10p.m., re-fired at 4:10p.m., shutdown@5:27p.m., restart at 8:57-shutdown@11:57p.m. Flare continued to burn at 10+ CFM.
11-30 through 12-2-2018	Monitored all during the day and night to see if flare was continuing to burn at 10 CFM
12-3-2018	Monitored all during the night to see if flare was continuing to burn at 10 CFM. Site visit to restart system started at 11:45a.m. --Flared using skid at 24CFM 12:45p.m. until 3:50p.m. Reset gravity Flare at 10+ CFM for the night.
12-4-2018	Monitored during the night to see if flare was continuing to burn at 10 CFM. Site visit to meet with tech from Unison. Worked with Curt Schiesl of Unison to try to resolve the problem with the skid. I shut the flare off at 9:00a.m. He changed out switches and tried all kinds of things to keep it running. He had to order parts shipped overnight, and will continue troubleshooting tomorrow.
12-5-2018	Monitored system with Curt Schiesl, Field Service and Start-up Technician for Unison by computer and phone as he continued to try and fix the problem with the skid. He left for his home stating that he thought the problem was that the Phase converters were overheating. We had a shut down and panel fault as before.
12-6-2018	Site visit to restart the system and found we had a shutdown but no loss of power to panel, it just faulted as before. All I had to do to start the skid and MT running was to press the start button. I still do not have any data on skid panel screen, but we are running. We had a shutdown and showing no power to Unison panel. I did a hard boot to PC and after a short pause the Unison panel lit up with information, it ran for about 30 minutes and shutdown still showing power to the Unison panel. I restarted without any numbers and it is running; if and when we have a shutdown, it will have to be restarted by onsite visit. I started the Gravity Flare burning at 10+ CFM and plan for it to run until Monday regardless of what the Skid and/or the MT does.
12-11-2018	Site visit to restart the system and found we had a shutdown, but no loss of power to panel. The Gravity Flare has been burning at 10+ CFM continuously since I left on 12-06. I met with Norman and Bryan of ProPump and plan for it to run until Monday regardless of what the Skid and or the MT does.

12-12-2018	Site visit, met with ProPump and we continued to troubleshoot along with Doug from Unison.
12-13-2018	Site visit to restart the system and found we had a shutdown, but no loss of power to panel. The Gravity Flare has been burning at 10+ CFM continuously since I left on 12-06. Met with Bryan from ProPump and we continued to troubleshoot along with Doug from Unison. We added some new parts and it seemed to be fixed. Then in the evening we continued to have shut downs, Flare still running.
12-14-2018	The Gravity Flare has been burning at 10+ CFM continuously since I left on 12-06. Bryan from ProPump came to site and he installed a part and we were running. I monitored and sent text to Norman and Bryan of ProPump, and Doug from Unison. We added some new parts and it seemed to be fixed. Then in the evening we continued to have shut downs. Flare still running. I monitored all weekend during that time I lost communication due to a power Failure by Surry-Yadkin, Flare continued to burn.
12-17-2018	Site visit to restart the system and found we had a shutdown but no loss of power to panel. The Gravity Flare continued to burn all weekend. At 10.0+ CFM. I met with Bryan of ProPump and we spent the day troubleshooting system with concentration on Phase converter. With the help of a conventional fan we were able to cool Phase converter enough to run until we could get parts to repair. Started running at 10:50a.m. We shut the gravity flare off on the restart of the Skid and MT and ran the flare hard until 3:15 PM.
12-18-2018	Monitored system remotely by SCADA and Camera The system has been running from 11:00a.m. Monday without a shut down. Gravity Flare is off.
12-19-2018	Site visit to do a system check, the parts did not arrive, so after the inspection and repair of a small leak, I traveled home to return tomorrow. Gravity Flare is off.
12-20-2018	Site visit to do a system check. I met with Bryan of ProPump and he installed fans and circuit boards in Phase converter. We restarted system and we are up and running. The Gravity Flare is off.
12-21-2018	Site visit to do a system check. I met with Matt Arsenault of Duke U. We have been running solid since we replaced PC Fans yesterday. The Gravity Flare is off.
12-30-2018	Site visit to do a system inspection. The Gravity Flare is off. System was working but computer was down.
12-31-2018	Site visit to do a system check The Gravity Flare is off. System was working but computer was down again. Rebooted it again Checked Team Viewer with Nancy at home.

The following table lists the compliance requirements as per the permit for the subject system, and the performance / compliance relative to each requirement:

	Description of Monitoring Requirement	Status	Result
1	Maintenance of adequate records by Permittee to track the amount of sludge/separated solids disposed.	N/A	No solids or sludge disposal occurred during the reporting period; some sludge returned to the anaerobic digester for further breakdown in accordance with the Division approved Operations & Maintenance Plan.
2	Inspection of entire Innovative System waste collection, treatment, and storage structures and runoff control measures at a frequency to insure proper operation but at least monthly and after all storm events of greater than one (1) inch in 24 hours; Permittee maintenance of inspection log or summary including at least the date and time of inspection, observations made, and any maintenance, repairs, or corrective actions taken by Permittee.	☑	Inspections and observations conducted by representatives of Loyd Ray Farms, Inc., Cavanaugh & Associates, P.A., and DCOI. Observations recorded, and actions taken to adjust the operation of the System are recorded in log book kept onsite, and emailed in.
3	Maintenance of a log of all operational changes made to the Innovative System including at least the process parameter that was changed, date and time of the change, reason for the change, and all observations made both at the time of the change and subsequently as a result of the change by Permittee/ Permittee's designee.	☑	Log book entries, as described in item #2, above, maintained on site; copies attached to report (Appendix A).
4	Representative Standard Soil Fertility Analysis to be conducted annually on each application site receiving animal waste.	☑	NCDA&CS Agronomic Division Report No. FY19-SL009269, shows the results of the Predictive Home & Garden Soil Report for Loyd Ray Farms. The samples were compiled on 10/22/2018, and were completed on 11/01/2018, which are added to this report, they can also be accessed here: http://www.ncagr.gov/agronomi/
	Wastewater Analysis		
5	Quarterly tests shall be conducted once within each of the following windows w/ at least sixty (60) days between any 2 sampling events. Water quality samples include analysis of copper, zinc, total suspended solids, pH, total nitrogen, TKN, NO2 + NO3, phosphorus, ammonia, and fecal coliform.		
	Quarter 3 (July 1 – September 30)	☑	Sample Collected: 8/17/2018 Sample Analyzed: 9/18/2018 Results Reported: 9/18/2018

			Results included in the attached report from Research & Analytical Laboratories, Inc. (Appendix B)
	Quarter 4 (October 1 – December 31)	☑	Sample Collected: 11/20/2018 Sample Analyzed: 12/20/2018 Results Reported: 12/20/2018 Retest of Fecal Coliform: Sample Collected: 1/9/2019 Sample Analyzed: 1/11/2019 Sample Reported: 1/11/2019 Results included in the attached report from Research & Analytical Laboratories, Inc. (Appendix B)
Ambient Air Sampling			
	Fall Season Ambient Air Sampling	☑	A fall season ambient air sample taken on September 25, 2018. Results included in the Explanation of Results and Sampling Methods.
	Waste Treatment and Storage System	☑	
	Barns	☑	
	Sprayfields	☐	
	Winter Season Ambient Air Sampling	☑	A second ambient air sample (winter analysis) was completed on December 19th, by Duke University, and has been added to the report. Results included in the attached Explanation of Results and Sampling Methods.
	Waste Treatment System	☑	
	Barn Exhaust	☑	
	Sprayfields	☐	
Odor Sampling			
6	Permittee shall monitor for odor compliance quarterly at both upwind and downwind locations on the property boundary. Permittee shall document monitoring locations on a site map, indicating prevailing wind direction, for each monitoring event.		
	Quarter 3 (July 1 – September 30)	☑	Odor sampled by Duke University Explanation of Results and Sampling Methods. September 25, 2018.

MB018708

7	Quarter 4 (October 1 -December 31)	☑	Odor sampled by Duke University Explanation of Results and Sampling Methods. December 19, 2018.
		Record Keeping	
8	All records, including operation, maintenance, and repair records, shall be maintained on site and in chronological and legible form for a minimum of five (5) years by the Permittee; records shall be maintained on forms provided by or approved by the Division and shall be readily available for inspection.	☑	A copy of the report and all monitoring records are maintained in a binder in the System Control Building; the electronic form combines inspection and operations records on a single form, entitled "Loyd Ray Farms Inspection, Operations & Maintenance Log Sheet" which are being collected electronically, and submitted to the Regional Office via email.

EXPLANATION OF RESULTS AND SAMPLING METHODS

1. Amount of Sludge or Separated Solids Disposed

N/A. No disposal of sludge or separated solids was required from the Innovative System during the 7/1/2018-12/31/2018 reporting period. Some sludge was returned from the aeration basin to the anaerobic digester for further breakdown, as per usual and typical operations, in accordance with the design and Operation and Maintenance Manual.8

2. Log of System Inspections

See Operator Log Book, Appendix A. (digitally attached)

3. Log of Operational Changes to the Innovative System

See Operator Log Book, Appendix A. (digitally attached)

4. Results of Standard Soil Fertility Analysis

Two separate reports, by NCDA & CS Agronomic Division, analyze independent soil samples which were taken at Loyd Ray Farms on October 22, 2018, as stated in the reports completed on November 1, 2018. The actual test results and recommendations for each sample can be found in Appendix C. The following tables are compiled to easily view the aggregated results.

Loyd Ray Farms Report No. FY19-SL009268

	Sample #	1A 01	1B 02	IC03	3A	3B	3C	9B
HM	Percent humic matter	0.41	0.41	0.41	0.41	0.36	0.42	0.51
W/V	Weight per volume	1.12	1.15	1.16	1.08	1.10	1.09	1.08
1	Cation exchange capacity	7.2	7.4	7.6	9.8	9.4	10.2	9.4
9	Manganese Index	165	167	172	119	120	140	232
Zn-1	Zinc Index	782	486	443	542	492	629	499
Cu-I	Copper Index	135	143	137	102	106	128	110
128	Sulfur Index	32	32	32	31	32	34	33

P-1	**Phosphorus Index**	**53**	**57**	**56**	**84**	**91**	**92**	**86**
K-1	**Potassium Index**	41	39	41	**474**	50	**363**	**345**
pH	**Acidity**	**6.4**	**7.2**	**7.2**	**7.2**	**7.2**	**7.0**	**6.7**

Loyd Ray Farms Report No. **FY19-SL009269**

	Sample #	2	4	5	6	7	8	9A	9B
HM	Percent humic matter	0.41	0.41	0.46	0.41	0.51	0.36	0.51	0.51
W/V	Weight per volume	1.07	1.08	1.10	1.04	1.07	1.02	1.07	1.10
CEC	Cation exchange capacity	10.7	10.7	12.1	11.2	9.9	11.4	9.0	8.8
Mn-I	Manganese Index	153	150	131	162	198	166	222	224
Zn-1	Zinc Index	616	608	1601	735	569	696	475	445
Cu-I	Copper Index	147	141	128	121	105	114	108	108
S-I	Sulfur Index	36	35	36	35	32	33	32	29
P-1	**Phosphorus Index**	**87**	**89**	**116**	**90**	**88**	**91**	**85**	**83**
K-1	**Potassium Index**	**535**	**539**	**643**	**574**	**595**	**618**	**334**	**351**
pH	**Acidity**	**7.1**	**7.1**	**7.2**	**7.2**	**7.3**	**7.3**	**6.8**	**6.8**

In almost all samples, the Phosphorus Index (P-I) and Potassium Index (K-I), were found to be *Above Optimum*. The range for *Optimum* is between 50 and 70, Sample 1B 02, and 1C 03 were a little below the *Optimum* range, but all others were very desirable. All of the samples in the 0269 group, in bold lettering above, exceeded those limits, and were *Above Optimum.* All of the samples in the 0268 group were at least at *Optimum* level, and many of which were in the *Above Optimum* range. The pH test for acidity results were higher than the 5.8 to 6.5 *Optimum* range, averaging about 7.1 on Report #FY19-SL009269. Similarly, the Sample # FY19-SL009268, was also in the *Optimum* range, averaging about 6.9.
The exact agronomist's comments and recommendations for fertilizer application can be found in the Actual Soil Reports See **Appendix C.**

5. Results of Water and Air Quality Sampling

a. Results of Waste Water Analysis
Water quality samples were taken in each quarter, a synopsis of the results is found below. Samples were analyzed by Research Analytical Laboratories, Inc. in Kernersville. The 4th quarter sample of 2018, as well as 1st and 2nd quarters of 2018, resulted in higher fecal coliform counts than expected, and thus, additional samples were taken. While the re-sampling was done in January 2019, we have added it to the report for clarity. The following table compares the results of the water quality analysis of the final effluent from the Innovative System:

Parameter	8/17/2018	11/21/2018
TOT N	1080	972
TKN	1080	972
NO_2+NO_3	0.27	<.05

TP	62.2	215
NH_3-N	689	702
COPPER	0.088	0.334
ZINC	0.489	2.32
TS	848	1300
FECAL	1400000	33000000
pH	8.23	8.17

The fecal coliform count for most of the sampling events exceeded the permit limit, and this has not been resolved. Almost all other constituent parameters as recorded above are decreasing since the beginning of the year, as indicated in the final effluent recordings in the chart above. The chart above describes the waste water analyses that is required to be conducted on a quarterly basis. These parameters are: total N, NH_3-N, NO_3-N/NO_2-N, total P, % solids, copper, zinc, pH and pathogens. Samples are to be taken from the digester and the effluent (leaving the aeration basin). All sampling was conducted:

1. Given the resampling produced fecal coliform counts that were quite high compared to the permit limit, an additional resampling event was conducted on January 9, 2019. Again, a composite sample was obtained of the effluent, split into three (3) sample bottles, then sent to the laboratory for analysis. The results are as follows:

    1. Sample ID: Effluent #1; Fecal Coliform – MPN = 400000 MPN/100mL
    2. Sample ID: Effluent #2; Fecal Coliform – MPN = 1700000 MPN/100mL
    3. Sample ID: Effluent #3; Fecal Coliform – MPN = 330000 MPN/100mL

The results were much improved over the previous fecal coliform samples.

b. **The Results of Air Sampling**

Duke University's Dr. Marc Deshusses took Fall and Winter ambient Air Samples on September 25, 2018, and December 19th, 2018, respectively, the results of which are described below.

Odor Sampling #1

Odor was monitored to comply with Section I.6.b.ii of the Swine Animal Waste Management Permit. Two monitoring events occurred over this compliance period. The first monitoring event was conducted on September 25, 2018.

Sampling took place at about 11:30 am. It was an overcast day (70° F) with relatively steady wind (1.3-1.8 m/s). Several measurements for wind speed and direction were taken. The predominant wind direction and sampling points for odor were selected as shown in Figure 4.

Odor was monitored by Marc Deshusses, whose findings are reported here. Odor panelist rules were listed in the previous report and are not repeated here. Odor was monitored using a Nasal Ranger (http://www.nasalranger.com/) field olfactometer, following the manufacturer recommended instructions.

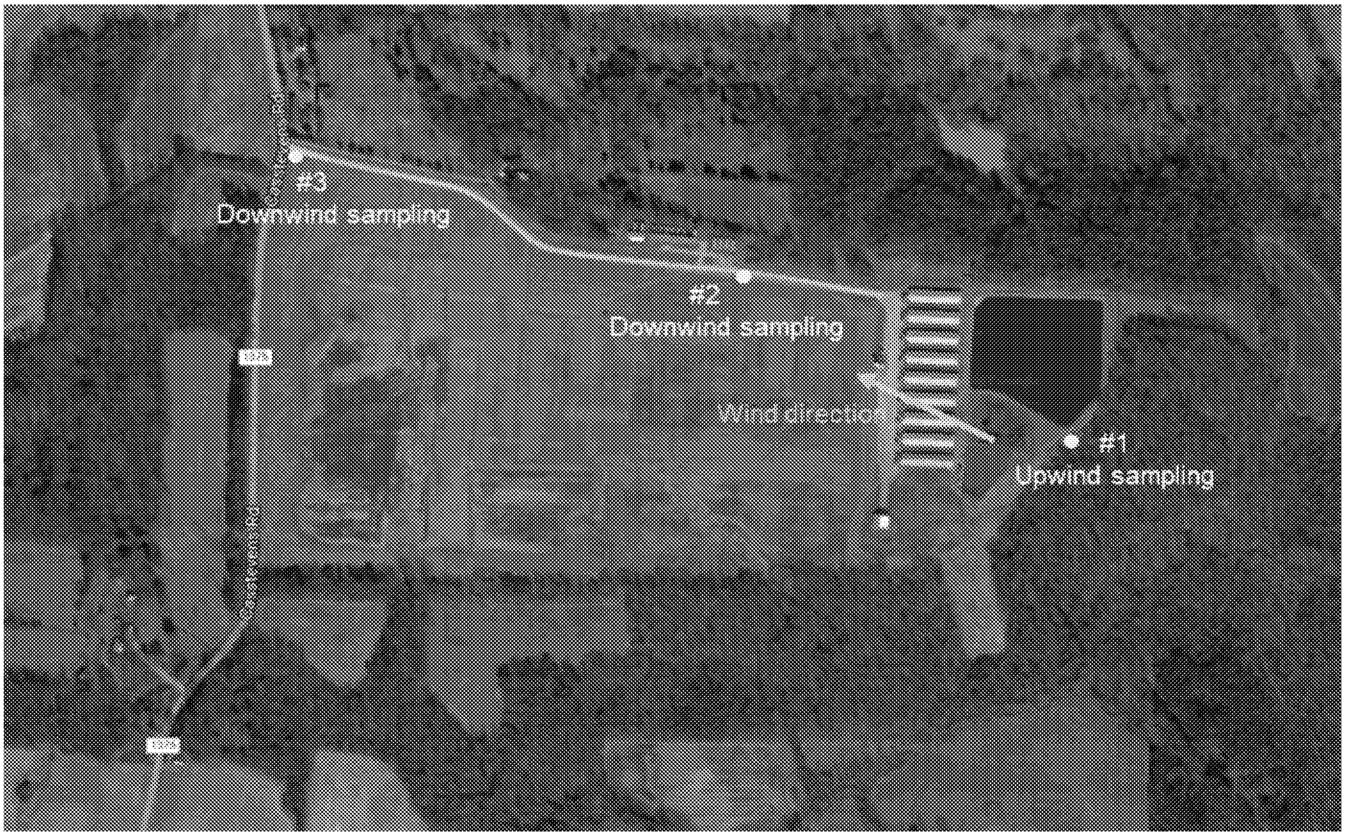

Figure 4. Aerial view of the facility and location of the monitoring points for odor for the June 26, 2018 sampling. The arrows indicate the prevailing wind direction the day of the sampling.

<u>Sampling upwind</u>
Odor could not be detected at the 2 D/T level. This indicates that the odor level was lower than 2 D/T. Then the Nasal Ranger was taken off the nose and ambient air was sniffed and compared to odorless air from the Nasal Ranger. This was to determine whether a difference could be detected between ambient air and odorless air from the Nasal Ranger. No significant difference could be detected.

<u>Sampling downwind</u>
Odor was measured at first downwind odor monitoring point (Downwind #2, see Figure 1). Odor could be detected at the 7 D/T level, but this location is still on the property. A second monitoring point was chosen at the property line, as specified in the permit (Downwind #3), no odor could be detected at the 2 D/T level at this location. This indicates that the odor level was lower than 2 D/T. Then the Nasal Ranger was taken off the nose and ambient air was sniffed and compared to odorless air from the Nasal Ranger. This was to determine whether a difference could be detected between ambient air and odorless air from the Nasal Ranger. No difference could be noticed.

These results indicate that odor levels complied with Section I.6.b.ii of the Swine Animal Waste Management Permit.

Odor Sampling #2

Odor was monitored to comply with Section I.6.b.ii of the Swine Animal Waste Management Permit. A second ambient air sampling was conducted on December 19, 2018, and monitored by Marc Deshusses.

Sampling took place at about 9:00 am. It was a partly overcast cold day (29° F) with quasi no wind (barely measurable to 0.3 m/s). Several measurements for wind speed and direction were taken. Although wind was quasi nil, the predominant wind direction and sampling points for odor were selected as shown in Figure 5.

Odor panelist rules were listed in the previous report and are not repeated here. Odor was monitored using a Nasal Ranger (http://www.nasalranger.com/) field olfactometer, following the manufacturer recommended instructions.

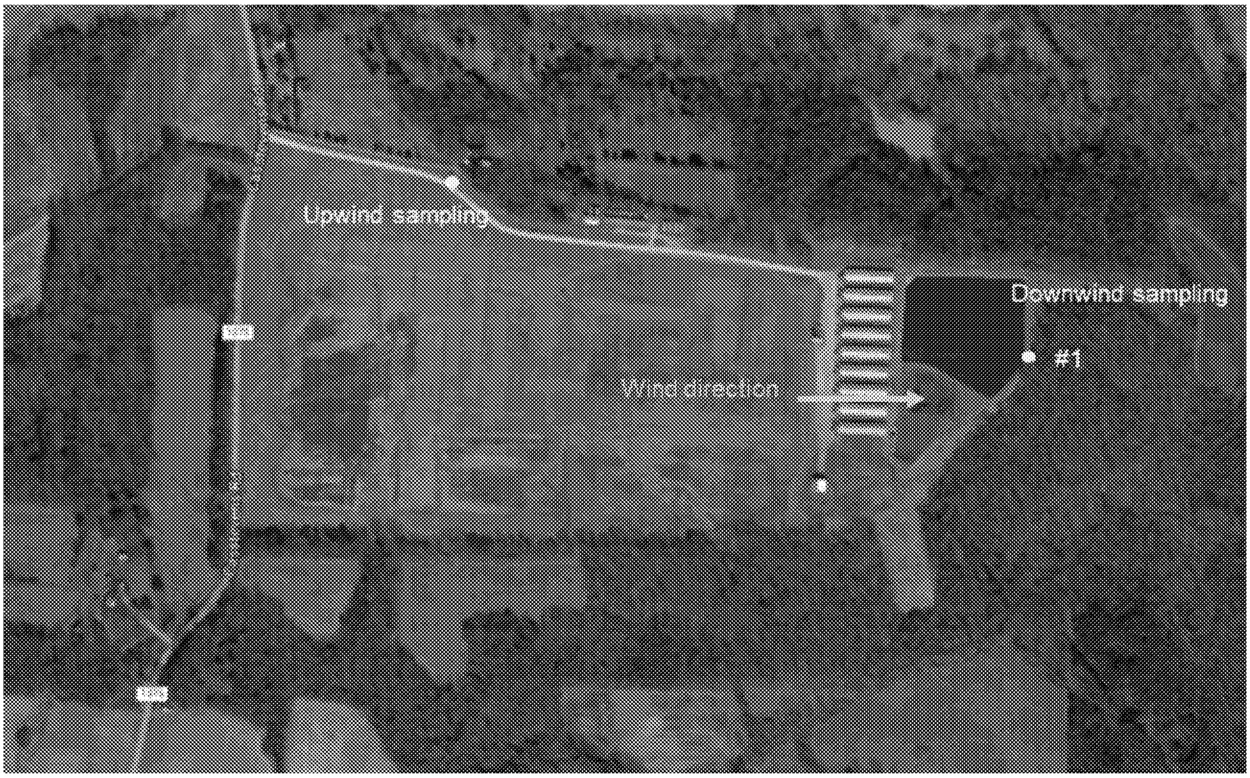

Figure 5. Aerial view of the facility and location of the monitoring points for odor for the June 26, 2018 sampling. The arrows indicate the prevailing wind direction the day of the sampling.

<u>Sampling upwind</u>
Odor could not be detected at the 2 D/T level. This indicates that the odor level was lower than 2 D/T. Then the Nasal Ranger was taken off the nose and ambient air was sniffed and compared to odorless air from the Nasal Ranger. This was to determine whether a difference could be detected between ambient air and odorless air from the Nasal Ranger. No significant difference could be detected.

Sampling downwind
No odor could be detected at the 2 D/T level at location #1. This indicates that the odor level was lower than 2 D/T. Then the Nasal Ranger was taken off the nose and ambient air was sniffed and compared to odorless air from the Nasal Ranger. This was to determine whether a difference could be detected between ambient air and odorless air from the Nasal Ranger. There was a faint piggery/barn odor with notes of ammonia, but as mentioned before these odors were below the 2 D/T level.

These results indicate that odor levels complied with Section I.6.b.ii of the Swine Animal Waste Management Permit. Ammonia nitrogen emissions from the aeration basin and lagoon were quantified to determine if significant volatilization of NH_3-N occurred from this part of the waste management system. Emissions from the water surfaces were determined using a buoyant convective flux chamber (BCFC) which method was described in detail and illustrated with pictures in the February 15, 2012 report.

Emissions from Animal Waste Treatment and Storage System – September 25, 2018

Ammonia nitrogen emissions from the aeration basin and lagoon were quantified to determine if significant volatilization of NH_3-N occurred from this part of the waste management system. Emissions from the water surfaces were determined using a buoyant convective flux chamber (BCFC) which method was described in detail and illustrated with pictures in the February 15, 2012 report. Sampling took place at about 12 pm. It was an overcast day (70° F) with relatively steady wind (1.3-1.8 m/s).

Results were as follows:

- Size of the chamber: 52.1 cm wide by 52.1 cm long and 2.5 cm in headspace height.
- Air sampling flow rate: 0.30 L/min
- **Average ammonia concentrations** in sweep air from the aeration basin while aeration was off: **114 ppm** (3 samples) or on average in mass concentration 0.064 g-N/m^3
- Ammonia concentrations in sweep air while aeration was on was not measured, earlier monitoring indicated that ammonia concentration in sweep air during aeration was slightly lower.

The total emission from the aeration basin can be calculated from the air sampling flow rate, the surface of the chamber and the surface area of the aeration basin. The latter surface is nominally 24,500 ft^2 (or 2277 m^2). Emission rate is calculated as follows:

NH_3 emission rate = NH_3 concentration × Sampling flow rate × Aeration basin area / Buoyant chamber area

After unit conversion, one obtains values of 9.7 g/h. This corresponds to a NH_3 emission rate of **1.63 kg NH_3-N/week.** This is a very low value compared to the **allowable emissions of 106 kg NH_3-N/week** from the swine waste treatment and storage structures as specified in Section I.6.a.i of the Swine Animal Waste Management Permit.

Surface emission rate of NH_3 from the **lagoon** was determined following the same method. Average concentration of ammonia in the sweep air (with the same chamber and at the same flowrate of 0.3 L/min) was 120 ppm (2 samples). With the surface area of the lagoon (19,425 m^2), emission of NH_3 from the lagoon are estimated to be **14.7 kg NH_3-N/week**.

Results for the emissions from the aeration basin and the lagoon are summarized in the table below. Total ammonia (TAN) in the aeration basin and lagoon at the time of sampling is also reported for information. These numbers show the system is performing as expected.

	Aeration basin	Lagoon
Surface area	2277 m^2	4.8 acres = 19,425 m^2
TAN	955 mg-N/L	215 mg-N/L
Emission rate	1.63 kg NH_3-N/week	14.7 kg NH_3-N/week
Total emission (lagoon + aeration basin)	**16.4 kg NH_3-N/week**	

Thus, together lagoon and aeration basin contribute to the emission of **16.4 kg NH_3-N/week**. This is well below the allowable 106 kg NH_3-N/week.

Emissions from the Barns

Ammonia emissions from the barns were also determined on September 25, 2018. It should be noted that accurate determination of emissions from animal houses is a difficult exercise. This is because of the variable nature of the emission, the difficulty in accurately measuring air flow from the fans on the animal houses, and the fact that fan operation is automated, i.e., they are turned on and off automatically triggered by a thermostat. Thus, uncertainties on the numbers reported below exist and can be important.

Ammonia in the exhaust air from the barns was determined using Draeger tubes. Details on the concentrations and number of fans on at the time of sampling are shown in the table below.

Barn	NH_3 Concentration (ppm)	Small Fans working	Large Fans working
1	4	1	1
2	1	0	2
3	1.5	1	1
4	0.9	1	0
5	2.7	0	2
6	1.5	1	2
7	5	1	1
8	4	1	2
9	3.5	1	1

The total emission of ammonia can be estimated by multiplying the ammonia concentration in each of the barn's exhausts by the exhaust flowrate of that barn (33,000 cfm for large fans and 13,000 cfm for the small fans). At the time of sampling, total exhaust flow was 487,000 cfm and concentrations ranged from 0.9 to 5 ppm (see Table above). The calculated total weekly ammonia emissions from the barns was **216 kg NH_3-N/week.**

Adding the emission from the treatment system and the lagoon (**16.4 kg NH_3-N/week**) to the emissions from the barns (371 kg NH_3-N/week) amounts to a **total of 232.1 kg NH_3-N/week** from the swine farm**.** This is below the allowable value of 476 kg NH_3-N/week specified in Section I.6.a.iii of the Swine Animal Waste Management Permit.

Emissions from Animal Waste Treatment and Storage System – December 19, 2018

Ammonia nitrogen emissions from the aeration basin and lagoon were quantified to determine if significant volatilization of NH_3-N occurred from this part of the waste management system. Emissions from the water surfaces were determined using a buoyant convective flux chamber (BCFC) which method was described in detail and illustrated with pictures in the February 15, 2012 report. Sampling took place on December 19, 2018 between 9:30 am and 11:00 am. It was a partly overcast cold day (29° F) with quasi no wind (barely measurable to 0.3 m/s). Temperature was 29° F.

Results were as follows:

- Size of the chamber: 52.1 cm wide by 52.1 cm long and 2.5 cm in headspace height.
- Air sampling flow rate: 0.30 L/min
- **Average ammonia concentrations** in sweep air from the aeration basin while aeration was off: **90 ppm** (3 samples) or on average in mass concentration 0.051 g-N/m^3
- Ammonia concentrations in sweep air while aeration was on was not measured, earlier monitoring indicated that ammonia concentration in sweep air during aeration was slightly lower.

The total emission from the aeration basin can be calculated from the air sampling flow rate, the surface of the chamber and the surface area of the aeration basin. The latter surface is nominally 24,500 ft^2 (or 2277 m^2). Emission rate is calculated as follows:

NH_3 emission rate = NH_3 concentration × Sampling flow rate × Aeration basin area / Buoyant chamber area

After unit conversion, one obtains values of 7.7 g/h. This corresponds to a NH_3 emission rate of **1.29 kg NH_3-N/week.** This is a very low value compared to the **allowable emissions of 106 kg NH_3-N/week** from the swine waste treatment and storage structures as specified in Section I.6.a.i of the Swine Animal Waste Management Permit.

Surface emission rate of NH_3 from the **lagoon** was determined following the same method. Average concentration of ammonia in the sweep air (with the same chamber and at the same flowrate of 0.3 L/min) was 65 ppm (2 samples). With the surface area of the lagoon (19,425 m^2), emission of NH_3 from the lagoon are estimated to be **7.97 kg NH_3-N/week**.

Results for the emissions from the aeration basin and the lagoon are summarized in the table below. Total ammonia (TAN) in the aeration basin and lagoon at the time of sampling is also reported for information. These numbers show the system is performing as expected.

	Aeration basin	**Lagoon**
Surface area	2277 m^2	4.8 acres = 19,425 m^2
TAN	1048 mg-N/L	277 mg-N/L
Emission rate	1.29 kg NH_3-N/week	7.97 kg NH_3-N/week
Total emission (lagoon + aeration basin)	**9.27 kg NH_3-N/week**	

Thus, together lagoon and aeration basin contribute to the emission of **9.27 kg NH_3-N/week**. This is well below the allowable 106 kg NH_3-N/week.

Emissions from the Barns

Ammonia emissions from the barns were also determined on December 19, 2018. It should be noted that accurate determination of emissions from animal houses is a difficult exercise. This is because of the variable nature of the emission, the difficulty in accurately measuring air flow from the fans on the animal houses, and the fact that fan operation is automated, i.e., they are turned on and off automatically triggered by a thermostat. Thus, uncertainties on the numbers reported below exist and can be important.

Ammonia in the exhaust air from the barns was determined using Draeger tubes. Details on the concentrations and number of fans on at the time of sampling are shown in the table below. It should be noted that at least one barn was empty, and that since it was a relatively cold day, several barns only had one fan operating, some fans where toggling on and off. Still a value of 1 fan on was used for these barns and thus emissions reported may be overestimated.

Barn	NH_3 Concentration (ppm)	Small Fans working	Large Fans working
1	5	1	0
2	18	1	0
3	not determined	0	0
4	8	1	0
5	8	1	0
6	12	1	0
7	11	1	0
8	9	1	0
9	15	1	0

The total emission of ammonia can be estimated by multiplying the ammonia concentration in each of the barn's exhausts by the exhaust flowrate of that barn (33,000 cfm for large fans and 13,000 cfm for the small fans). At the time of sampling, total exhaust flow was 104,000 cfm and concentrations ranged from 5 to 18 ppm (see Table above). The calculated total weekly ammonia emissions from the barns was **181 kg NH_3-N/week.**

Adding the emission from the treatment system and the lagoon (**9.27 kg NH_3-N/week**) to the emissions from the barns (371 kg NH_3-N/week) amounts to a **total of 190.0 kg NH_3-N/week** from the swine farm**.** This is below the allowable value of 476 kg NH_3-N/week specified in Section I.6.a.iii of the Swine Animal Waste Management Permit.

Additional Observations

The previous DWR Inspection mentioned that interior portion and aeration basin was eroding, and that vegetation should be established to control briars and other broadleaf weeds on embankments. The monitoring staff has been working with the Loyd Ray Farm staff to correct this situation, and has been actively seeding this area, with plans to re-seed again in Spring of 2019. Any undergrowth, including sprouting small trees or broadleaf weeds on the embankments are designated to be cut as soon as the ground can hold the equipment. The application fields appear to be well vegetated.

Agronomist's Comments:

This report provides Test Results and Recommendations for each sample submitted for testing. Look for Lime Recommendations and N-P-K Fertilizer Recommendations. The lime recommendation is always listed next to the first crop and will be based on the higher target pH if the pH targets for crop 1 and crop 2 differ. Application at the indicated rate will raise soil pH to the optimal level for the plant you specified and should be sufficient for 2 to 3 years, depending on soil type. Common target pH values are as follows: 5.0 for azalea, camellia, rhododendron and mt. laurel; 5.5 for centipedegrass; 6.0 for other lawn grasses, shrubbery, and; flowering plants; and 6.5 for vegetable gardens. N-P-K Recommendations are based on the nitrogen (N) needs of the plants being grown and the soil test results for phosphorus (P-I) and potassium (K-I); a 50 to 70 index for either is optimum. If the exact fertilizer cannot be found, find the closest match and adjust the rate accordingly. Refer to "Understanding the Soil Report" (last page of this report) for additional explanation and links to helpful information.

Understanding the Soil Report

Lime

Application of lime at the recommended rate will raise soil pH to the optimum range. Do not apply too much lime. When soil pH becomes too high, lowering it is very difficult. Often, the best solution then is to choose plants that can tolerate a high pH.

Choosing dolomitic lime can be advantageous because it contains the nutrients calcium and magnesium. Pelleted lime is easier to spread uniformly than powdered lime.

Lime can be applied at any time of year, but because it reacts slowly, it is best to apply it several months before a new planting. Mixing it into the soil will speed the reaction time. Lime applied to the soil surface takes much longer to correct soil pH.

A surface application should not exceed 60 lb per 1,000 sq ft. If a soil report recommends more than this, apply 60 lb per 1,000 sq ft initially and the rest in similar increments every 6-9 months until the full rate is applied.

Fertilizer

Soil tests do not measure nitrogen (N) since it is very unstable in soils; the N recommendations provided on the soil report are based on plant needs. If soil-test P-I and K-I values are adequate (>50), only nitrogen is recommended- Group D below. A mixed (N-P-K) fertilizer is recommended if P-I and
K-I values are less than optimum- Groups A - C below. Although a specific fertilizer grade may be recommended (e.g., 5-10-10), other equivalent options are likely to be available (e.g., any fertilizer in Group A from Table 1).

Tips on Fertilizer Application

- To determine how much fertilizer to buy, estimate (in feet) the length (L) and width (W) of the area to be treated: L × W = sq ft. Square off curves to make estimates easier. If the recommendation is 20 lb per 1,000 sq ft and your area is 5,000 sq ft, then you need 100 lb (20 × 5) for your 5,000-sq-ft area.
- Calibrate your spreader according to manufacturer settings. Apply half the total rate in one direction; apply the rest at a 90° angle. This cross-hair pattern provides a more uniform application.
- After application, sweep up any fertilizer on hard surfaces and apply to fertilized areas so rainfall does not carry fertilizer to a storm drain.

Table 1. Groups of equivalent fertilizers that supply 1 lb of N per 1,000 sq ft.*

Group A: low P-I + low K-I		Group B: low P-I + high K-I		Group C: high P-I + low K-I		Group D: N only	
5-10-10	@ 20 lb	5-10-5	@ 20 lb	8-0-24	@ 12 lb	15-0-0	@ 7 lb
3-9-9	@ 30 lb	18-46-0	@ 6 lb	15-0-14	@ 7 lb	21-0-0	@ 5 lb
10-10-10	@ 10 lb	18-24-10	@ 6 lb	6-6-18	@ 18 lb	16-0-0	@ 6 lb
11-15-11	@ 10 lb	9-13-7	@ 11 lb	5-5-15	@ 20 lb	28-0-4	@ 4 lb
8-10-8	@ 12 lb	9-17-8	@ 11 lb	10-0-14	@ 10 lb	12-6-6	@ 8 lb

* Since these rates supply 1 lb N per 1,000 sq ft, use half the rate if centipede is the grass type.

Report Abbreviations

CEC	cation exchange capacity
Cu-I	copper index
HM%	percent humic matter
Mn-I	manganese index
pH	soil pH
S-I	sulfur index
SS-I	soluble salt index
W/V	weight per volume
Zn-I	zinc index

Time Fertilizer Application to Coincide with Plant Growth Cycle:

Bermudagrass: May, July, Sept
Centipedegrass: May
St. Augustine grass: May, August
Tall fescue: Sept, Nov, Feb
Zoysia: May, July
Flowers/shrubs: prior to planting or during the growing season
Vegetables: prior to planting

Agronomist's Comments:

This report provides Test Results and Recommendations for each sample submitted for testing. Look for Lime Recommendations and N-P-K Fertilizer Recommendations. The lime recommendation is always listed next to the first crop and will be based on the higher target pH if the pH targets for crop 1 and crop 2 differ. Application at the indicated rate will raise soil pH to the optimal level for the plant you specified and should be sufficient for 2 to 3 years, depending on soil type. Common target pH values are as follows: 5.0 for azalea, camellia, rhododendron and mt. laurel; 5.5 for centipedegrass; 6.0 for other lawn grasses, shrubbery, and; flowering plants; and 6.5 for vegetable gardens. N-P-K Recommendations are based on the nitrogen (N) needs of the plants being grown and the soil test results for phosphorus (P-I) and potassium (K-I); a 50 to 70 index for either is optimum. If the exact fertilizer cannot be found, find the closest match and adjust the rate accordingly. Refer to "Understanding the Soil Report" (last page of this report) for additional explanation and links to helpful information.

Understanding the Soil Report

Lime

Application of lime at the recommended rate will raise soil pH to the optimum range. Do not apply too much lime. When soil pH becomes too high, lowering it is very difficult. Often, the best solution then is to choose plants that can tolerate a high pH.

Choosing dolomitic lime can be advantageous because it contains the nutrients calcium and magnesium. Pelleted lime is easier to spread uniformly than powdered lime.

Lime can be applied at any time of year, but because it reacts slowly, it is best to apply it several months before a new planting. Mixing it into the soil will speed the reaction time. Lime applied to the soil surface takes much longer to correct soil pH.

A surface application should not exceed 60 lb per 1,000 sq ft. If a soil report recommends more than this, apply 60 lb per 1,000 sq ft initially and the rest in similar increments every 6-9 months until the full rate is applied.

Fertilizer

Soil tests do not measure nitrogen (N) since it is very unstable in soils; the N recommendations provided on the soil report are based on plant needs. If soil-test P-I and K-I values are adequate (>50), only nitrogen is recommended- Group D below. A mixed (N-P-K) fertilizer is recommended if P-I and
K-I values are less than optimum- Groups A - C below. Although a specific fertilizer grade may be recommended (e.g., 5-10-10), other equivalent options are likely to be available (e.g., any fertilizer in Group A from Table 1).

Tips on Fertilizer Application

- To determine how much fertilizer to buy, estimate (in feet) the length (L) and width (W) of the area to be treated: L × W = sq ft. Square off curves to make estimates easier. If the recommendation is 20 lb per 1,000 sq ft and your area is 5,000 sq ft, then you need 100 lb (20 × 5) for your 5,000-sq-ft area.
- Calibrate your spreader according to manufacturer settings. Apply half the total rate in one direction; apply the rest at a 90° angle. This cross-hair pattern provides a more uniform application.
- After application, sweep up any fertilizer on hard surfaces and apply to fertilized areas so rainfall does not carry fertilizer to a storm drain.

Table 1. Groups of equivalent fertilizers that supply 1 lb of N per 1,000 sq ft*

Group A: low P-I + low K-I		Group B: low P-I + high K-I		Group C: high P-I + low K-I		Group D: N only	
5-10-10	@ 20 lb	5-10-5	@ 20 lb	6-0-24	@ 12 lb	15-0-0	@ 7 lb
3-9-9	@ 30 lb	18-46-0	@ 6 lb	15-0-14	@ 7 lb	21-0-0	@ 5 lb
10-10-10	@ 10 lb	18-24-10	@ 6 lb	6-6-18	@ 16 lb	16-0-0	@ 6 lb
11-15-11	@ 10 lb	9-13-7	@ 11 lb	5-5-15	@ 20 lb	28-0-4	@ 4 lb
8-10-8	@ 12 lb	9-17-8	@ 11 lb	10-0-14	@ 10 lb	12-6-6	@ 8 lb

* Since these rates supply 1 lb N per 1,000 sq ft, use half the rate if centipede is the grass type.

Report Abbreviations

CEC	cation exchange capacity

Environmental Justice v NC Dept of Env. Quality

information together?
A. Yes.
Q. So let's start by, can you briefly explain what a nitrification/denitrification system is here?
A. In Missouri, Class 1A farms, which are the larger farms, much larger than the farms we are discussing here, as part of an agreement agreed to put in nitrification/denitrification systems in Northern Missouri which took the effluent from primary lagoons to convert ammonia to dinitrogen gas, with the goal of reducing nitrogen minimum by 50 percent.
Q. Okay.
A. So on these very large farms would have a central nitrification/denitrification system on the farms listed here.
Q. And that process is all of their waste?
A. Yes. The majority of their waste is processed through that. I think it is very important to understand that in Northern Missouri this only occurs -- it only operates during the summer months because it is too cold in the winter for it to operate properly.
So it only processes -- or processes the

effluent from say -- and I may not be exactly right on this but somewhere between April and, say, October.

Q. You mentioned that the farms involved in that are larger than the four farms that we're talking about here in North Carolina; is that right?

A. Yes. For the most part, yes.

Q. Does that make a difference? Why is that significant?

A. I don't know that it is significant or not. I just thought I'd point it out, Class 1A farms.

Q. Thanks. Making sure I wasn't missing something.

Does it work? In other words, the goal of 60 percent reduction of nitrogen levels?

A. Yes. In Missouri, it does reduce nitrogen levels by 50 percent or more. We can debate whether that is good or not, but it does what it is intended to do.

Q. What does Smithfield do with the removed nitrogen compounds, or I guess -- that's a bad question because it is going off of dinitrogen gas?

A. Yes, sir.
Q. Forget I said that.
A. I didn't hear it.
Q. Another question about the way these facilities are set up, are these facilities also pretty significant in collecting biogas?
A. They are today, yes. The first one to produce biogas was the Ruckman Farm in about 2014 or '15, I believe.
Since then, all of these listed with the exception of Terre Haute and Badger/Wolf have biogas collection and conversion of renewal natural gas.
Q. Okay. And I assume the biogas collection is happening prior to the nitrification/denitrification process?
A. That is correct.
Q. So the biogas collection and the nitrification/denitrification systems are compatible with each other; is that right?
A. They are compatible.
Q. At those facilities in Missouri, do they also employ any kind of solid liquid separation technology?
A. Yes. The digesters themselves are akin

to solid/liquid separation; nothing beyond that.
Q. Are there other forms of treatment technology being used at those facilities separate and apart from digesters and the nitrification/denitrification? Are there other add-on processes going on there?
A. Treatment technologies, no.
Q. Let's see, are those -- let me back up.
Have you been involved with the biogas project at those Missouri facilities that have installed that, you personally?
A. Yes, very involved.
Q. So are they successful? Are they -- from a business standpoint are they successful?
A. Yes. They're doing what we expected them to do, yes.
Q. Are they profitable?
MR. JOHNSON: I'll object to the relevance of this. You can go ahead and answer.
THE WITNESS: We're hoping this year they're profitable. They have not been profitable to date.
BY MR. TORREY:
Q. Does Murphy-Brown have any reason to be dispute doing nitrification/denitrification

process at the four North Carolina operations that we're talking about would reduce nitrogen levels in wastes at those North Carolina operations?

A. So your question is would nitrification/denitrification reduce nitrogen levels if that was installed in North Carolina in the effluent, that's your question?

Q. Yes, in the effluent from biogas digesters.

A. Yes, it would. That technology would reduce nitrogen in the effluent.

Q. Would Murphy-Brown have any reason to think it would perform differently in terms of the amount of reduction that you see in Missouri in a North Carolina setting at these facilities?

A. Yes. Because in Missouri, as stated before, there is only -- the biology that supports both biogas production and denitrification and nitrification only occurs part of the year, at most eight months -- seven to eight months out of the year. The rest is too cold for biological processes.

In Eastern North Carolina, that biological activity occurs year-round so you see much lower levels of nitrogen as a starting point then to apply to crops which is part of the neutral management plan.

You are not only spending money to do that, you are spending electricity, energy, greenhouse gases, et cetera, to destroy nitrogen that has value.

Q. Let me go back to my question because I'll try to ask it a better way.

The nitrogen that's reduced through the nitrification/denitrification process, does that include ammonia?

A. Yes. Ammonia would be one component.

Q. So would nitrification/denitrification apply to digester waste in North Carolina at these facilities, if you were to do that, reduce the ammonia levels in the waste, in the digester waste at those facilities in North Carolina?

A. Yes. Nitrification/denitrification could reduce ammonia levels, yes -- nitrogen levels including ammonia.

Q. Would changing the amount of cover crop that's grown reduce the need for nitrogen through land applications?

A. What's grown is as much a function to the entirety of the farming enterprise, and what's

Abstract

A full-scale treatment system for swine manure was developed to eliminate discharge to surface and ground waters and contamination of soil and groundwater by nutrients and heavy metals, along with related release of ammonia, odor, and pathogens. The system greatly increased the efficiency of liquid–solid separation by polymer injection to increase solids flocculation. Nitrogen management to reduce ammonia emissions was accomplished by passing the liquid through a module where bacteria transformed ammonia into harmless nitrogen gas. Subsequent alkaline treatment of the wastewater in a phosphorus module precipitated phosphorus and killed pathogens. Treated wastewater was recycled to clean swine houses and for crop irrigation. The system was tested during one year in a 4400-head finishing farm as part of the Agreement between the Attorney General of North Carolina and swine producers Smithfield Foods, Premium Standard Farms and Frontline Farmers to replace traditional waste treatment anaerobic lagoons with environmentally superior technology. The on-farm system removed 97.6% of the suspended solids, 99.7% of BOD, 98.5% of TKN, 98.7% of soluble ammonia (NH_4^+–N), 95.0% of total P, 98.7% of copper and 99.0% of zinc. It also removed 97.9% of odor compounds in the liquid and reduced pathogen indicators to non-detectable levels. Based on performance obtained, it was determined that the treatment system met the Agreement's technical performance standards that define an environmentally superior technology. These findings overall showed that cleaner alternative technologies are technically and operationally feasible and that they can have significant positive impacts on the environment and the livestock industry.

Keywords: Manure treatment; Pathogen inactivation; Nitrification–denitrification; Phosphorus and ammonia removal; Confined swine production; Piggery

1. Introduction

Minimizing livestock manure's impact on the environment is one of USA agriculture's major challenges. When properly managed, manure can be used to provide nutrients to crops and to improve soil properties through accretion of soil organic matter. However, improperly managed manure can pose a threat to soil, water, and air quality in addition to human and animal health. Anaerobic lagoons are widely used to treat and store liquid manure from confined swine production facilities (Barker, 1996). Environmental and health concerns with the lagoon technology include emissions of ammonia (Aneja et al., 2000; Szogi et al., 2005), odors (Loughrin et al., 2006; Schiffman et al., 2001), pathogens (Sobsey et al., 2001; Vanotti et al., 2005a), and water quality deterioration (Mallin, 2000). Thus, there is a major interest in developing alternative swine manure treatment systems that can also address these environmental and health problems.

doi:10.1016/j.biortech.2006.07.009

Widespread objection to the use of anaerobic lagoons for swine manure treatment in North Carolina prompted a state government-industry framework to give preference to alternative technologies that directly eliminate anaerobic lagoons as a method of treatment. The full-scale treatment demonstration described in this paper was conducted within this framework. In July 2000, the Attorney General of North Carolina reached an Agreement with Smithfield Foods, Inc., and its subsidiaries, the largest hog producing companies in the world, to develop and demonstrate environmentally superior waste management technologies for implementation on farms located in North Carolina that are owned by these companies. In October 2000, the Attorney General reached a similar agreement with Premium Standard Farms, the second largest pork producer in the USA. The agreement defines an environmentally superior technology (EST) as any technology, or combination of technologies, that (1) is permittable by the appropriate governmental authority; (2) is determined to be technically, operationally, and economically feasible; and (3) meets the following five environmental performance standards (Williams, 2001):

1. Eliminate the discharge of animal waste to surface waters and groundwater through direct discharge, seepage, or runoff.
2. Substantially eliminate atmospheric emissions of ammonia.
3. Substantially eliminate the emission of odor that is detectable beyond the boundaries of the swine farm.
4. Substantially eliminate the release of disease-transmitting vectors and airborne pathogens.
5. Substantially eliminate nutrient and heavy metal contamination of soil and groundwater.

Selection of EST candidates to undergo performance verification involved a request of proposals and competitive review by the Agreement's Designee and a Panel representing government, environmental and community interests, the companies, and individuals with expertise in animal waste management, environmental science and public health, and economics and business management. This process yielded 18 technologies candidates among about 100 submitted projects. Subsequently, the selected technologies completed design, permitting, construction, startup, and performance verification under steady-state operational conditions. In July 2005, five of the 18 technologies tested were shown to be capable of meeting the environmental performance criteria necessary for the technologies to be considered environmentally superior (Williams, 2004, 2005). Four of the five technologies selected treated separated manure solids using composting, high-solids anaerobic digestion, or gasification processes, and only one of the technologies selected treated the entire swine waste stream on-farm. This on-farm technology used liquid–solid separation, nitrification/denitrification, and soluble phosphorus removal processes linked together into a practical system. It was developed to replace anaerobic lagoon technology commonly used in the USA to treat swine waste (Vanotti et al., 2005b).

In this new manure treatment system, solids and liquid are first separated with polyacrylamide (PAM) polymer and filtration process, followed by treatment of the liquid stream using biological nitrogen (N) removal process, and then by phosphorus (P) extraction using a lime precipitation process. Flocculation treatment using PAM increases separation of suspended solids and carbon compounds from liquid swine manure (Vanotti and Hunt, 1999). Along with the solids, there is a significant separation of organic nutrient elements contained in small suspended particles typical of these wastes. For example, Vanotti et al. (2002) analyzed the fractions in liquid swine manure that are potentially removable by phase separation and found that 80% of the total suspended solids (TSS), 78% of the N and 93% of the P were contained in particles less than 0.3 mm in size. Soluble ammonia (NH_4^+–N) and soluble P (PO_4), which usually constitute 35–65% of total N and 15–30% of total P, are mostly unaffected by polymer separation. Biological removal of N by combined nitrification and denitrification processes (NDN) is regarded as the most efficient and economically feasible method available for removal of N from wastewaters (Focht and Chang, 1975; Tchobanoglous and Burton, 1991; Furukawa et al., 1993). Once NH_4^+–N and carbonate alkalinity concentrations are substantially reduced with nitrification treatment, the subsequent addition of hydrated lime [$Ca(OH)_2$] rapidly increases the pH of the liquid above 9, thereby promoting formation of calcium phosphate precipitate with small amounts of chemical added (Vanotti et al., 2003b).

The treatment system was first pilot tested for two years at the North Carolina State University's Lake Wheeler Road Swine Unit (Vanotti et al., 2003a). A full-scale version of the system was subsequently constructed in a swine farm in North Carolina for demonstration and performance verification of environmentally superior technology. In this paper, we report the water quality improvements by the treatment system operating at full scale. In addition, we report on characteristics of the separated solid fractions, energy balance of the system, and operational considerations. Performance verification was done during a one year period and included cold and warm weather conditions.

2. Methods

2.1. Site description

The full-scale demonstration facility was installed on Goshen Ridge farm (Unit 1) near Mount Olive, Duplin Co., North Carolina, and evaluated intensively during one year under steady-state conditions. The production unit contained six swine barns with 4360-head finishing pigs total, and a traditional anaerobic lagoon (0.9 ha) for treatment and storage of manure. Manure was collected

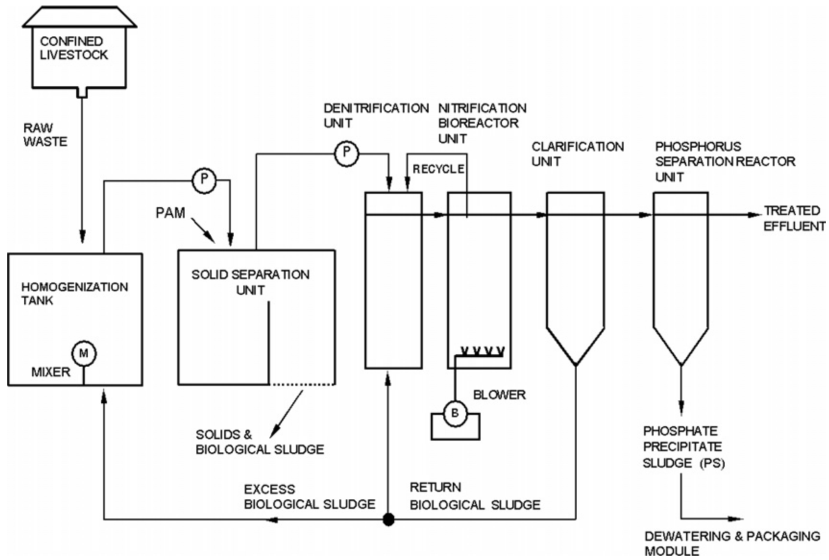

Fig. 1. Schematic drawing of the swine waste treatment system without lagoon.

under the barns using slatted floors and a pit-recharge system typical of many farms in North Carolina (Barker, 1996). The production unit with its traditional lagoon system was operational for about four years before the new waste treatment plant started operation. During traditional management, every week the liquid manure contained in the pits was completely drained by gravity into the anaerobic lagoon. After treatment in the lagoon (retention time = 180 days), the liquid was sprayed onto nearby fields growing small grains and forages. Lagoon liquid was also recycled (in a closed loop) to recharge the pits under the barns and facilitate flushing of the newly accumulated manure.

Once the treatment plant was operational, flow of raw manure into the lagoon was discontinued. Barn pits were flushed once a week as it was done before, but liquid manure was diverted into a 388-m^3 homogenization tank. Transfer rate was rather quick using a high capacity pump (1.9 m^3/min). Typically, half of the six barns were emptied on Monday and the other half on Thursday. The manure collected in the homogenization tank was kept well mixed using a submergible mixer (3.5 kW, 12.1 m^3/min flow, ABS Pumps Inc., Meriden, CT[1]). From there, the liquid manure received continuous treatment. The treatment system consisted of three process units in series: polymer-enhanced solid–liquid separation, biological N removal, and alkaline phosphorus extraction (Fig. 1).

2.2. On-farm treatment system

The treatment system used was a system without lagoon (Vanotti et al., 2005b, Fig. 1) comprised of (a) a solid separation unit, wherein flocculants are used to clump suspended solids and increase separation efficiency, (b) a denitrification unit in direct fluid communication with a clarified effluent from the solid separation unit, (c) a nitrification unit in fluid communication with the denitrification unit, (d) a phosphorus separation reactor unit in fluid communication with the liquid effluent from the nitrification unit, and (e) a clarification unit between the nitrification unit and phosphorus unit. Homogenization and storage tanks were added to the system to integrate discontinuous operations, such as flushing and barn pit recharge, with continuous operation of the treatment system (Fig. 2).

The on-farm system was constructed and operated by a private firm, Super Soil Systems USA of Clinton, North Carolina. It was implemented using three process units or modules (Fig. 3). The first process unit in the system – the Ecopurin solid–liquid separation module, developed by the Spain-based firm Selco MC of Castellon – quickly separated solids and liquid using polymer flocculation and dewatering equipment. The solid–liquid separation module was housed in a building of its own. It was automated through the use of a programmable logic controller (PLC) for a 24-h/day operation (Square D, Schneider Electric, North Andover, MA). Treatment parameters such as polymer rate, wastewater flow, and mixing intensity were set by the operator using a tactile screen in a control panel. Well mixed raw manure was continuously pumped from the homogenization tank to the separation module. Flow rate was uniform at 2 m^3/h during the year-long demonstration. The liquid manure was first reacted in a mixing chamber with a polymer solution (cationic polyacrylamide) that flocculated the suspended solids, and then it was passed through a rotating screen (0.2 mm opening size) that separated the flocs. Subsequently, a dissolved air flotation unit (DAF) polished the liquid effluent while a small belt filter press (Monobelt, Teknofanghi S.R.L., Italy) further dewatered the screened solids. The solid–liquid

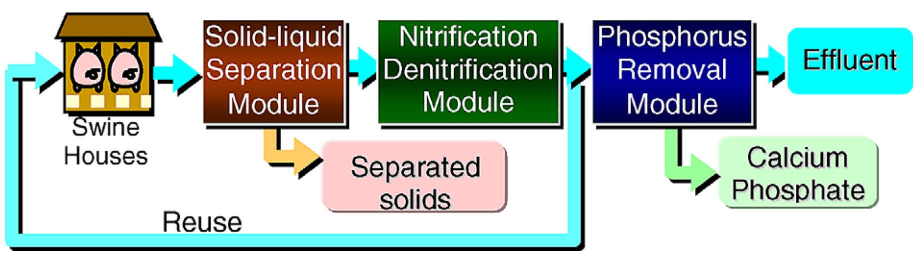

Fig. 3. Diagram of the swine manure treatment system with individual modules implemented at Goshen Ridge farm, North Carolina.

separation module produced a solids stream and a liquid stream. The solids were removed daily from the farm and transported in trailers to a centralized solids processing plant where they received aerobic composting. The liquid was lifted into the nitrogen removal module.

The second process unit in the system used a Biogreen nitrogen removal module (Hitachi Plant Engineering & Construction Co., Tokyo, Japan) that used nitrification/denitrification (NDN) to biologically convert NH_4^+–N into N_2 gas. The Biogreen process has a pre-denitrification configuration where nitrified wastewater is continuously recycled to an anoxic denitrification tank (Fig. 1). In this tank, suspended denitrifying bacteria uses soluble manure carbon contained in the liquid after separation to remove the nitrate and nitrite. The nitrification tank uses nitrifying bacteria immobilized in polymer gel pellets to increase the concentration and effectiveness of bacterial biomass (Vanotti and Hunt, 2000). Nitrifying 3-mm bio-cube pellets are kept inside the nitrification tank by means of a wedge-wire screen structure (1.5 mm opening). The full-scale Biogreen unit contained a 263-m^3 anoxic denitrification tank to remove soluble manure carbon and nitrate-N (NO_3–N), a 110-m^3 nitrification tank for conversion of NH_4^+ to NO_3^-, and a 33-m^3 tank for settling and recycling of suspended biomass solids to the denitrification tank or wasting excess biomass to the separation module (Fig. 1). The height of the liquid in these tanks was 4 m. The denitrification tank contained a submergible mixer (1.7 kW, 9.8 m^3/min flow, ABS Pumps Inc., Meriden, CT) and a concentration of 3–6 g/l mixed liquor suspended solids (MLSS). The nitrification tank contained 125 fine-bubble air diffusers (22.9-cm diameter) and 12 m^3 of polyethylene glycol (PEG) immobilized pellets. Air was provided with a 11.2 kW, rotary lobe blower (Kaeser Omega DB 165, Kaeser Compressors, Fredericksburg, VA). Nitrification activity of the pellets after 5 weeks of initial acclimation was 850 g N/100 l pellets/day. Corresponding nitrification activity of the 110-m^3 reactor tank (containing 12-m^3 of pellet media) was 102 kg N/day, or 0.93 kg N/m^3 reactor/day. Hydraulic retention time (HRT) of nitrification varied from 2.6 to 3.6 days (average = 2.8 day). Nitrified liquid and settled sludge were recirculated to the first denitrification tank at a rate average of 4.4 and 1.8 times the inflow rate, respectively.

After biological N treatment, the effluent was discharged into a 299-m^3 tank that stored water needed to recharge pits under the barns after barns were flushed. Excess water flowed by gravity from this storage tank into the phosphorus separation module developed by USDA-ARS (Vanotti et al., 2003b). This was the third and final process unit in the system. It was designed to recover soluble P (as calcium phosphate) and destroy pathogens by alkaline pH. In this module, liquid was first mixed with hydrated lime slurry in a reaction chamber. The lime slurry was a 30% $Ca(OH)_2$ suspension supplied in standard tote containers and ready to use (Chemical Lime Company, Charlotte, NC). A pH probe and controller linked to the lime injection pump kept the process pH at 10.5–11.0. The liquid and precipitate were subsequently separated in a 9-m^3 settling tank. The precipitated calcium phosphate was removed from the bottom of the tank with a pump and it was further dewatered using a 12-filter bag Draimad unit that also bagged the sludge (Teknobag-Draimad, Aero-Mod, Inc., Manhattan, KS). Anionic polymer was added in-line to the P precipitate to enhance separation by filter bags (Szogi et al., 2006). Bags containing the wet calcium phosphate were left to dry on a drying concrete pad and removed from the farm on a monthly basis. Process automation was provided by sensors integrated to another PLC for 24-h/day operation. Treatment parameters such as process pH or frequency of sludge transfer were set by the operator using a tactile screen located in the plant control panel. Clarified effluent from the P module was stored in the existing lagoon before use in crop irrigation. Cylindrical tanks used in the system were standard structures made of glass-fused to steel (Slurrystore, Engineered Storage Products Company, Dekalb, IL), while settling tanks were custom-made of stainless steel.

2.3. Wastewater sampling and monitoring

Liquid samples were collected twice per week using four refrigerated automated samplers (Sigma 900max, American Sigma, Inc., Medina, NY) placed before and after each of the treatment modules in the system as follows: (1) the untreated liquid manure in the mixing tank before solids separation, (2) the effluent from the solid–liquid separation treatment (post-separation), (3) the effluent after the nitrification–denitrification treatment (post-N removal), and (4) the effluent after the phosphorus and pathogen elimination treatment (post-P removal). Each sample was the composite of four sub-samples taken over a 3.5-day period. Samples were transported on ice to the ARS Coastal Plains Research Center in Florence, SC, for water quality analyses, or overnight shipped with cold packs to the ARS Sustainable Agricultural Systems Laboratory and Environmental Microbial Safety Laboratory in Beltsville, MD, for microbiological analyses.

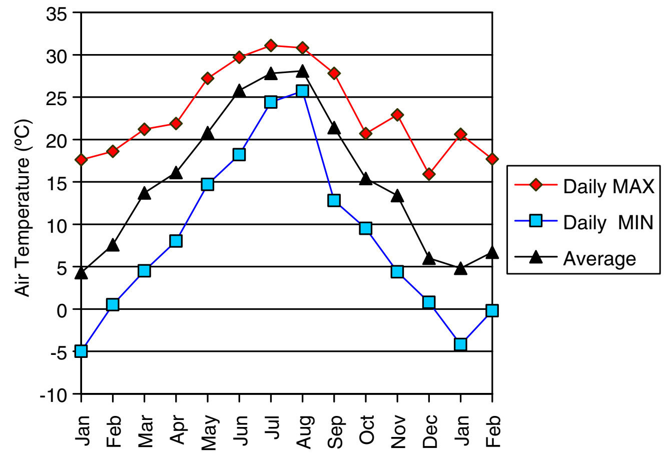

Fig. 4. Air temperature during January 2003–February 2004. Data are max and min of average daily temperatures and monthly average of average daily temperatures.

Wastewater flows throughout the system were measured with several calibrated flowmeters adapted to the characteristics of the liquid: raw manure transported from the barns into the homogenization tank was measured with a doppler flowmeter, liquid and sludge flows in the N and P modules were measured with magnetic flowmeters, and treated effluent was measured with a paddle-wheel flowmeter. Monitoring and process data were obtained every 5 min using a SCADA network (Monitor Pro v7, Schneider Automation, Inc., North Andover, MA) connected to the programmable logic controller (PLC) that provided plant automation. The data were temporarily stored in an industrial computer (IPC-6806, Advantech Co., Cincinnati, OH) at the farm and transmitted weekly to the Florence laboratory for analysis and summarization using SAS software (SAS, 2003).

To calculate electrical power use, we measured run-time (hours/day) of all electrical devices (35) installed in the plant that contributed to the power consumption by the system. This was done with the SCADA monitoring system that counted total hours of use during a 275-day period (April 2003–January 2004). Average run-time was multiplied by power use of each electrical device (kW) to calculate daily power requirements (kW h/day).

Performance evaluation included cold and warm weather conditions with average daily air temperatures ranging from −4.2 to 31.1 °C (Fig. 4).

2.4. Analytical methods

Wastewater analyses were performed according to Standard Methods for the Examination of Water and Wastewater (APHA, AWWA and WEF, 1998). Total solids (TS), total suspended solids (TSS), and volatile suspended solids (VSS) were determined with Standard Method 2540 B, D, and E, respectively. Total solids are the solids remaining after evaporation of a sample to constant weight at 105 °C and include TSS and dissolved solids (DS). Total suspended solids are the solids retained on a 1.5-μm glass microfiber filter (Whatman grade 934-AH, Whatman, Inc., Clifton, NJ) after filtration and drying to constant weight at 105 °C, while VSS is the fraction of the TSS lost on ignition in a muffle furnace at 500 °C for 15 min.

Chemical analyses consisted of pH, electrical conductivity (EC), chemical oxygen demand (COD), soluble COD, 5-d biochemical oxygen demand (BOD_5), soluble BOD_5, ammonia (NH_4^+–N), nitrate plus nitrite ($NO_3^- + NO_2^-$), total Kjeldahl N (TKN), orthophosphate-P (PO_4), total P (TP), copper (Cu), and zinc (Zn). For COD, we used the closed reflux, colorimetric method (Standard Method 5220 D). The orthophosphate (PO_4–P or soluble P) fraction was determined by the automated ascorbic acid method (Standard Method 4500-P F) after filtration through a 0.45-μm membrane filter (Gelman type Supor-450, Pall Corp., Ann Arbor, MI). The same filtrate was used to measure NH_4–N by the automated phenate method (Standard Method 4500-NH_3 G), and $NO_3^- + NO_2^-$ by the automated cadmium reduction method (Standard Method 4500-NO_3^- F). Total P and TKN were determined using acid digestion (Gallaher et al., 1976) and the automated ascorbic acid and phenate methods adapted to digested extracts (Technicon Instruments Corp., 1977). The organic P fraction is the difference between total P and PO_4 analyses and includes condensed and organically bound phosphates. The organic N fraction is the difference between Kjeldahl N and NH_4^+–N determinations. Alkalinity was determined by acid titration to the bromocresol green endpoint (pH = 4.5) and expressed as mg $CaCO_3$/l. Cu and Zn were measured in acid digestion extracts using inductively coupled plasma (ICP) analysis (Standard Method 3125A).

Solids samples were analyzed for moisture content using a microwave moisture analyzer. Dry solids samples were digested with concentrated acid, and the extracts were analyzed for TKN and TP with the automated methods described before. Carbon content was determined using a dry combustion analyzer.

Reduction in odor was characterized by measuring concentration of six odor compounds characteristic of swine manure (phenol, *p*-cresol, *p*-ethylphenol, *p*-propylphenol, indole, and skatole) directly in the liquid using gas chromatography and the method of Loughrin et al. (2006). Microbiological analyses of liquid samples were done using the standard protocols for pathogens and indicator microbes for the examination of wastewater (Vanotti et al., 2005a).

3. Results and discussion

3.1. Livestock and manure inventory

Pig inventory, live weight, and manure production data are summarized in Table 1. New batches of pigs were received January–February 2003, June–July 2003, November–December 2003, and March 2004. The pigs did not receive antibiotics, and the meat was marketed with a different label indicating this change. Total live animal weight (LAW) in the production unit averaged 237,000 kg but varied greatly within a growing cycle from a low of about 90,000 to 150,000 kg to a high of about 350,000 to 365,000 kg.

Manure production varied from 30.7 to 43.2 m^3 per day (Flushed manure, Table 1). Volume production was generally higher in warmer months. The system treated an average of 39 m^3 per day of raw manure flushed from the barns (Table 2). On the average, the flushed manure contained 33% recycled treated water (used to refill and flush the pits) and 67% manure and wasted water (urine, feces, water wasted by pigs). The manure and wasted water production (raw flushed manure – effluent recycled to barns, Table 2), which constitutes the newly generated manure, averaged 26.3 m^3 per day or 110 l/1000 kg LAW/day. This is consistent with expected table values of 101 l/1000 kg LAW/day (1.62 ft^3/1000 lb/day or 6.2 l/pig/day) for manure and wasted water production in feeder-to-finish operations in the USA (average pig weight = 135 lb or 61.2 kg) (Chastain et al., 1999). On the other hand, the total amount of flushed manure treated by the plant (manure/wasted water plus recycled water) was much lower than what is considered typical in feeder-to-finish operations in the USA. For example, the average 39 m^3 per day of raw manure flushed from the barns (Table 2) was equivalent to 165 l/1000 kg LAW/day. This is 2.6 times lower than the volume of 424 l/1000 kg LAW/day (6.80 ft^3/1000 lb/day or 25.9 l/pig/day) considered typical for pit-recharge systems in the USA (Chastain et al., 1999). This lower volume was obtained by a change in pit management incorporated with the new system that reduced the amount of recycle liquid into the barns to a minimum needed for effective

Table 1
Inventory of pigs and manure volume generation at Goshen Ridge farm (Unit 1) during demonstration of the new wastewater treatment system

Pigs and manure information	March	April	May	June	July	August	September	October	November	December	January
Number of pigs	3978	3975	3441	978	2787	4115	4015	3749	2831	4120	3814
Weight/pig (kg)	51.7	79.4	101.6	84.4	20.9	48.1	75.8	98.0	65.8	45.4	85.7
Total weight (Mg)	206	316	347	122	87	198	304	365	149	186	326
Flushed manure (m^3/day)[a]	30.7	32.6	36.3	36.0	43.2	45.0	55.3	48.1	33.3	36.0	34.1
Pit recharge (m^3/day)[b]	–	19.3	17.8	17.8	16.7	7.9	8.7	15.1	6.8	10.6	8.7

[a] Flushed manure is the average daily volume received in the homogenization tank.
[b] Pit recharge is the average daily volume treated liquid recycled from the clean water storage tank to the barns.

Table 2
Wastewater flows through the swine wastewater treatment system

Flow path	Total volume[a] (m^3)	Average flow rate (m^3/day)
Raw flushed manure to homogenization tank	12,050	39.0
Separated effluent to nitrogen module	12,070	39.1
N-treated effluent recycled to refill barns	3934	12.7
N-treated effluent to phosphorus module	8179	26.5
P-treated effluent to storage pond (former lagoon)	7975	25.8

[a] Monitoring values for period April 15, 2003, to March 1, 2004 (10.5 months).

cleanup of the barn pit. In turn, this change in management resulted in a lower volume (38%) of total flushed manure compared with management in traditional lagoon systems, which increased efficiency in terms of equipment (tanks, pumps, pipes, mixers), footprint, etc.

3.2. Water quality improvement by treatment system

System performance data were obtained during 10.5 months from April 15, 2003, to March 1, 2004, when all three modules were in-line. The on-farm system removed 97.6% of TSS, 98.9% of VSS, 97.4% of COD, 99.7% of BOD, 98.5% of TKN, 98.7% of NH_4^+–N, 95.0% of TP, 94.1% of soluble P, 98.7% of Cu, and 99.0% of Zn (Table 3).

Data in Table 3 and Fig. 5 show the unique contributions of each technology component to the efficiency of the total treatment system. Solid–liquid separation was effective separating suspended solids and organic nutrients. By capturing the suspended particles early in the process, most of the volatile and oxygen-demanding organic compounds were removed from the liquid stream. This early removal of suspended solids in the treatment train is a significant departure from wastewater treatment processes typically used in municipal systems because (1) it recovers the organic carbon and nutrient compounds contained in liquid manure, therefore enabling conservation and generation of organic value-added products, and (2) instead of breaking down organic compounds, the oxygen in subsequent biological aerobic treatment is used efficiently to convert NH_4^+–N. This is particularly important in animal treatment systems because as shown in Table 3, the effluent after solid–liquid separation contained significant amounts of N (953 mg/l), mostly soluble forms (NH_4^+). The NH_4^+–N was treated effectively in the biological N removal module. This module also consumed remaining carbon (BOD, COD) during denitrification, and alkalinity during nitrification. Soluble P contained in the liquid was not significantly changed by either liquid–solid separation or N treatment, but it was reduced significantly after treatment in the P-module (Table 3), and recovered as a solid calcium phosphate material.

Table 3
Removal of suspended solids, COD, BOD, nutrients, and heavy metals by on-farm wastewater treatment system at Goshen Ridge farm, North Carolina[a]

Water quality parameter	Raw liquid swine manure, mg/l (±s.d.)	After solid–liquid separation treatment, mg/l (±s.d.)	After biological N treatment, mg/l (±s.d.)	After phosphorus treatment, mg/l (±s.d.)	Removal efficiency with system (%)
TSS	11,051 (5914)	823 (637)	122 (68)	264 (154)	97.6
VSS	8035 (5016)	591 (456)	77 (54)	85 (50)	98.9
TS[b]	13,216 (5394)	4452 (1475)	3710 (694)	3339 (586)	74.7
COD	16,138 (8997)	3570 (2104)	617 (192)	445 (178)	97.4

Oxidized N[c]	1 (3)	1 (3)	224 (100)	224 (105)	–
Total N[d]	1584	954	258	247	89.4
Total P	576 (224)	174 (53)	147 (30)	29 (16)	95.0
Soluble P	135 (40)	121 (33)	134 (24)	8 (7)	94.1
Organic P	440 (197)	49 (41)	13 (19)	19 (16)	95.7
Copper	26.8 (12.2)	1.54 (1.82)	0.53 (0.28)	0.36 (0.26)	98.7
Zinc	26.3 (11.9)	1.47 (1.85)	0.40 (0.28)	0.25 (0.30)	99.0
Alkalinity	5065 (1791)	4345 (1555)	529 (323)	735 (263)	85.5
pH	7.60 (0.19)	7.91 (0.15)	7.24 (0.74)	10.49 (0.57)	–
EC (mS/cm)	10.44 (3.09)	10.39 (2.87)	5.13 (0.79)	4.86 (0.87)	–

[a] Values are mean (standard deviation) for 121 sampling dates (April 15, 2003–March 1, 2004).
[b] Total solids (TS) = Total suspended solids (TSS) + Dissolved solids.
[c] Oxidized-N = NO_3–N + NO_2–N (nitrate plus nitrite).
[d] Total N = TKN + Oxidized-N. System efficiency for total N = 89.4% on a mass balance basis. This considers that 33% of the N-treated effluent was recycled in a closed loop to refill barns where oxidized N was eliminated (Table 2).

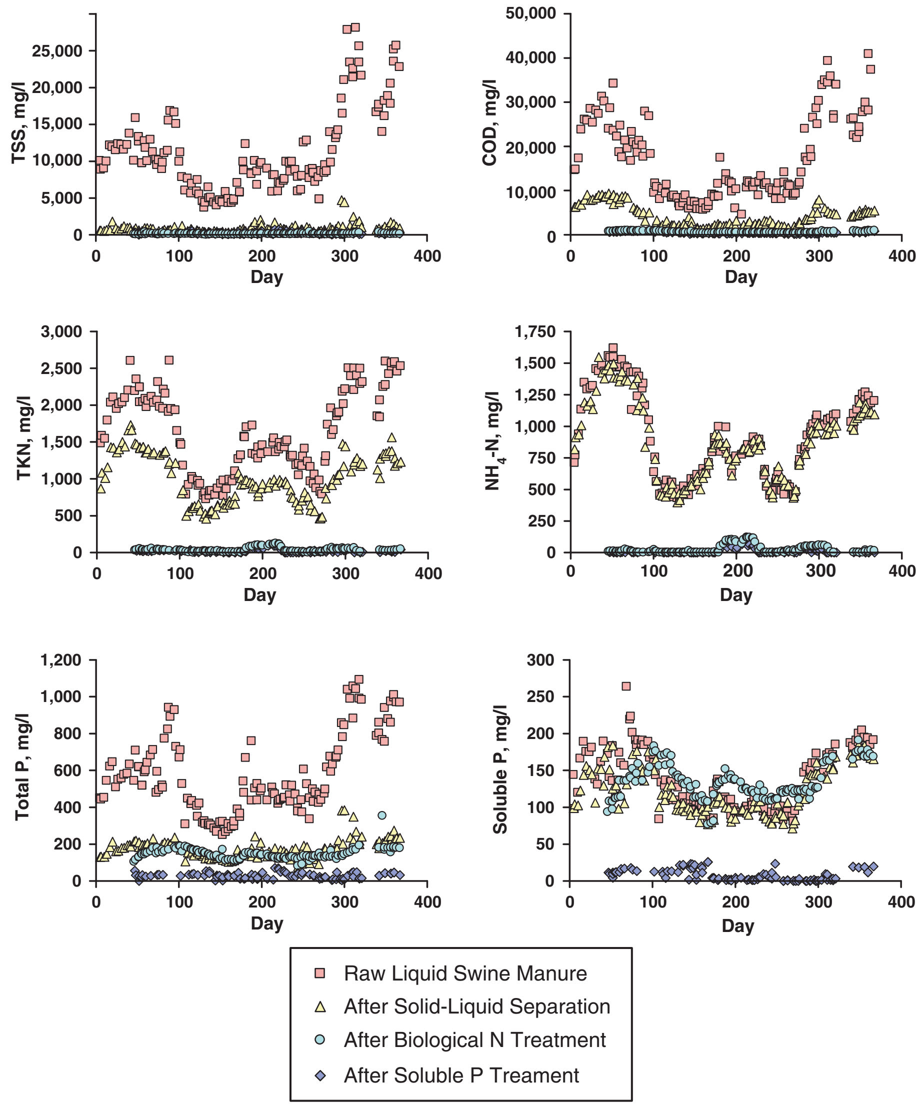

Fig. 5. Water quality improvements (TSS, COD, TKN, NH_4^+–N, TP and soluble P) in the on-farm wastewater treatment system at Goshen Ridge farm, North Carolina, as liquid swine manure passes through solid–liquid separation, biological N removal, and soluble P removal modules. Data show performance verification at steady-state conditions from March 1, 2003 (day = 1) to March 1, 2004 (day = 367).

The treatment system was also effective in reducing odor-generating compounds and pathogen indicator microorganisms contained in the liquid (Table 4). By measuring directly in the liquid the concentration of compounds typically associated with bad smell in animal wastes, we were able to quantify the potential of the effluent to produce offensive odors and the effect of each treatment step on odor reduction. The largest odor reduction

Table 4
Removal of odor compounds and pathogen indicator microorganisms by on-farm wastewater treatment system at Goshen Ridge farm, North Carolina

	Raw liquid swine manure	After solid–liquid separation treatment	After biological N treatment	After phosphorus treatment	Removal efficiency with system (%)
Odor compounds, ng/ml (±s.e.)[a]	206.78 (52.62)	181.69 (77.98)	4.61 (2.00)	4.29 (2.44)	97.6
Total fecal coliforms, $\log_{10}$/ml (±s.e.)[b]	3.74 (0.36)	3.09 (0.29)	1.01 (0.23)	BDL	>99.9

[a] Values are means (standard error) of five determinations (September–October 2003). Odor compounds are the sum of concentrations of six malodorous compounds contained in the liquid (phenol, *p*-cresol, *p*-ethylphenol, *p*-propylphenol, indole, and skatole) that are characteristic of swine manure.
[b] Values are means (standard error) of $\log_{10}$ colony forming units (cfu) per ml for duplicate samples of four determinations (July–December, 2003). BDL = below detectable limit, indicates there were no colonies to count.

was observed after the liquid passed through aeration in the nitrogen treatment. Overall, the treatment system eliminated 97.9% of the odor compounds. Microbiological analyses showed a consistent trend in reduction of fecal coliforms as a result of each step in the treatment system. It confirmed pilot studies (Vanotti et al., 2005a) that the phosphorus removal step via alkaline calcium precipitation produces a sanitized effluent.

3.3. Solid–liquid separation module

Efficiency of solid–liquid separation using polymer flocculation was consistently high with an average of 93% TSS separation. This high-separation efficiency was obtained with liquid manure TSS concentrations that varied from about 4000 mg/l to 28,000 mg/l (Fig. 5). Application rate of PAM varied from 106 to 178 g/m^3 (average = 136 g/m^3) corresponding to the changes in wastewater strength. The solids separation module also removed 93% of the volatile suspended solids, 78% of COD, 40% of TKN, 94% of zinc and copper, and 70% of TP from the wastewater (Table 3). As mentioned before, this reduction of organic compounds such as COD is an important system consideration for the efficiency of subsequent nitrification treatment. Soluble NH_4^+ and P concentrations changed little (4.2% and 10.4% reduction, respectively) with solids separation treatment. In contrast, organic N and P were effectively captured in the solids, resulting in average concentration reductions of 84.4% and 88.9%, respectively.

A total of 748 m^3 of solids were separated and left the farm in a 10.5-month period. This amount of manure weighed 596,200 kg and contained 18.2% (±1.3%) solids (81.8% moisture), 40,805 kg of carbon, 5379 kg of N, 3805 kg of P, 280 kg of Cu, and 281 kg of Zn. The separated solid waste was composted in a centralized solids processing facility and converted into organic plant fertilizer, soil amendments, and plant growth media (Vanotti, 2005).

3.4. Biological N removal module

Ammonia (NH_4^+–N) removal efficiencies of the Biogreen process were consistently high (average = 97%, Table 3). These high process efficiencies were obtained with influent NH_4^+–N concentrations varying from about 400 to 1500 mg/l (Fig. 5) and loading rates varying from about 18 to 45 kg N/day (average = 32 kg/day). After solids separation, most of the TKN was made of NH_4^+–N; therefore, removal efficiencies for TKN were also high (96%). Influent TKN concentration varied from 460 to 1730 mg/l, and loading rates varied from 20 to 50 kg N/day (average = 37 kg/day). Nitrogen loading rates into the N removal module fluctuated greatly (150%) within production cycles. These N loading fluctuations were well correlated ($r = 0.83$) with changes in total pig weight in the barns [N load (kg TKN/day) = 17.4 + 0.0820 live weight (Mg)]. The biological N removal process responded well to these highly changing N loading conditions as well as cold temperatures experienced during evaluation. Water temperatures during cold weather (December 2003–February 2004) were 11.9–13.0 °C for the monthly averages and >4.2 °C for the daily average. Corresponding air temperatures were 4.8–6.7 °C for monthly averages and >−4.2 °C for the daily average (Fig. 4).

Due to additional denitrification in the pits under the barns, a mass balance was required to understand system removal of total N. Mass balance utilized nutrient concentration (Table 3) as well as corresponding water flows (Table 2). Oxidized N contained in the recycled water was reduced from 224 mg/l to 1 mg/l after 7-day retention in the pits under the barns. We calculated that an additional 870 kg of oxidized N was removed by denitrification in this closed loop during the 10.5-month period summarized in Tables 2 and 3. The amounts of total N (TKN + oxidized N) contained in the flushed manure and the treated effluent were 19,100 kg and 2020 kg, respectively. Thus, total N removal on a mass basis ($TN_{in} - TN_{out}$) was 89.4%. A significant amount of N was further removed by denitrification in the former lagoon that stored the final effluent produced by the treatment plant. For example, oxidized N in the system effluent was reduced from 241 to 11 mg/l after storage in the former lagoon (average June 2003–May 2004), with lower final concentration (average 2 mg/l) during warmer months and higher final concentration (average 20 mg/l) during coldest months, thus indicating a biological process. This additional N removal by denitrification in the former lagoon increased total N removal efficiency of the system from 89.4% to 97.9%. Thus, when the new treatment system is retrofitted into a typical North Carolina facility and the old lagoon is used for water storage, removal of N by de-nitrification during final storage is an important consideration for total N removal design of the entire system.

The biological N removal system generated very little amount of waste sludge. This is because most of the organic compounds were separated by the liquid–solids separation before NDN treatment. All the separated biological sludge solids left the farm mixed in the manure solids, and the separated liquid was returned to the biological N system. Biological sludge was wasted every day by diverting <1 m^3 of the return sludge from the settling tank into the homogenization tank for dewatering in the solid–liquid separation module (Fig. 1). A total 24.54 m^3 of sludge was wasted per month with an average TSS concentration of 6346 mg/l that contributed 145 kg of dry solids per month to the separated manure solids (93% separation efficiency). Thus, the waste sludge from NDN process contributed only 1.4% to the total amount of separated waste (596,200 kg containing 18.2% solids in 10.5 months, Section 3.3).

3.5. Soluble phosphorus separation module

Removal efficiencies of the soluble phosphate using the P-removal module averaged 94% for wastewater containing 77–191 mg/l PO_4–P (Table 3). The process is based on the distinct chemical equilibrium between phosphorus and calcium ions when natural buffers are substantially eliminated (Vanotti et al., 2003b). It was discovered that reduction of carbonate and ammonium buffers during nitrification substantially reduces the $Ca(OH)_2$ demand needed for optimum P precipitation and removal at high pH (Vanotti et al., 2005b). For example, the biological N removal step eliminated 97% of the NH_4^+–N and substantially reduced bicarbonate alkalinity (from 4345 to 529 mg/l) which, in turn, affected the succeeding P separation step by promoting formation of calcium phosphate with smaller amounts of lime added. The average lime consumption to reach the set point pH of 10.5 was 567 g/m^3.

The high pH (10.5) in the phosphorus removal process is necessary to produce calcium phosphate and kill pathogens (Vanotti et al., 2005a). The liquid is poorly buffered, and the high pH in the effluent decreases readily once in contact with the air. For example, treatment of 1 l liquid effluent using 2 l/min aeration in bench studies reduced the pH from 10.5 to <9 in about 2 h (Vanotti et al., 2003a). However, natural aeration during storage may be equally effective to lower pH.

A total of 285 bags of calcium phosphate product containing 526 kg of P was produced and left the farm during a 9-month period. The concentration grade was $24.4 \pm 4.5\%$ P_2O_5. Each bag weighed an average of 34.8 kg and contained 8.1 kg of dry matter (23.3% solids and 76.7% moisture). The phosphorus was >90% plant available based on standard citrate P analysis used by the fertilizer industry.

3.6. Electrical power use

Data in Table 5 show the electrical power use by each process unit and the entire system in both kW h/day (first column) and kW h/m^3 to compare with other processes. A total of 404 kW h/day was needed to operate the treatment system on the 4360-pig farm. The separation portion of the treatment consumed 37% of the total power used by the system; 36% of this (54.17 kW h/day) was used to mix manure in the homogenization tank, while the remainder (94.6 kW h/day) was used to operate the separation equipment (pumps, polymer mixer, rotating screen, DAF, and filter press). The biological N removal module consumed 57% of the total power (230.27 kW h/day); 59% of this (136.62 kW h/day) was used to power the air blower, and the remainder was consumed by mixers and pumps. The phosphorus separation module consumed <6% of the total power, and <1% was used to flush the barns and recycle the water to the barns.

Table 5
Electrical power use by the wastewater treatment system

Unit process	Power consumption per process unit and system (kW h/day)	Power consumption per m^3 of wastewater treated[a] (kW h/m^3)
Barn flush (lift station) and recycle to barns	2.60	0.050
Homogenization tank	54.17	1.389
Solids separation	94.60	2.426
Biological N treatment	230.27	5.889
Phosphorus treatment	22.30	0.842
Total system	403.94	10.357

[a] Volumes treated are shown in Table 2. Total system calculation uses total raw flushed manure volume (30 m^3/day).

3.7. Operator requirements

A manual of operation and maintenance was developed as part of the demonstration. The system requires an operator with a high-school education. The operator needs to receive 2 weeks training by the company that includes detailed information on plant equipment, operation and maintenance, safety and health aspects, identification and reporting of malfunction, and simple troubleshooting. Our observations indicate that a trained operator can safely operate two farms within a 20-mile radius, each farm providing treatment to 4500–9000 pigs. In addition to the plant operator, successful operation of the technology also requires support from an engineer technician having a 2–4-year engineer technology degree and mechanical/electrical skills. This person can provide support to about 10 farms so that each plant is visited about twice a month to work on specialized maintenance issues such as system checks, software, electronics, or parts replacement.

4. Conclusions

Treatment technologies are needed that can replace lagoons, capture nutrients, reduce emissions of ammonia and nuisance odors, kill harmful pathogens, and generate value-added products from manure. A system of swine wastewater treatment technologies was developed to accomplish all of these tasks. The system was tested at full scale in a 4400-head finishing farm as part of an Agreement between the Attorney General of North Carolina and swine producers Smithfield Foods and Premium Standard Farms to replace current anaerobic lagoons with Environmentally Superior Technology.

Major goals in the demonstration and verification of a new wastewater treatment system for swine manure were achieved including replacement of anaerobic lagoon treatment and consistent treatment performance under cold and warm weather conditions, with varying solid and nutrient loads typical in animal production. The on-farm system greatly increased the efficiency of liquid–solid separation by polymer injection to increase solids flocculation. Nitrogen management to reduce NH_3 emissions was accomplished by passing the liquid through a module where bacteria transformed NH_4^+ into harmless nitrogen gas. Subsequent alkaline treatment of the wastewater in a P module precipitated P and produced a disinfected liquid effluent.

It was verified that the treatment system was technically and operationally feasible. Based on performance results obtained, it was determined that the treatment system met the Agreement's technical performance standards that define an Environmentally Superior Technology (Williams, 2004). These findings overall showed that cleaner alternative technologies can have significant positive impacts on the environment and the livestock industry. This project was considered an important milestone in the search of alternative treatment technologies in the USA and justified moving ahead with innovation and evaluation of second-generation systems.

Acknowledgements

This research was part of USDA-ARS National Program 206: Manure and Byproducts Utilization; ARS Project 6657-13630-001-00D "Improved animal manure treatment methods for enhanced water quality." Technology verification was partially funded by North Carolina State University and its sponsor Smithfield Foods, Inc., through USDA Agreement 58-6657-2-202, NCSU Subcontract #2001-0478-02. The authors are grateful to Dr. Mike Williams, NCSU Animal & Poultry Waste Management Center; Dr. Ryke Longest, NC Attorney General Office; and to the scientists, engineers, and personnel from technology providers Super Soil Systems USA, Selco MC of Spain, and Hitachi Plant Engineering & Construction Co. of Japan for their contribution to the success of this project. The authors are also grateful to Premium Standard Farms for providing the pig production data and help with the performance verification, and to Dr. John Loughrin, Aprel Ellison and David Ingram of USDA-ARS for odor, water quality, and pathogen determinations.

This study determined the water quality improvements in swine lagoons by an innovative swine manure treatment system operating at full-scale during five pig production cycles. The system performed high-rate solid-liquid separation, biological ammonia treatment and phosphorus treatment. The treatment system met the environmental performance standards for swine waste management systems in new or expanding operations in North Carolina. The system substantially reduced odor by 99.9%; pathogens by 99.99%, nutrients (phosphorus and nitrogen) by $>$ 90%, and heavy metals by 99%. As the treated effluent and/or rainwater renovated the liquid in the anaerobic lagoons, they became aerobic (Eh $>$ 300 millivolts). By the end of the second year, the NH_4-N concentration in the lagoons liquid declined from the initial 370–485 mg L^{-1} to lower than 15. After conversion, the sludge accumulation in the former lagoons was halted. This was a significant outcome because one converted lagoon served twice the number of animals than before implementation of the innovative manure treatment system, which is similar to a situation of herd expansion. These findings showed that environmentally superior waste management technologies can have substantial positive impacts on water quality in intensive swine production.

Keywords: water quality, solid-liquid separation, flocculants, nutrient recovery, swine lagoons, pig manure, nitrification, recovered calcium phosphate

INTRODUCTION

Typically, waste from confined swine production operations in the southeastern U.S. is stored and treated in large, open anaerobic lagoons prior to application on cropland (Barker, 1996a; Westerman et al., 2010). After year 2000, there was great public interest in developing new swine manure treatment systems in the region to address multiple environmental and health concerns associated with the anaerobic lagoon system. These concerns included emissions of ammonia (Aneja et al., 2008), pathogens (Sobsey et al., 2001; Vanotti et al., 2005), odors (Schiffman and Williams, 2005; Loughrin et al., 2006), and deterioration of water quality (Mallin, 2000). Consequently, demonstrations of new treatment systems were conducted on-farm to demonstrate feasibility of environmental superior waste management technologies (EST) that could address five environmental standards: "1. Eliminate the discharge of animal waste to surface waters and groundwater through direct discharge, seepage or runoff; 2. Substantially eliminate atmospheric emissions of ammonia; 3. Substantially eliminate the emission of odor that is detectable beyond the boundaries of the parcel or tract of land on which the swine farm is located; 4. Substantially eliminates the release of disease-transmitting vectors and airborne pathogens; and 5. Substantially eliminates nutrient and heavy metal contamination of soil and groundwater" (Williams, 2009). Nutrients of concern were nitrogen (N) and phosphorus (P), and heavy metals of concern were copper (Cu) and zinc (Zn). As a result of this process, new legislation in North Carolina was enacted enforcing the environmental performance standards of EST for the construction of new swine farms or expansion of existing swine farms (NC Legislature, 2007; 15A NCAC 02T, 2010; Sommer et al., 2013).

Typically, the separation efficiencies of mechanical solid–liquid separators are less than 68% (Chastain et al., 2001) and typically less than 34% (Riaño and García-González, 2014). Organic nutrients (N and P) are contained mostly in fine manure particles < pore size 0.3 mm (Vanotti et al., 2002) that are not separated with normal screening (Riaño and García-González, 2014). However, new advances in both equipment and flocculant polymer applications developed for high-rate separation treatment have improved removal efficiency of solids and plant nutrients (N and P) (Vanotti and Hunt, 1999; Hjorth et al., 2010; Chastain, 2013). More and more often, new treatment systems for manure encompass three or four process units in tandem to meet various environmental standards and nutrient recovery targets. The swine waste management system described in this work is a manure treatment system developed to meet the EST environmental standards referenced above (Vanotti et al., 2010). The system consisted of high-rate solid-liquid separation followed by ammonia treatment and phosphorus recovery. A detailed description of this system as well as system drawing, first year performance of the treatment plant, and economic considerations, are found in Vanotti et al. (2009). While treatment performance of the system *per se* can be correctly assessed at steady state over relatively short periods during cold and warm weather conditions, its effect on water quality needs longer periods of monitoring due the large volume and slow hydraulic retention time of existing lagoons. In a previous study, we were able to evaluate side by side the water quality of a swine lagoon (total volume 24,145 m^3) being cleaned with the treated effluent from a multiple-stage treatment system (4,360-head swine unit) compared with an identical control anaerobic swine lagoon receiving raw effluent from another 4,360-head swine unit (Vanotti and Szogi, 2008). Results of that evaluation showed the converted lagoon was transformed into an aerobic reservoir (dissolved oxygen, DO, 6.95 mg L^{-1}) within a year, and by the second year, the following concentration reductions in the lagoon liquid were realized: 73% of total suspended solids (TSS), 77% of biochemical oxygen demand (BOD), and 92% of ammonium (NH_4-N) (Vanotti and Szogi, 2008). In the present study, the multi-stage treatment system (performing the same environmental functions as before) was retrofitted into a 5,145-swine farm that for the previous 11–12 years used two anaerobic lagoons (16,552 and 13,120 m^3) to treat the manure (**Figure 1**). With the implementation of the new system, one lagoon was discontinued, and the other lagoon was used as effluent storage and received the effluent from all the barns after treatment in the new plant (**Figure 2**). This lagoon served twice the animals as before, similar to a situation of herd expansion. Thus, it presented unique conditions that have not been experimented before or could be predicted without experimental data on water quality.

FIGURE 1 | Aerial picture of waste treatment system and barns. It treated all the manure flushed from seven barns with 735 pigs each. Existing lagoons are shown in the foreground.

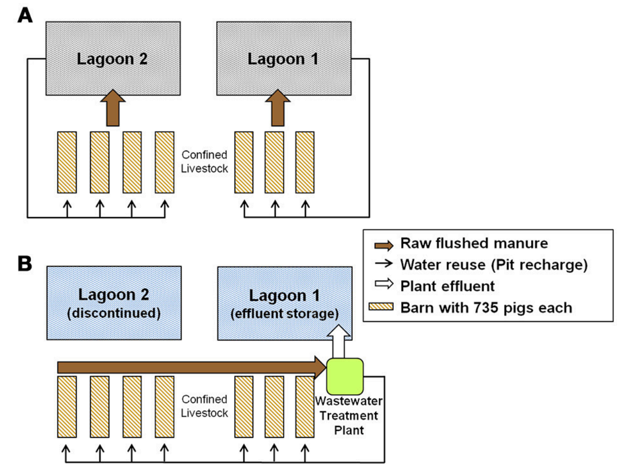

FIGURE 2 | Wastewater treatment system retrofitted into a 5,145-head swine finishing farm. **(A)** The previous system that used two anaerobic lagoons (0.6 ha each) for manure treatment and storage. **(B)** After installation of the new system, all the flushed manure was treated in the new plant and the treated effluent was stored in lagoon 1 while lagoon 2 was discontinued.

The objectives of this study were to: (1) Report the overall treatment efficiency consisting of high-rate solid-liquid separation followed by ammonia and phosphorus treatment evaluated intensively at steady state over a 2 years period and five swine production cycles. (2) Report the corresponding water quality improvements in the converted lagoons. (3) Report the changes in the sludge depth of the lagoons during a 6 years period of the new system operating at full-scale.

MATERIALS AND METHODS

Farm Description

The full-scale manure treatment system was installed on a swine farm near Clinton, Sampson Co., North Carolina and evaluated intensively with regards to water quality during 2 years under steady-state conditions that included five complete swine production cycles. The evaluation monitored the treatment plant and lagoons. Changes in the sludge depth in the lagoons were not clear in the first 2 years. For this reason, measurements of sludge depth were collected and reported for an additional 4 years of operation of the new treatment system.

The farm had 12.9 ha (32 acres) with a permitted capacity of 5,145-head feeder-to-finish swine placed in seven barns (735 heads/barn). The traditional anaerobic lagoon system (Barker, 1996a; NRCS, 2004), which is typical in North Carolina, was used for about 11 years before the new treatment system started operation in Dec. 2006. Production records during the three growing cycles before the start of the new plant showed the farm produced an average of 584,000 kg total live weight (487,000 kg net gain production) per growing cycle (5,296 pigs/cycle). The manure was collected under the barns using slatted floors and a pit-recharge system (Barker, 1996b). The liquid manure contained in the pits was emptied weekly by gravity into the anaerobic lagoons. There were two anaerobic lagoons for treatment and storage of the manure flushed from the barns (**Figure 2A**). Lagoon 2 received the flushes from four barns (1–4); it had a surface of 0.62 ha, a depth of 3.66 m and a design volume of 16,552 m^3. This volume included (1) a minimum treatment volume of 11,240 m^3 based on Steady State Live Weight (SSLW) (2,940 head × 61.24 kg/head =180,045 kg) and anaerobic treatment volume guidelines of 6.243 m^3/100 kg SSLW (1 ft^3/lb SSLW), and (2) a temporary storage volume of 5,016 m^3 based on waste volume generated stored for 180 days (0.00849 m^3/100 kg SSLW/d or 0.00136 ft3/lb SSLW/d), a positive balance of rain – evaporation (17.78 cm) and an additional 17.78 cm storage for a "25-year, 24 h" storm event. Lagoon 1 received the flushed raw manure from three barns (5–7); it had a surface of 0.60 ha, a depth of 2.74 m and a design volume of 13,120 m^3. This volume included (1) a minimum treatment volume of 8,433 m^3 based on SSLW (2,205 heads × 61.24 kg/head = 135,034 kg) and same anaerobic treatment volume guidelines, and (2) a temporary storage volume of 4,312 m^3 also based on waste volume generated stored for 180 days, rain – evaporation of 17.78 cm, and a "25-year, 24-h" storm storage of 17.78 cm. After treatment in the lagoons, the liquid was sprayed onto the farms's fields growing small grains and forages with a permitted capacity to utilize a total 5,390 kg of plant available N per year (average N application rate of 417.8 kg N/(ha.year). The lagoon supernatant liquid was recycled into the subfloor pits to facilitate waste flushing (**Figure 2A**).

With the new treatment system, the flow of raw wastewater into the lagoons was discontinued; instead, all the raw wastewater was sent to the treatment plant (**Figure 2B**). The barn pits were flushed once a week as before, but the flushed manure (barns 1–7) was diverted into a homogenization tank that mixed the manure before the solid-liquid separation step. A portion of the water after ammonia treatment was used to recharge the barn pits for the flushing (**Figure 3**). Water in excess of that needed for barn pit recharge was treated in the phosphorus treatment + disinfection module and stored in lagoon 1 for use in crop irrigation. As mentioned before, the new treatment system was evaluated intensively during five growing cycles of pigs (**Figure 4**). Within production cycles, the total pig weight in the seven barns varied greatly, from a low monthly average of 71.8 Mg to a high of 519.3 Mg (**Figure 4**). The average live animal weight (LAW) in the seven barns during the 5-cycle evaluation period was 335.8 Mg. This value is also referred to as steady-state live weight (SSLW, dotted line **Figure 4**). During the 5-cycle evaluation period, the farm sold an average of 624,345 ± 21,867 kg total live weight (516,239 ± 13,791 kg net gain produced) in each of the five growing cycles (5,265 ± 132 pigs/cycle).

The water quality of the two lagoons was monitored intensively during a 3 years period: the year before the project started when both lagoons performed anaerobic treatment, and the following 2 years when lagoon 1 received effluent from the alternative treatment system and lagoon 2 received only rain water. To help comparison of results of water quality monitoring, the same 36 months scale was used in the figures in this paper. After the intensive 3 years evaluation by the ARS

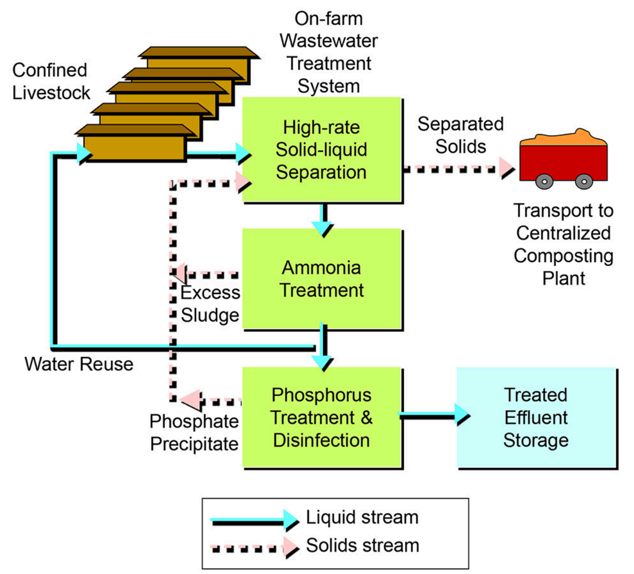

FIGURE 3 | Schematic diagram of wastewater treatment system using high-rate solid-liquid separation, ammonia treatment and phosphorus treatment.

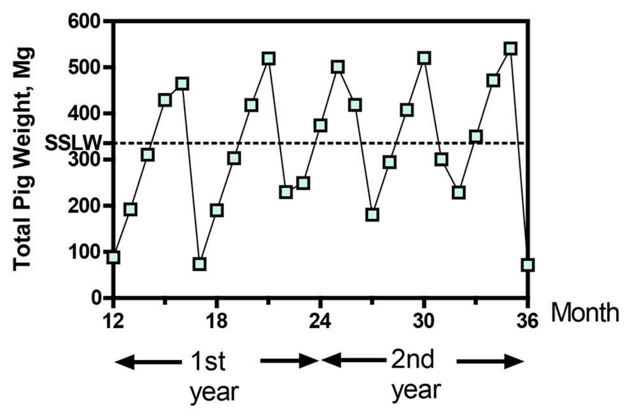

FIGURE 4 | Average monthly total live weight of the pigs during five production cycles in seven barns during demonstration of new wastewater treatment process. Dotted line is the steady state live weight (SSLW).

team (2006–2008), the treatment system kept operating full-scale without changes in swine inventory for an additional 4 years. As part of the permit No AWI820164 for using the innovative animal waste management system, the operator had to report to the State Permitting Authority the following parameters: daily volume of separated solids, the quarterly total volumes of the system wastewater influent and effluent, and quarterly chemical analyses of Total N, NH_4-N, NO_3+NO_2-N, BOD_5, Total P, TS, Cu, Zn, pH, and fecal coliforms in the separated solids (except BOD_5), the influent into the homogenization tank and the plant effluent from the phosphorus settling tank. After 3 years of successful compliance, the frequency of sampling and chemical analyses was reduced to two times per year to demonstrate compliance in both summer and winter seasons. During this extended period, the analyses were also done at ARS laboratory.

Wastewater Treatment System Description

The multistage system (Vanotti et al., 2010) consisted of three steps or process units in tandem: high-rate solid-liquid separation, biological ammonia treatment, and phosphorus treatment/disinfection (**Figure 3**). For a completed description and the schematic drawing of this system, see Vanotti et al. (2009). Before the first step, subfloor wastewater was emptied weekly by gravity into a receiving pit and pumped by a 946 L min^{-1} pump into a 379 m^3 capacity homogenization tank. The manure was kept well mixed using a 3.5 kW, 12.1 m^3 min^{-1} submersible mixer. The homogenized liquid manure was conveyed into the first step in the system—the liquid/solid separation process—at a process flow of 9.1 m^3 h^{-1}. The process used polymer flocculation to enhance the separation of fine suspended particles (Vanotti and Hunt, 1999; Garcia et al., 2007). Solids were separated by a rotary press separator (Fournier Industries Inc., Quebec, Canada) with a dual 1.2 m rotary press, two polymer preparation tanks, a polymer metering pump, manure feed pump and in-line flocculator. The polymer was dry cationic, linear polyacrylamide (PAM) with 35% mole charge (SNF Floerger, Riceboro, GA). The prepared polymer solution contained 2.14 g PAM L^{-1} (0.2%) and was mixed with the liquid manure at a rate of 6%. This resulted in a final polymer dosage of 128 mg L^{-1}. Separated manure solids were transported offsite to a solids processing facility and composed with cotton gin waste to produce value-added organic fertilizers, soil amendments and plant growth media (Vanotti et al., 2006). The separated wastewater was stored in another 379 m^3 tank and then pumped continuously into the second step of the system – the biological ammonia treatment process. This process used nitrification-denitrification (NDN) with a Modified Ludzack-Ettinger (MLE) configuration (Tchobanoglous et al., 2003). There were three tanks in the second step: the first tank was an anoxic tank (277 m^3) for denitrification (DN), the second tank was an aeration tank (227 m^3) for nitrification, and the third tank was a settling tank for clarification. Nitrification converted NH_4-N into NO_2-N and NO_3-N. The nitrified wastewater was continually recycled into the DN tank using the pre-denitrification configuration (MLE). In the DN tank, suspended denitrifying bacteria used soluble manure carbon in the separated manure to transform NO_2 and NO_3 into N_2 gas. The nitrification process used high-performance nitrifying bacterial sludge (HPNS), which was developed for high-ammonia wastewater and cold temperatures (Vanotti et al., 2013). To start the nitrification process, the aeration tank was inoculated with one liter of HPNS. Then a multiplication step was conducted in the same tank during 40 days to achieve full-scale nitrification activity prior to starting the complete system (Vanotti et al., 2009). Air was supplied continuously with a 10 HP rotary lobe blower and 98 fine-air diffusers. The DN tank contained a 1.7 kW, 9.8 m^3 min^{-1} submersible mixer. A settling tank (14.3 m^3) with conical bottom clarified the effluent after nitrification. The settled sludge was returned into the DN tank. The rates of sludge and nitrified liquid recycling into the DN tank were 0.5 and 3.5 times the inflow rate, respectively. The clarified effluent was stored in a 277 m^3 tank and used to refill the barn pits (**Figure 2B**). The average mixed liquor suspended solids (MLSS) and mixed liquor volatile suspended solids (MLVSS) in the nitrification tank during evaluation were 2,450 $\pm$ 1,680 mg L^{-1} and 1,980 $\pm$ 1,440 mg L^{-1}, respectively. Target MLSS concentrations were $>$ 2,000 and $<$ 4,000 mg L^{-1}. Once a week, the operator used a settling test (15 min, 1 L graduated cylinder) to estimate the MLSS in both denitrification and nitrification tanks based on an empirical relationship obtained at the site: [settled solids vol. (mL L^{-1}) = $-66.7 + 0.1132$ MLSS (mg L^{-1}); $r^2 = 0.759$] so that the settled solids volume in the 15 min test stayed between 160 and 390 mL L^{-1} (corresponding to the 2,000–4,000 mg MLSS L^{-1} target). This information was used by the operator to divert more or less sludge from the settling tank into the solids separator up-front to meet the MLSS target range. Considering a specific nitrification activity of 20.76 mg N/g MLVSS/ h and a nitrification tank volume of 227 m^3, the nitrification capacity of the unit was 223 kg N/day. In the third step of the system—the phosphorus treatment/disinfection process - the soluble P was recovered as a calcium phosphate solid (Vanotti et al., 2003), and pathogens were substantially reduced by the alkaline environment (Vanotti et al., 2005). The effluent was treated with hydrated lime slurry [12% $Ca(OH)_2$] in a 0.3 m^3 reaction chamber. The pH of the process was maintained at 9.5 by a pH probe and pH controller linked to the lime injection pump. The average lime consumption rate was 1.18 kg m^{-3}. The P precipitate (calcium phosphate) was separated in a settling tank with conical bottom (8.8 m^3) and further dewatered using the solid/liquid separation unit in the first unit of the system (Garcia et al., 2007). Phosphorus and manure solids as well as excess NDN sludge were combined in one solids stream for off-farm transport (**Figure 3**).

The average wastewater flows though the new treatment system (2 years averages) were the following: 36.3 m^3 d^{-1} of raw manure were flushed from the barns and treated (plant influent); 6.2 m^3 d^{-1} after N treatment were recycled to refill the barn's pit recharge system; 31.6 m^3 d^{-1} after P treatment (plant effluent) were stored in lagoon 1 for use in crop irrigation. On average, the flushed manure volume from the barns contained 17.1% recycled effluent from the treatment system and 82.9% of newly generated manure, urine, and water wasted by pigs. The newly generated wastewater stream (flushed manure—water reuse) averaged 30.1 m^3 day^{-1} or 40.8 L per 455 kg live animal weight (LAW) per day. For comparison, the industry average in feeder to finish operations using pit-recharge systems is 45.8 L per 455 kg LAW per day (1.62 ft^3 per 1,000 lbs. LAW per day) (Chastain et al., 1999).

Water Sampling and Monitoring

For the treatment system, composite liquid samples were collected twice per week during a 2 years period from four locations: (i) the homogenization tank containing raw flushed manure (plant influent), (ii) after solid-liquid separation treatment, (iii) after N treatment, and (iv) after P treatment (plant effluent). Samples were composited of four sub-samples taken over 3.5 days periods using refrigerated automated samplers (Sigma 900max, American Sigma, Inc., Medina, NY). Wastewater flows throughout the system were measured with five liquid-level ultrasonic probes and data logger (SR50 Sonic Ranging Sensor and CR800 data logger, Campbell Scientific Inc., Logan, UT). The ultrasonic probes measured liquid levels in the homogenization tank, separated water tank, clean water tank, and settling tank. The measurements of liquid height and area of the tanks were used to calculate actual volume dynamics and flows. The data logger also monitored air and water temperatures, precipitation, DO, ORP, and process pH. Average monthly maximum, average and minimum air temperatures and total monthly rain are shown in **Figure 5**. Average monthly minimum and maximum of daily air temperatures ranged from −8.4 to 38.8°C, average monthly air temperature was 16.5°C, and it ranged from 5.5 to 27.2°C, and precipitation averaged 1,048 mm per year.

Lagoon liquid samples were collected monthly during a 3 years period to monitor water quality characteristics at least 1 year before and 2 years after the treatment system was implemented. Sub-samples were collected from the lagoon supernatant within a 0.30 m depth using a 500 mL polyethylene dipper with a 3.6 m handle. From each lagoon, two composite

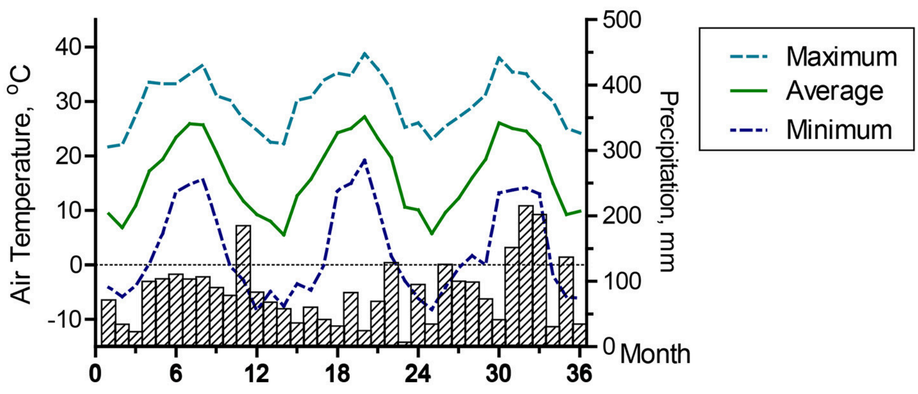

FIGURE 5 | Air temperature and precipitation during the 3-yr water quality monitoring period. Data are monthly maximum, average, and minimum of daily air temperatures, and monthly precipitation.

samples were obtained by mixing in a bucket eight sub-samples collected around the lagoon.

Collected samples were: (1) transported on ice to the ARS Coastal Plains Research Center in Florence, SC, for water quality analyses, or (2) overnight shipped with cold packs to the ARS Sustainable Agricultural Systems Laboratory and Environmental Microbial Safety Laboratory in Beltsville, MD, for microbiological analyses, and to the ARS Animal Waste Management Research Unit in Bowling Green, KY, for odor analyses.

The sludge depth in the lagoons was monitored yearly during 9 years: 3 years before and 6 years after the new system was implemented. The distance from the liquid surface level to the top of the sludge layer was measured with a sonar and the distance from the liquid surface to the lagoon bottom (soil) was measured with a pole. From 2004 to 2006, the sonar measurements were made from a boat at 8 or 10 sampling points per lagoon. Afterwards, the sonar measurements were done with a remote control boat that collected $1,150 \pm 170$ points per lagoon. Sludges were sampled five times to measure chemical characteristics using Sludge Judge probes 4.5 m long $\times$ 3.2 cm outside diameter (OD). Volume of sludge was calculated based on height using the formula volume of a trapezoid and design dimensions of the lagoons.

Analytical Methods

Water quality analyses were performed according to Standard Methods for the Examination of Water and Wastewater (APHA, 1998). Total solids (TS), total suspended solids (TSS), and volatile suspended solids (VSS) used Standard Method 2540 B, D, and E, respectively. Chemical analyses consisted of chemical oxygen demand (COD) using Method 5220 D, 5 days biochemical oxygen demand (BOD_5) using Method 5210 B, ammonia (NH_4-N) using Method 4500-NH_3 G, nitrate plus nitrite ($NO_3 + NO_2$ -N) using Method 4500-NO_3^- F, pH using Method 4500-H^+ B, electrical conductivity (EC) using Method 2510 B, alkalinity using Method 2320 B and endpoint pH of 4.5, soluble P (SP or PO_4) using Method 4500-P F after filtration through a 0.45-μm membrane filter. Total P (TP) and total Kjeldahl N (TKN) were determined using acid digestion (Gallaher et al., 1976) and colorimetric phosphorus and nitrogen methods adapted to acid digests (Technicon Instruments Corp, 1977). Organic P was the difference between total P and PO_4 analyses. Organic N was the difference between Kjeldahl N and NH_4-N analyses, and Total N was the sum of TKN and nitrate + nitrite. The potassium (K), calcium (Ca), magnesium (Mg), sodium (Na), copper (Cu), and zinc (Zn), were determined using nitric acid/peroxide block digestion (Peters, 2003) and inductively coupled plasma (ICP) analysis (Method 3125 A). Oxidation-reduction potentials (ORP) were measured at the time of sampling using a Ag/AgCl reference electrode and corrected to standard hydrogen electrode (Eh) values (Standard Method 2580 B). Reduction in odor was characterized as described by Loughrin et al. (2009) that measured in the liquid the concentration of five odor compounds characteristic of swine manure (phenol, *p*-cresol, *p*-ethylphenol, indole, and skatole) using extraction with Twister stir bars (Gerstel, Baltimore, MD) coated with polydimethylsiloxane followed by thermal desorption and gas chromatography-mass spectrometry. Total aromatic malodors were the sum of the five odor compounds. Microbiological analyses of liquid samples were done using standard protocols for pathogens and indicator microbes for the examination of wastewater (Vanotti et al., 2005).

Statistical Analysis

Data management, descriptive statistics (PROC MEANS), regression (PROC REG), and mean comparison for repeated measurements (PROC MIXED) analyses were performed with SAS (SAS Institute, 2008).

RESULTS AND DISCUSSION

Water Quality Improvements by Treatment System

The wastewater treatment performance of the plant are presented in **Table 1**; the various columns show changes in water quality indicators as the liquid manure passed through the three treatment steps as well as the overall system efficiency. The intensive evaluation period encompassed five cycles of pig production; this allowed assessment of the performance of the system through varying environmental conditions and waste loadings. High treatment efficiencies were obtained consistently despite air temperatures varying from −8.4 to 38.8°C (**Figure 5**) and large fluctuations in the strength of the manure. Taken on average through the evaluation period, flushed manure had high strength (TS $3.0 \pm 1.2\%$) according to the manure strength scale of Garcia-González and Vanotti (2015). The variation in concentrations because of changes in pig weight during production cycles was big: volatile solids, for example, averaged 17,800 mg L^{-1}, but ranged from 2,850 mg L^{-1} up to about 41,800 mg L^{-1} while BOD_5 averaged 7,360 mg L^{-1} and ranged from to 730 to over 25,000 mg L^{-1} (**Table 1**). Other quality parameters such as TKN (average 2,050 mg L^{-1}, range 810–4,220 mg L^{-1}) and NH_4-N (average 1,290 mg L^{-1}, range 310–3,445 mg L^{-1}) were also distinctive of a high-strength swine wastewater. The variations in wastewater volumes were also big because of the pig production cycles: average monthly volume of flushed wastewater was 1,095 m^3, but ranged from 396 up to 2,233 m^3. Similarly, the clean treated effluent volumes averaged 963 m^3 per month, and ranged from 290 to 1,666 m^3. In terms of mass loadings, the total nitrogen load into the treatment system (flushed manure) during the five pig cycles averaged 80.6 kg N d^{-1} (29,510 kg N yr^{-1}) and the monthly averages ranged from 20.9 to 211.5 kg N d^{-1}. The average NH_4-N load was 51.9 kg d^{-1} (range 13–150 kg d^{-1}), and the average TP load was 21.4 kg d^{-1}. The on-farm system removed 67.75% of TS, 90.2% of VS, 97.2% of TSS, 98.4% of VSS, 96.3% of COD, 99.4% of BOD_5, 95.7% of TKN, 96.5% of NH_4-N, 93.3% of TP, 98.8% of Zn, 98.8% of Cu, 56.0% of EC, and 77.5% of alkalinity (**Table 1**).

High-Rate Solid-Liquid Separation

The first step of the system was a high-rate solid-liquid separation via polymer flocculants (Chastain, 2013). The separation up-front allowed recovery of the organic materials in the manure, which can be utilized for the manufacture of composts, biochars,

TABLE 1 | Wastewater treatment plant performance by treatment step and overall system efficiency[a].

and other value-added products. It also allowed treatment of the liquid through biological nitrogen steps and phosphorus recovery/disinfection in an economical way to meet specific environmental standards. Compared to the flushed manure, the separation process concentrated the suspended solids > 25 times. It produced a relatively dry manure cake with 24.9% solids. The capture of the fine suspended solids through flocculation resulted in large decreases in TSS (90%) and COD (63%) concentrations (**Table 1**). TKN and total P were reduced by approximately 30% and 70%, respectively. Organic N and P were reduced 69 and 84%, respectively. In contrast, the soluble ammoniacal nitrogen (NH_4-N) and soluble P were unaffected by the solids separation process. The high-rate solid-liquid separation was also effective reducing heavy metals Cu and Zn concentrations; this was one of the five environmental treatment objective of EST. Initial Cu and Zn concentrations (16.8 and 25.4 mg L^{-1}) were both reduced > 88% just with the high-rate solid-liquid separation.

Biological Ammonia Treatment

The NDN step using the MLE process configuration treated NH_4-N effectively. Nitrification was accomplished using high performance nitrifying sludge (HPNS) adapted to high-ammonia and low temperatures (Vanotti et al., 2013). The pre-denitrification configuration of the MLE process allowed suspended denitrifying bacteria to consume most of the COD and BOD_5 remaining in the wastewater after solid-liquid separation. The average ratio COD/TN of the manure liquid after solid-liquid separation was 5.6 and appeared a good balance for N removal in this system without external carbon addition. On average, the NDN step reduced COD by 87% and BOD_5 by 98% relative to their concentration after solid-liquid separation (**Table 1**). The average ammonia (NH_4-N) removal efficiency was high (average = 90%) in spite of large variations of influent NH_4-N concentrations (310–3,445 mg L^{-1}) and monthly NH_4-N loading rates (14.7–117.3 kg NH_4-N d^{-1}; average load = 47.7 kg d^{-1}). Average TKN removal efficiency was 91%. Influent TKN concentration varied from 810 to 4,220 mg L^{-1}, and the N mass loading rates varied monthly from 16.8 to 166.1 kg TKN d^{-1} (average TKN load = 58.7 kg d^{-1}). The process responded well to cold temperatures experienced during evaluation. Monthly average water temperatures during cold weather (Dec–Feb) were 9.1–11.3°C, and corresponding daily minimum average water temperatures were 8.0–9.1°C. The N removal performance in this study was consistent with the performance obtained by Riaño and García-González in a full-scale, on-farm treatment plant in Castilla y Leon region, Spain, that also used a combination of high-rate solid-liquid separation with flocculants and nitrification-denitrification to treat raw swine manure: nitrification-denitrification step alone removed 84.5% of COD, 95.9% of TKN and 98.0% of NH_4-N, while the combined system removed 97% of COD, 97% of TKN and 89% of TP. In France, a combination of solid-liquid separation using centrifuges and biological NDN treatment have been successfully established at large scale in approximately 300 units treating about 15% of the swine effluents produced in Brittany region to remove N surplus and also the P excess (Bernet and Béline, 2009).

The N removal unit produced a cleaner and oxidized effluent with 124 mg L^{-1} of NH_4-N, 221 mg L^{-1} of NO_3-N + NO_2-N, 227 mg L^{-1} of TSS, 62 mg L^{-1} of BOD_5, and ORP 202 mV (**Table 1**). Part of the N treated effluent was recycled on the farm to refill the pits under the barns and facilitate flushing (under the previous anaerobic lagoon system, the anaerobic lagoon liquid supernatant was used for the flushing). This recycling of clean water with low ammonia into the barns improved the environment in the barns that benefited health and productivity of the animals. Production records for the five growth cycles before and the five cycles after conversion of waste management technology showed improvements in several animal productivity and health indicators. With the new manure treatment system, the animal mortality was decreased 47%, daily weight gain was increased 6.1%, and feed conversion was improved 5.1%. As a result, the farmer sold 28,100 kg more hogs (a 5.8% increase) per growth cycle using the new system compared to the previous anaerobic lagoon management.

Phosphorus Recovery Treatment

The clarified effluent from the biological N removal step was treated with hydrated lime that precipitated the phosphorus at process pH of 9.5. Removal efficiencies of the soluble phosphate with the treatment system averaged 80% for wastewater containing an average of 94 ± 63 mg PO_4-P L^{-1} (**Table 1**). The overall treatment system (three steps) recovered 93.3% of the TP, with two steps contributing significantly: the high-rate solid-liquid separation (first step) removed the organic P efficiently (from 380 to 62 mg P L^{-1}), and phosphorus module (third step) removed the soluble P efficiently (from 76 to 19 mg PO_4-P L^{-1}).

Odor and Pathogen Reductions

The substantial elimination of malodorous compounds was an important environmental standard to meet. A complete odor evaluation in this system have been reported by Loughrin et al. (2009). Five characteristic aromatic malodor compounds (phenol, p-cresol, p-ethylphenol, p-propylenphenol, indole, and skatole) were measured in the liquid at the successive stages of the treatment system (**Table 2**). Results obtained showed a 99.9% reduction of total odors (the sum of concentration of the five malodor compounds) in the treated effluent compared to the untreated swine manure. The solid-liquid separation step was not efficient to separate the malodorous compounds in the flushed manure and 89% of these compounds remained in the liquid fraction. However, they were effectively destroyed during the

TABLE 2 | Removal of odor compounds and pathogen indicator microorganisms by on-farm wastewater treatment system using high-rate solids separation coupled with ammonia and phosphorus treatment.

	Raw flushed swine manure (system influent)	After solid-liquid separation treatment	After ammonia treatment	After phosphorus treatment (system effluent)	Removal efficiency with system
Odor Compounds[a]			ng mL^{-1}		%
Total	71,269 ± 14,733	63,642 ± 12,366	40 ± 17	44 ± 11	99.9
Skatole	2,943 ± 496	2,540 ± 420	0 ± 0	0 ± 0	100.0

Total fecal coliforms (Mac+ 44.5)	4.11 ± 0.19	3.47 ± 0.16	0.84 ± 0.23	0.17 ± 0.18	99.99
Enterococci (mEnt)	5.11 ± 0.13	3.62 ± 0.18	1.53 ± 0.34	1.14 ± 0.35	99.99
Salmonella (XLT4)	1.79 ± 0.11	1.14 ± 0.30	0.00 ± 0.00	0.00 ± 0.00	100.00

[a] *Data are means ± standard error of 15 monthly determinations that included cold and warm weather months. Total odor compounds are the sum of concentrations of five malodorous compounds contained in the liquid (phenol, p-cresol, p-ethylphenol, indole, and skatole) that are characteristic of swine manure.*
[b] *Data are means ± standard error of log_{10} colony forming units (cfu) per mL for duplicate samples of six determinations that included cold and warm weather conditions.*

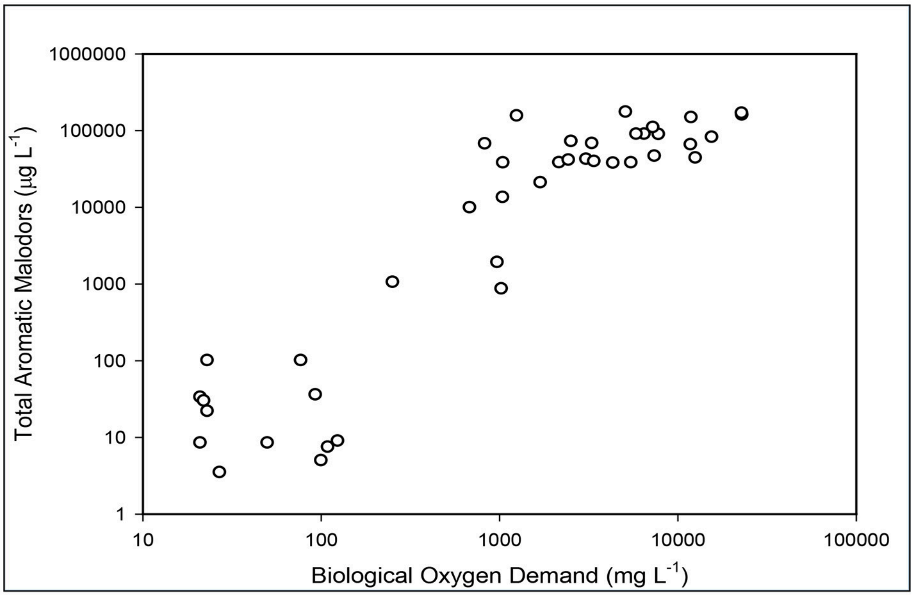

FIGURE 6 | Relationship between total odor compounds in the liquid and BOD_5 concentration as the liquid is being treated in the new plant.

subsequent biological ammonia treatment step. One important finding was that the concentration of total odor compounds in the liquid was related to BOD_5 concentration (**Figure 6**). This relationship was used later by the State Permitting Authority to determine the level of odor acceptable using this innovative animal waste management system, as a replacement of measuring odor intensity levels at the property level, which was more complicated to measure. It was stablished that, to demonstrate odor compliance, the BOD_5 concentration in the effluent samples shall not exceed 150 mg L^{-1}.

The substantial elimination of pathogens was another important environmental standard to meet. The multistep treatment system was efficient reducing pathogens in the liquid swine manure (**Table 2**). Results showed a steady reduction of microbial indicators and pathogens by each step in the treatment system. The largest reduction was obtained in the biological ammonia removal step (2.63 and 2.09 log10 reductions for total fecal coliforms and enterococci, respectively). The phosphorus treatment with its high pH provided a level of disinfection needed to meet the EST criteria of 4-log pathogen indicator reduction (99.99%). Salmonella, which was present in the raw manure at 1.79 log 10 cfu/mL, was eliminated by the second step in treatment system.

Water Quality Improvements in Lagoons

Initial Lagoon Conditions

Table 3 and **Figure 7** show the water quality changes in the two study lagoons during the 36 months monitoring period. **Table 3** show yearly changes of all the water quality parameters measured, and **Figure 7** show monthly changes of selected parameters. This monitoring period includes a common year before the project started (0–12 months) when both lagoons received raw manure directly from the barns (anaerobic lagoon management, **Figure 3A**) and the subsequent 2 years (12–36 months) when lagoon 1 received all the effluent from the new treatment plant, while lagoon 2 stopped receiving wastewater (raw or treated) (new manure management, **Figure 3B**). During initial conditions (0–12 months), the liquid characteristics in the two lagoons were similar as determined by water quality indicators shown in **Table 3**. The average TKN and NH_4-N concentrations (539–671 mg L^{-1} and 371–485 mg L^{-1}, respectively) were consistent with range values of 340–650 mg TKN L^{-1} and 280–570 mg NH_4-N L^{-1} reported for liquid in 10 swine lagoons in North Carolina (Bicudo et al., 1999). Under traditional management, the monthly average TKN concentrations varied significantly within a year, from a low of about 325 to a high 829 mg L^{-1} in lagoon 1 and 487–819 in lagoon 2 (**Figure 7**). The NH_4-N, which comprised 71% of the TKN, followed the same cyclic variation within a year. These N concentration cycles in the traditional lagoon followed seasonal temperature variations (**Figure 5**) with the lowest NH_4-N concentrations at the end of summer and highest at the end of winter. This is consistent with the previous study that monitored NH_4-N in traditional lagoon during 3 years (Vanotti and Szogi, 2008).

Lagoon Liquid Cleanup

In month 12 of the 3 years water quality monitoring period, manure flushes to both lagoons were halted and the conventional anaerobic lagoon treatment was discontinued. At that point, lagoon 1 received all the treated effluent generated by the new wastewater treatment plant. It went from receiving raw waste from 3 barns (permitted for 2,205-head feeder-to-finish swine) to receiving treated waste from 7 barns (5,145-heads). Lagoon 2 did not receive any effluent (treated or untreated), only rainwater,

[a]*Data are means ± standard deviations of monthly samples. During the previous year, both lagoons were managed as typical anaerobic swine lagoons receiving raw swine manure. Afterwards, lagoon 1 received all the swine effluent after being treated in the new plant, and lagoon 2 did not receive any swine influent (treated or untreated). Monthly changes for selected parameters are shown in* ***Figure 7****.*

[b]*Units in mg L^{-1} except for ORP, EC, and pH. ORP values are standard hydrogen electrode (Eh).*

and its situation resembles that of an inactive lagoon after depopulation of pigs (Sheffield, 2000). Excess water over storage capacity of the lagoons was applied onto crops and forages on the farm. Rainfall averaged 1,026 mm per year and contributed 7,500 m^3 of rain water annually to each lagoon (drainage area of each lagoon was 0.634 ha) or 13,000 m^3 of rainwater per lagoon in the 2 years period. Actual lagoon volumes were 9,565 ± 750 m^3 (lagoon 1) and 13,057 ± 1,180 m^3 (lagoon 2). Thus, rain alone renovated 70 and 50% of the total lagoon volumes per year (lagoon 1 and 2, respectively). Lagoon 1 received also the clean plant effluent, 11,552 m^3 per year (31.6 m^3 d^{-1}) with a renovation capacity of 1.2 lagoon volumes per year (HRT = 0.8 years).

Statistical tests showed significant reduction with time on most water quality parameters measured in the lagoons ($P <$ 001), an effect that was consistent across lagoons (**Table 3**). The exceptions were K, Na, TP, and pH, which were not significantly changed with time. In three instances when statistical differences ($P < 0.01$) in water quality parameters between lagoons occurred (Cu, Zn, and Fe, **Table 3**), the concentration decrease was quicker in lagoon 1 that received the treated water (**Table 3** and **Figure 7**). By the second year of new treatment operation, the following average reductions in water constituents were realized in lagoon 1 (**Table 3**): 61% of TSS, 66% of VSS, 57% of BOD_5, 74% of TKN, 82% of NH_4-N, 48% of Zn, 82% of Cu, 47% alkalinity, and 26% of EC. Corresponding reductions in lagoon 2 (inactive) were: 33% of TSS, 31% of VSS, 68% of BOD_5, 79% of TKN, 88% of NH_4-N, 41% of Zn, 67% of Cu, 49% alkalinity, and 40% of EC. Therefore, when multistep EST treatment technology is implemented in a swine operation with anaerobic lagoons, an additional environmental benefit is obtained: the progressive cleanup of the lagoon liquid without having to stop production.

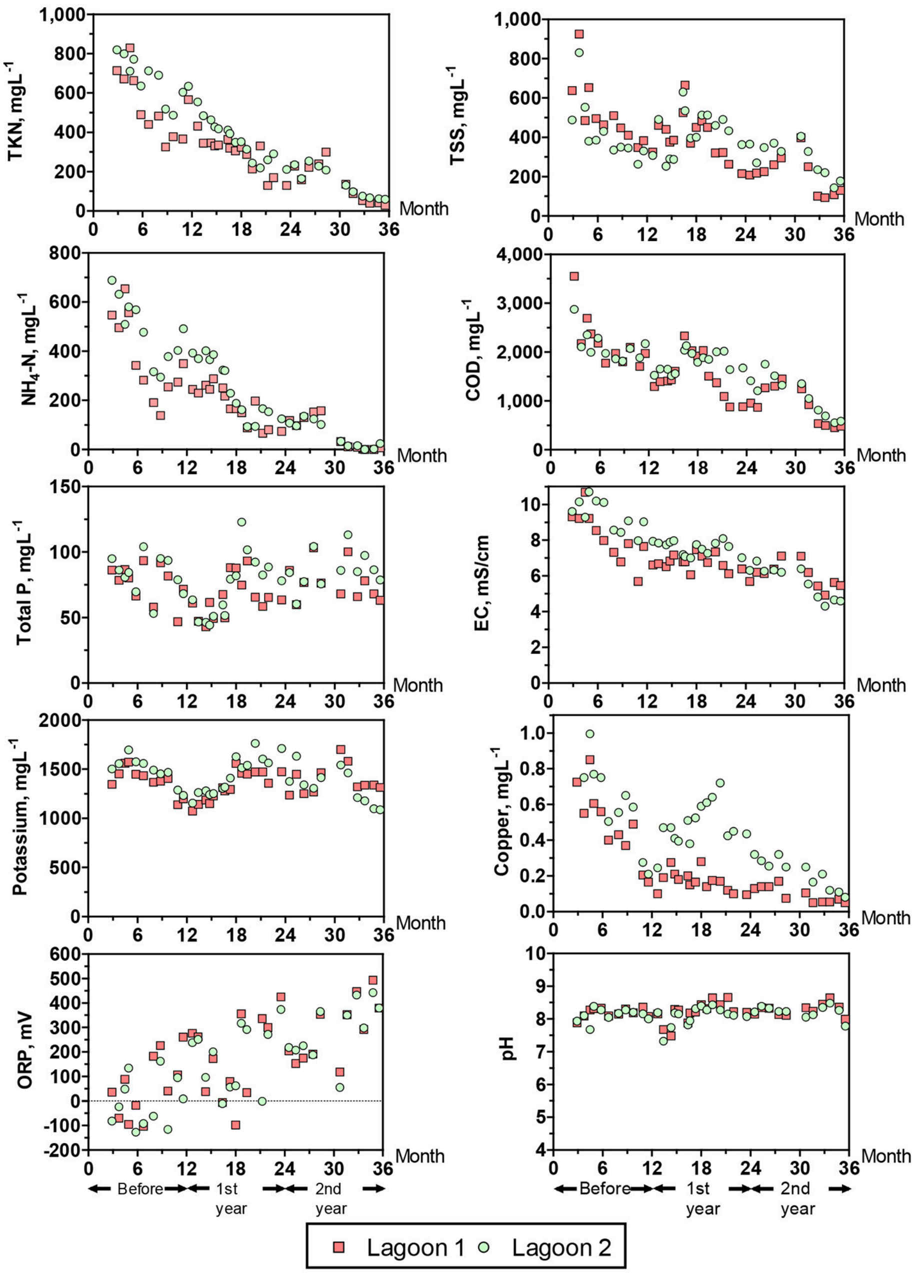

FIGURE 7 | Water quality changes in the two study lagoons during a 36 months period. 0–12 months = lagoons being managed as typical anaerobic swine lagoons receiving raw swine manure. Thereafter, lagoon 1 received all the swine effluent after treatment in the new plant, and lagoon 2 did not receive any swine influent (treated or untreated). Yearly averages are shown in **Table 3**.

Even though lagoon 1 served the production of more than twice the number of animals than it did before with the traditional lagoon system (average LAW increased from 144 to 336 Mg), remarkably, the overall cleaning performance of the new plant effluent on lagoon 1 liquid was similar to the cleaning performance by rainwater alone under lagoon inactivation and abandonment of production (lagoon 2). Indeed, the results of this study were used by the State Permitting Authority to issue Permit No AWI820164 using the innovative animal waste management system that would allow the expansion of total swine animal capacity in this farm from 5,145 to 11,015 feeder-to-finish using the same acreage (12.9 ha).

The NH_4-N concentration in the lagoons before the project started were 371 ± 167 mg L^{-1} in lagoon 1 and 485 ± 128 mg L^{-1} in lagoon 2 (**Table 3**). During the last 6 months the NH_4-N concentrations were very low: 10.0 ± 11.9 mg L^{-1} in lagoon 1 and

FIGURE 8 | Swine lagoon conversion into aerobic pond. Picture on the left shows Lagoon 1 under traditional management before start of the project, and picture on the right shows the same lagoon after the wastewater treatment plant (background) was in operation for about 10 months.

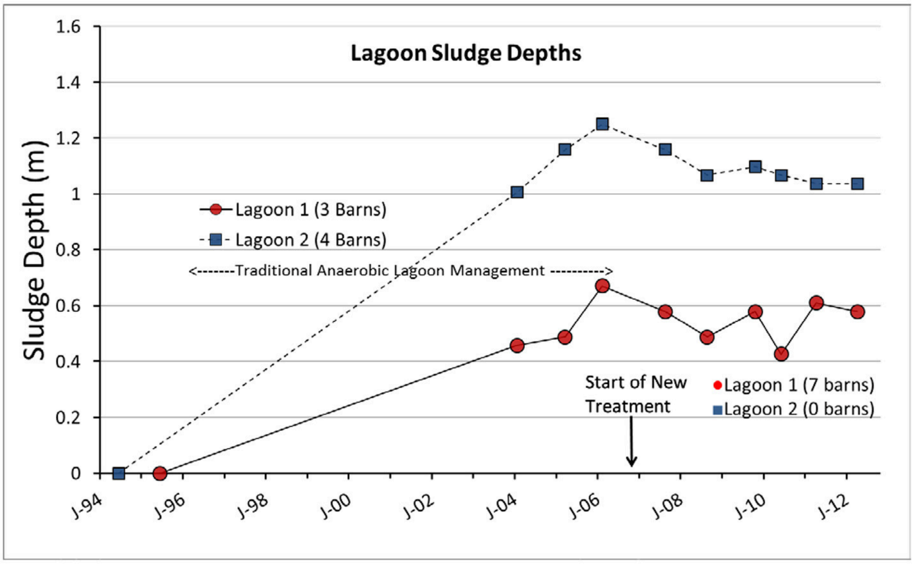

FIGURE 9 | Sludge depth dynamics of the two swine lagoons. The new treatment plant was installed after 11–12 years of conventional anaerobic lagoon treatment.

14.9 ± 12.5 mg L^{-1} in lagoon 2 (months 30–36, **Figure 7**); they approached average concentration of 4 mg NH_4-N L^{-1} reported for 30 lagoons in swine operations in North Carolina that were depopulated and inactive for 6 ± 4 years (Sheffield, 2000). In a companion paper, Ro et al. (2018) measured the ammonia emissions from this project including lagoons using open-path tunable diode laser and found that the ammonia emissions were reduced to below detectable levels. Another important parameter is the effect on EC (water salinity) that is an important water quality guideline on crop productivity, for example FAO (1994) guidelines indicate that the yield potential of irrigated cotton is reduced from 100 to 90% to 75 and 50% with irrigation water EC of 5.1, 6.4, 8.4 and 12 mS cm^{-1}, respectively. In the study, the average EC of the lagoon liquid before the project started was 8.19–9.37 mS cm^{-1} in lagoon 1 and 2, respectively. The EC was lowered to 5.33 ± 0.37 and 4.51 ± 0.19 mS cm^{-1} during the last quarter (**Figure 7**), which is optimal for cotton irrigation. As clean plant effluent and/or rain water replaced the liquid in the two lagoons, they become aerobic. From the point of view of microbial metabolism, a redox potential (ORP) > 300 millivolts is associated with aerobic, oxidized conditions (Reddy et al., 2000). The transition from anaerobic to aerobic, oxidized conditions took about 1.5 years. Average ORP were −4.8 to 60 millivolts during traditional management before the project started (**Table 3**); they increased steadily with time to reach consistent levels > 300 millivolts in the second half of second year (months 30–36, **Figure 7**). In addition to these chemical indicators of aerobic conditions, in 10 months of the new manure management the lagoon 1 changed color from brown to blue (**Figure 8**).

Changes in Sludge Accumulation in the Lagoons

Before the conversion and under traditional anaerobic lagoon management, the sludge in lagoon 1 accumulated to a depth 0.67 m (or 2,620 m^3) in 11 years of continuous swine production (serving 2,205-head feeder-to-finish) and sludge

TABLE 4 | Chemical composition of the lagoon sludges[a].

Component	Sludge lagoon 1	Sludge lagoon 2
	$g\ L^{-1b}$	
TS	208.3 ± 111.4	177.3 ± 60.9

in lagoon 2 accumulated to a depth of 1.25 m (volume 4,440 m^3) in 12 years of continuous swine production (serving 2,940-head feeder-to-finish) (**Figure 9**). Therefore, the average rate of sludge accumulation in the two lagoons was 0.1170 ± 0.0127 m^3 sludge/feeder-to-finish head/year. It was consistent with the sludge generation standard for NC anaerobic swine lagoons of 0.1249 m^3 sludge/feeder-to-finish head/year (33 gal/animal of 135 lb/year) (AG-604, 2000).

After conversion, the sludge accumulation on both lagoons was halted (**Figure 9**). During the 6 years of new treatment, the sludge depth in lagoon 1 (that received all the plant effluent) did not increase; it was stabilized at a depth of about 0.55 ±0.07 m (volume = 2,100 ± 290 m^3). Similarly, lagoon 2 (discontinued lagoon) did not accumulate more sludge after discontinuation; the sludge depth remained about constant at 1.08 ±0.05 m (volume = 3,750±180 m^3).

Table 4 shows the composition of the sludges in the two lagoons determined five times at the beginning of the study (months 0–24). The sludges were of mineral nature, thick, black, with tar like smell, with similar chemical composition in the two lagoons (**Table 4**). A salient characteristic is the large amount of P contained in the lagoon sludges. Considering sludge volume and P concentration, there were 17.2 and 29.2 metric tons of P (39.5 and 66.9 metric tons P_2O_5) in lagoon 1 and 2, respectively. Therefore, new technologies that could harvest the P contained in lagoon sludges could have a great impact on global P cycling. One such technology is the Quick Wash process presented in this special issue (Szogi et al., 2018). It recovered 80% of the P from swine lagoon sludges.

CONCLUSION

More and more often, new treatment systems for manure combine three or four process units to meet various environmental standards and recovery targets. In North Carolina, USA, construction of new swine farms or expansion of existing swine farms are required new waste management systems that can replace anaerobic lagoon treatment for the waste and meet new environmental standards of ammonia and odor emissions, pathogens release, and the substantial elimination of soil and groundwater contamination by nutrients (phosphorus and nitrogen) and heavy metals. A treatment system that met these multiple standards was implemented at full-scale in a swine farm and operated for 6 years. It combined high-rate solid-liquid separation with N and P removal processes. The treatment plant removed from the manure: 97% of TSS, 90% of VS, 99% of BOD_5, 96% of TKN and NH_4-N, 93% TP, 99% of Zn and Cu, 99.9% odors and 99.99% pathogens. This study determined the water quality improvements in lagoons by an innovative swine manure treatment system operating at full-scale during five pig production cycles. After conversion, the sludge accumulation in the lagoons was halted. As plant effluent or rainwater replaced the liquid in the old lagoons, they became aerobic (Eh > 300 millivolts). In 2 years, the NH_4-N concentration in the lagoons liquid was reduced from the 370 to 485 to lower than 15 mg L^{-1}. While clean water is more valuable for both environmental quality and crop production, it is significant that the treatment process transformed the lagoon's water from a constituent-laden legacy condition to relatively cleaner water. Moreover, the transformation was accomplished while doubling the number of animals.

AUTHOR CONTRIBUTIONS

The author MV has designed and conducted the full-scale project, performed data summarization, and written the manuscript. KR measured ammonia emissions. AS assisted with water quality work. JL did odor quantification. PM did the pathogen assessment.

FUNDING

This research was part of USDA-ARS National Program 212: Soil and Air; ARS Project 6082-12630-001-00D Improvement of Soil Management Practices and Manure Treatment/Handling Systems of the Southern Coastal Plain. The research was partially funded by the North Carolina Department of Justice, Office of the Attorney General through the Smithfield Foods Environmental Enhancement Fund Grant Agreement, USDA-ARS Project 6657-13630-003-04/NCSU Subcontract #2005-0978-03.

ACKNOWLEDGMENTS

The treatment system was constructed and operated by Terra Blue Inc. of Clinton, NC. We acknowledge the field and laboratory assistance of Aprel Ellison and William Brigman, USDA-ARS, Florence, SC, and the lagoon sludge sampling assistance of Diana Rashash, North Carolina Extension Service/North Carolina State University. Mention of trade names or commercial products in this article is solely for the purpose of providing specific information and does not imply recommendation or endorsement by the U.S. Department of Agriculture.

High-Rate Solid-Liquid Separation Coupled With Nitrogen and Phosphorous Treatment of Swine Manure: Effect on Ammonia Emission

A new treatment system was developed to meet multiple environmental performance standards including to substantially reduce ammonia emissions. It was tested full-scale for 2-years in a 5,145-head finishing swine farm with two anaerobic lagoons. The system combined high-rate solid-liquid separation with nitrogen and phosphorus removal processes. Both vertical radial plum mapping (VRPM) and floating static chamber techniques were used to measure NH_3 emission fluxes from anaerobic storage lagoons and the total farm-level NH_3 emission rates. The VRPM used an open-path tunable diode laser absorption spectroscopy (TDL) and the flux chamber used a photoacoustic gas analyzer to accurately measure NH_3 concentration. After the treatment system started, one of the two lagoons became inactive without receiving anymore flushed manure. The ammonia emission flux from the other lagoon with the treated effluent decreased from 43.9 to 6.8 kg-N ha^{-1} d^{-1} 1.5 years after implementation of the new treatment system. The NH_3 emission flux from the inactive lagoon also decreased similarly because the already stored old manure of the lagoon prior to inactivation was diluted with rainfalls and lost some NH_3 via volatilization. The total farm-level NH_3 emission rates decreased from 1.72 g s^{-1} to below detection level of the VRPM technique. Using the minimum detection level of the TDL with $R^2 > 90\%$ (i.e., 8.1 8.1 μL L^{-1}-m), the total farm-level NH_3 emission rates in the second year were less than 0.04–0.15 g s^{-1}. These results suggested that the impact of the new treatment system on NH_3 emission reduction was equivalent to closing conventional swine lagoons while actively growing 5,145 pigs with minimal ammonia emissions from the farm.

INTRODUCTION

Ammonia (NH_3) is an important fugitive gas mostly emitted from livestock operations in the United States (Doorn et al., 2002; Ro et al., 2017). Ammonia, a precursor of nitrate due to microbial nitrification/denitrification, causes acidification of both soil and surface water, and eutrophication in water bodies. It is also a principal source of atmospheric aerosols. Anaerobic lagoons are being widely utilized in the southeastern U.S. for storage and treatment of manure from confined swine production operations. The anaerobic treatment reduces the organic load of liquid manures but releases inorganic nitrogen as ammonia. Thus, ammonia emission from the lagoons is of environmental and health concerns in geographic areas with very intense confined swine production (Barker, 1996; Aneja et al., 2000; McCubbin et al., 2002; Szogi et al., 2006; Blunden and Aneja, 2008; Westerman et al., 2010). Addressing the environmental and health issues caused by ammonia emissions and potential contamination of water bodies with swine manure effluents Vanotti et al. (2010), developed an on-farm wastewater treatment system and demonstrated its high efficacy to meet multiple environmental performance standards (Vanotti et al., 2009) on a 5,145-head swine finishing farm. The multi-stage treatment system used solid separation, nitrification-denitrification, and phosphorous removal/disinfection processes. The new treatment system replaced the conventional anaerobic treatment lagoons of a swine farm and improved lagoon water quality dramatically. The treatment system removed 97% of total suspended solids (TSS), 99% of biochemical oxygen demand (BOD), 93% of total phosphorous (TP), 96% of total Kjeldahl nitrogen (TKN), and ammoniacal nitrogen (NH4-N) from the manure (Vanotti et al., 2018).

Although the new treatment system significantly improved the lagoon water quality (Vanotti et al., 2018) and reduced odors (Loughrin et al., 2009), its impact on ammonia (NH_3) emission had not been reported. The improved lagoon water quality would directly impact the NH_3 emissions from the lagoon and the animal houses using the cleaner plant-treated water for flushing manure (Szogi et al., 2006; Ro et al., 2008). Therefore, it is of great interest to assess the NH_3 emission reduction from the whole swine farm utilizing the new second-generation manure treatment system.

Micrometeorological techniques such as the integrated horizontal flux (IHF) and the backward Lagrangian stochastic (bLS) dispersion techniques can be used to measure the total ammonia emission from a swine farm. Although the bLS technique has shown its high accuracy in measuring gas emissions from point and distributed emission sources (Ro et al., 2009, 2011, 2013, 2014), one of the concerns for the use of the bLS technique in measuring emissions from a real farm with a variety of structures (buildings, stand pipes, etc.) is its underlying assumption of idealized wind flow over flat and homogenous terrain. The wind disturbance caused by farm building structures can be minimized by measuring downwind concentrations further downwind distance from the farm such as 10 times the height of the buildings (Flesch et al., 2005). However, measuring downwind concentration at longer distances from an emission source may not be feasible for certain conditions due to limited open space or dilution of emitted gas concentration below the detection limit of an analytical technique.

In contrast, the IHF technique, a mass-balance based method, is not very sensitive to changes in wind turbulence, which can used to measure an average gas emission rate of a large area (Wilson et al., 1983). The U.S. Environmental Protection Agency published the vertical radial plum mapping (VRPM) technique based on the IHF principles as Other Test Method 10 (OTM−10) in measuring fugitive gas emission rates from closed landfills (EPA, 2005). The VRPM technique estimates the horizontal flux of gas passing downwind of the emission source based on measured wind speed profiles and path integrated concentrations (PICs) (Ro et al., 2009, 2011; Viguria et al., 2015). The VRPM utilizes a bivariate Gaussian smooth basis function minimization (SBFM) to reconstruct a crosswind-smoothed mass-equivalent concentration map in a vertical plane from the downwind PIC data. Once all parameters for the bivariate Gaussian function are measured for a specific run, the VRPM procedure calculates the mass-equivalent concentration values for every square elementary unit (4×4 m) in a vertical plane. Then, the VRPM procedure computes and integrates the elementary unit flux over the entire vertical plane with corresponding wind speed data. Arcadis Inc. (Research Triangle Park, NC) developed the computer-based VRPM software which automatically calculates the emission rates based on the downwind PIC data, wind speed and direction information using the VRPM algorithm.

The objective of this study was to measure the ammonia emissions from the 5,145-head swine finishing farm with the new on-farm manure treatment system during a 2-year evaluation using the VRPM technique.

MATERIALS AND METHODS

Farm Description

The total NH_3 emissions from a finishing swine farm in North Carolina with a full-scale manure treatment system were measured from December 2006 to September 2008. The farm had seven swine houses with a permitted capacity of 5,145 head feeder to finish (735 head/barn). Two traditional anaerobic lagoons were used for about 11 years before the new manure treatment plant started operation in December 2006. With the new treatment system, the flushing of raw wastewater into the lagoons was discontinued. The treatment system consisted of three process units in series: polymer-enhanced solid-liquid separation, biological N removal, and alkaline phosphorus extraction and disinfection. More detailed description of the new manure treatment system and the farm operation can be found elsewhere (Vanotti et al., 2018).

Open-Path Tunable Diode Laser Absorption Spectroscopy

An open-path tunable diode laser absorption spectrometer (TDL; GasFinder2.0 for NH_3, Boreal Laser Inc., Edmonton, AB, Canada) was used to measure path-integrated concentrations (PICs) of NH_3. The TDL mounted on an automatic positioning device (APD; Model 20 Servo, Sagebrush Technology, Inc., Albuquerque, NM) emits a collimated beam (1,512 nm) aimed at distant three mirrors (retroreflectors) from which it is reflected to the TDL's detector. The TDL was designed for a sampling rate of about 1 Hz and had continuous internal calibration updates every 40 samples using an internal reference cell. The signal from the measurement path is compared with the signal from the internal reference cell and calculate the average gas concentration in the path as μL L^{-1}-m (i.e., μL L^{-1} multiplied by path length in m). The TDL also calculates the coefficient of determination (R^2) for each measurement to indicate the similarity between the waveform of the sample gas to that of the reference cell gas. A perfect match of the two waveforms would give R^2 of 1.0, and total mismatch would give R^2 of 0.0. Although the company recommends 5 μL L^{-1}-m as the minimum detection limit (MDL) for NH_3, we decided to determine the MDL for our TDL that would yield $R^2 > 90\%$. Determining the reliable value of MDL was important because the new manure treatment system dramatically improved the lagoon water quality and the NH_3 emission was so low that the path-integrated NH_3 concentrations measured with our TDL became at or below the MDL during the second year of the manure treatment operation in 2008.

The MDL of our TDL was determined by measuring PICs through a 4.5-m PVC pipe (5.1 cm diameter) in which 3 L min^{-1} of a mixture of pure N_2 and calibrated NH_3 gas (5.0 ppm, National Welders Supply Co., Inc., NC) flew through the PVC pipe. The two ends of the PVC pipe were sealed with transparent plastic film. Initially the PVC was filled with ultra-pure nitrogen gas (National Welders Supply Co., Inc.). Using a gas divider (SGD-710C, Horiba STEC, Sunnyvale, CA), gas mixtures of 10% NH_3 + 90% N_2 (0.5 μL L^{-1}-m NH_3), 30% NH_3 + 70% N_2 (1.5 μL L^{-1}-m NH_3), 50% NH_3 + 50% N_2 (2.5 μL L^{-1}-m NH_3), 70% NH_3 + 30% N_2 (3.5 μL L^{-1}-m), and 100% NH_3 (5.0 μL L^{-1}-m) were introduced into the PVC pipe. The measured PICs and the corresponding R^2-values were plotted as shown in **Figure 1**. We also plotted the average NH_3 PICs at different R^2-values (**Figure 2**). The average PIC was 5.3 μL L^{-1}-m at R^2 of 80% (**Figure 2**), which was similar to the NH_3 MDL (5.32 μL L^{-1}-m) reported by the U.S. Environmental Protection Agency's (EPA's) Environmental Technology Verification (ETV) statement (Myers et al., 2000). The MDL with R^2 of 90% was 8.1 μL L^{-1}-m. We used the MDL of 8.1 μL L^{-1}-m, when we observed the NH_3 PICs were below MDL during the second year of the new manure treatment system in 2008, to calculate the MDL for the VRPM NH_3 emission rate determination.

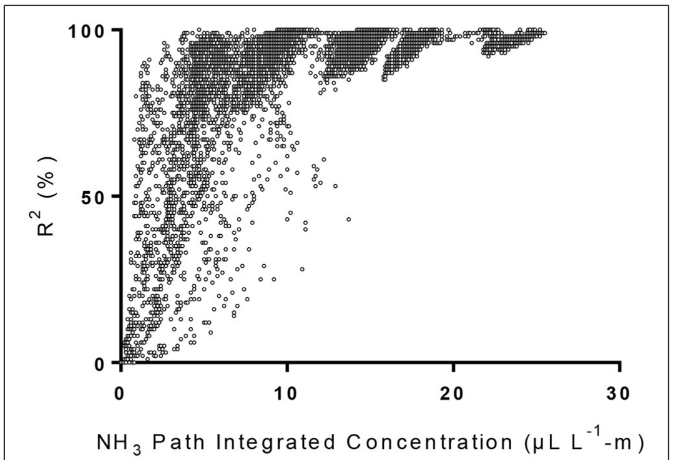

FIGURE 1 | Individual NH_3 path integrated concentrations (PICs) with associated R^2.

Total NH_3 Emission Rate Measurements Using the VRPM Technique

Total NH_3 emission rates from the swine farm (animal houses, lagoons, and the wastewater treatment system) were measured using the VRPM technique. The VRPM technique utilized the TDL mounted on the APD to measure downwind NH_3 PICs with 3 distant retroreflectors, one positioned at ground-level and the other two mounted on a weather station mast (10 or 20 m height). The upwind NH_3 concentrations were measured with a photoacoustic gas analyzer (INOVA, California Analytical, Orange, CA). The ranges of path lengths and the heights of the three retroreflectors are shown in **Table 1**. The path length between the TDL and the retroreflectors ranged from 129 to 266 m. The VRPM system was positioned downwind from the farm on a vertical plane, approximately perpendicular to the mean wind direction. The wind directions were mostly NNW or NNE. **Figure 3** shows the VRPM setup with the vertical plane approximately perpendicular to the NNE wind. The APD sequentially directed the infrared collimated beam of the TDL to each retroreflector. At each retroreflector, the TDL collected about 12–15 downwind PIC datasets before moving to the next position. Two cup anemometers (CS800-L Climatronics Wind Speed and Direction Sensor, Campbell Scientific, Logan, UT) mounted on the weather station mast at 2 and 10 m heights continuously measured wind speed and direction information during the emission monitoring campaigns.

The post-data filtering criteria recommended by the USEPA OTM−10 were used to remove error-prone data: concordance factor (CCF) > 0.8 (except when estimating the below minimum detection level emission rates with all PICs assuming to have the MDL of 8.1 μL L^{-1}-m) and the mean wind direction between -10^o and $+25^o$ from perpendicular to the vertical

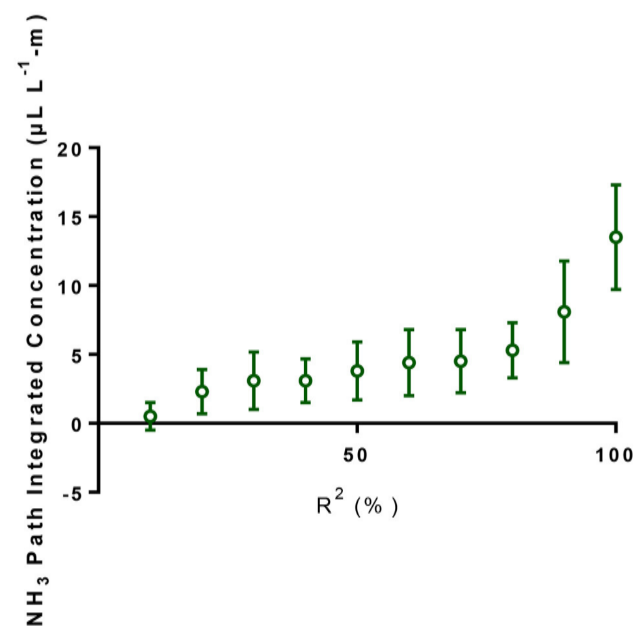

FIGURE 2 | Average NH_3 path integrated concentrations at desired R^2.

optical plane. After filtering data with the above criteria, the relative accuracies (calculated emission rate/actual emission rate) of the VRPM technique were 1.23 ± 0.17 (i.e., 23% over the actual emission rate) and 0.97 ± 0.44 (i.e., 3% less than the actual emission rate) for multi land emission sources and lagoon emission, respectively (Ro et al., 2011; Viguria et al., 2015).

Lagoon Emission

In addition to the VRPM technique for measuring whole farm NH_3 emission rates, the lagoon emissions were further verified using floating chamber techniques to compare the emission fluxes before and after the new treatment system reaching its steady state condition. The lagoon NH_3 emission fluxed were measured on June 18, 2007 while the treatment system was still under a startup period and on July 24, 2008 when the new treatment system was operating steady state.

Floating Static Chamber System

The static flux chamber was made of polyvinyl chloride (PVC) pipe (15.2 cm diameter and 29.8 cm length) one end sealed with an endcap. It was placed at the center of a 50.8 cm square foam sheet (thickness of 5.1 cm) to float on the lagoon water surface. The system was designed to submerge 11 cm of the PVC pipe under water to achieve a complete seal of the chamber headspace. The headspace gas was pulled from the chamber through Teflon tubing to the photoacoustic gas analyzer positioned at the bank of the lagoon and the analyzed gas was recirculated back to the chamber, thereby achieving well mixed condition inside the chamber. The floating flux chamber was launched into the lagoon at about 10 m away from the bank. The lagoon NH_3 emission was measured from 6 (3 points in each lagoon in 2007) to 10 (4 points in Lagoon 1 and 6 points in Lagoon 2 in 2008) different locations of the lagoons. After the treatment system started, Lagoon 2 became inactive without receiving anymore flushed manure from the pig houses. Instead, all manure flushed from the houses was treated first by the new treatment system and the treated effluent was stored in Lagoon 1 before use in crop irrigation. The increase in headspace NH_3 concentration was measured every 0.5–1 min with the photoacoustic gas analyzer for 10 min. The time-series headspace NH_3 concentration data were then used to calculate emission fluxes.

The NH_3 emission flux was calculated by fitting the time-series headspace NH_3 concentration data to a theoretical equation derived from performing a mass balance around the chamber. Assuming that the chamber is completely mixed and sealed, NH_3 mass balance around the chamber gives

$$\frac{dC}{dt} = k\,(C_S - C)\,d \tag{1}$$

TABLE 1 | Retroflector positions.

Retroreflectors	Height above ground (m)	Pathlength (m)
Retroreflector 1 (M1)	1.0	199.2–266.2
Retroreflector 2 (M2)	5.0 or10.0	128.6–228.5
Retroreflector 3 (M3)	10.0 or18.4	128.6–228.5

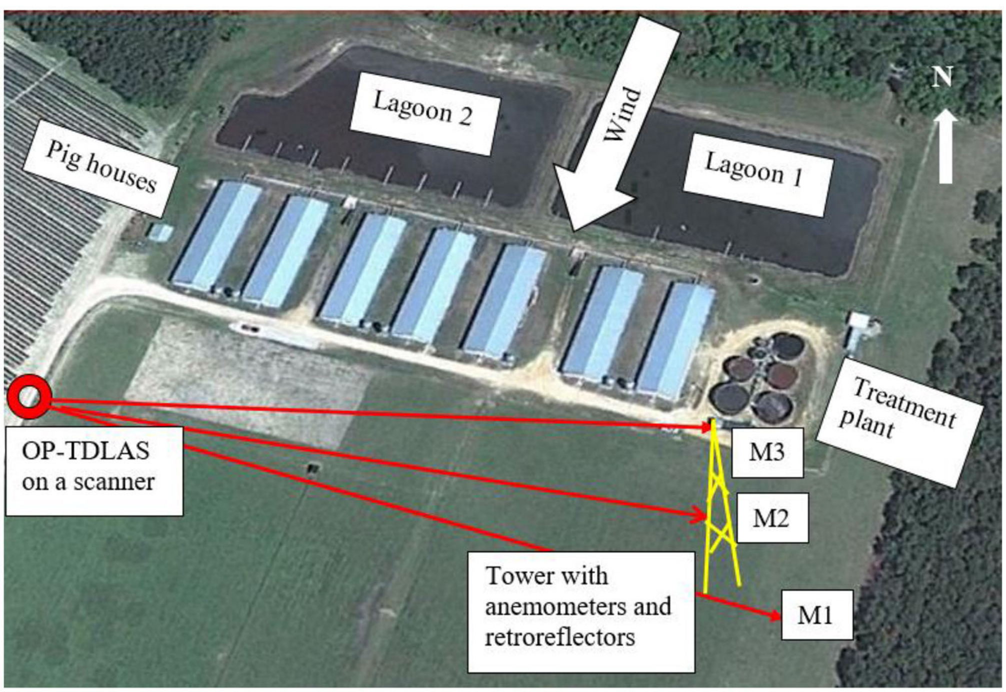

FIGURE 3 | VRPM beam geometry for NNE wind (M1, retroreflector 1 m above ground; M2, retroreflector at 5–10 m above ground; M3, retroreflector at 10–18.4 m above ground).

Where

C $=$ bulk headspace NH_3 concentration (mg m^{-3}),
C_S $=$ NH_3 concentration at the water surface (mg m^{-3}),
d $=$ mixing height of the flux chamber (m^2)
$= A_d/V$
A_d $=$ water surface area (m^2),
V $=$ headspace volume (m^3),
k $=$ mass transfer coefficient (m min^{-1}),
t $=$ time (min),

Integrating Equation (1) gives

$$C = C_S - (C_S - C_O)\exp\left(\frac{-kd}{t}\right) \quad (2)$$

Where CO $=$ initial headspace concentration (mg m^{-3}).

Instead of assuming initial concentration of ambient concentration, all three parameters (i.e., C_S, C_O, and k) were estimated simultaneously via non-linear regression analysis of the time-series headspace NH_3 concentration data using GraphPad Prism 7.03 (GraphPad Software, Inc., La Jolla, CA). This simultaneous regression of multi-parameters were recommended by the American Society of Civil Engineers (ASCE) in estimating oxygen transfer efficiency with the similar equation (ASCE, 1992). These three parameters estimated from fitting the time-series NH_3 concentration data to Equation (2). were then used to calculate the instantaneous flux (J) as time approached zero:

$$\left.\frac{dC}{dt}\right|_{t\to 0}\left(\frac{V}{A_d}\right) = J = k\,(C_S - C_O) \quad (3)$$

Statistical Analysis

The central tendency and precision of measurements were presented with arithmetic averages and standard deviations (given as $\pm$ values). All statistical parameters, analyses of variance (ANOVA) tests, and multi-regression analyses were obtained/performed using GraphPad Prism 7.03.

RESULTS AND DISCUSSION

Ammonia Emission Flux From Lagoons Using Floating Static Flux Chamber Technique

The increases in static flux chamber headspace NH_3 concentration with time at 6 (6/18/2007) and 10 (7/24/2008) different locations of the two lagoons and average NH_3 fluxes from each lagoon are shown in **Figure 4** and **Table 2**. Ammonia fluxes from the two lagoons ranged from 14.4 to 78.8 kg-N ha^{-1} d^{-1} with an average flux of 32.8 $\pm$ 24.2 kg-N ha^{-1} d^{-1} in 2007 (**Table 2**). These NH_3 emission fluxes were comparable to that from conventional swine lagoons without any manure treatment during summer months as reported in the literature (Arogo et al., 2003). It also indicated that the new treatment system had not yet been effective in reducing NH_3 emission from the lagoon 1 receiving treated effluent. Therefore, we decided to discontinue the VRPM monitoring of whole farm NH_3 emission rates until

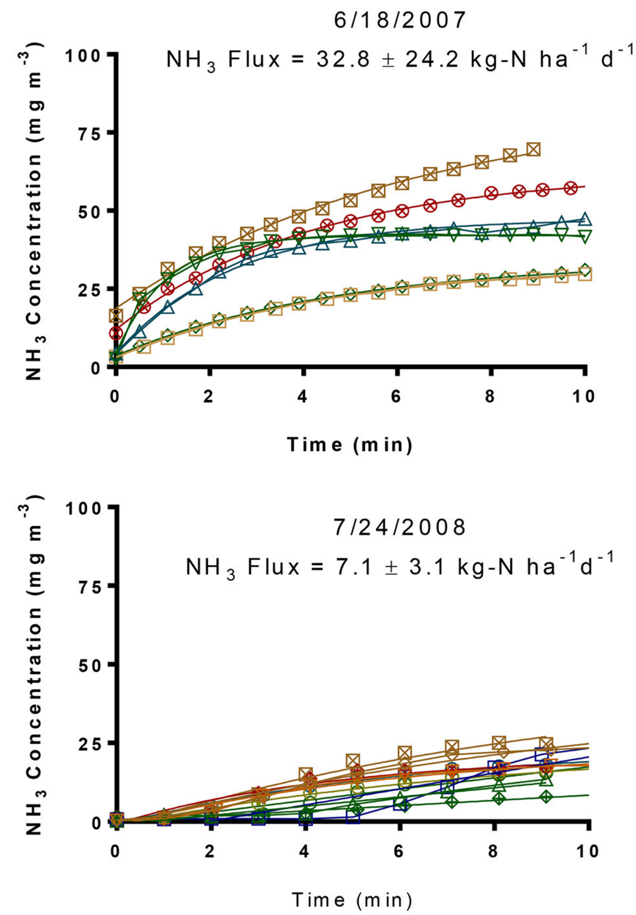

FIGURE 4 | Floating flux chamber headspace NH_3 concentrations from two treatment lagoons in summer 2007 and 2008.

TABLE 2 | NH_3 emission fluxes from the two lagoons.

	Emission Flux in June 2007 (kg-N ha^{-1} d^{-1})	Emission Flux in July 2008 (kg-N ha^{-1} d^{-1})
Lagoon 1	43.9 $\pm$ 32.4[a†]	6.8 $\pm$ 2.8[b]
Lagoon 2	21.7 $\pm$ 6.5[a]	7.3 $\pm$ 3.6[b]
Average for both lagoons	32.8 $\pm$ 24.2	7.1 $\pm$ 3.1

†*Emission flux values followed by the same superscript letter (a or b) were not significantly different at $P < 0.05$ (ANOVA).*

the new treatment system reached steady state and impacted NH_3 emission from the farm.

Figure 4 (bottom) shows that the flux-chamber time-series headspace ammonia concentrations increased to less than 25 mg L^{-1} after the chamber was deployed. In contrast, the NH_3 concentrations increased to 75 mg L^{-1} 10 min after deployment, indicating much higher emission fluxes in 2007 than in 2008. The NH_3 emission fluxes from the two lagoons ranged from 1.9 to 11.0 kg-N ha^{-1} d^{-1} with an average flux of 7.1 kg-N $\pm$ 3.1 kg-N ha^{-1} d^{-1}. The average NH_3 emission fluxes were 6.8 $\pm$ 2.8 kg-N ha^{-1} d^{-1} from Lagoon 1 and 7.3 $\pm$ 3.6 kg-N ha^{-1} d^{-1} from the inactive Lagoon 2. The significant decrease in NH_3 emission fluxes resulted from improving lagoon water quality by the new treatment system for Lagoon 1. The NH_3 emission flux from Lagoon 2 also decreased because the already stored old manure of the Lagoon 2 prior to inactivation was diluted with rainfalls and lost some NH_3 via volatilization. The decrease in NH_3 emission flux was further validated by the fact that the total ammoniacal N (TAN) of the lagoon liquid in June 2007 was 197 mg L^{-1} [or 20.0 mg L^{-1} $NH_{3\ (aq)}$-N] while that in July 2008 was only 32.7 mg L^{-1} {32.5 and 33.0 mg L^{-1} TAN [or 5.1 and 2.8 mg L^{-1} $NH_{3\ (aq)}$-N] for Lagoons 1 and 2, respectively} (Vanotti et al., 2018). These results suggested that the impact of the new treatment system on NH_3 emission reduction was equivalent to closing conventional swine lagoons while actively growing 5,145 pigs.

Whole Farm Ammonia Emission Reduction With the VRPM Technique

The NH_3 emission rates, measured with the VRPM technique, were the whole-farm emission rate that included three main NH_3 sources: (1) the NH_3 emissions from seven animal houses, (2) the new wastewater treatment system, and (3) the two lagoons (**Figure 3**). These NH_3 emissions rates were measured from 12/7/2006 to 9/17/2008 (**Table 3** and **Figure 5**). The start date (12/7/2006) was a day before the start date of the new wastewater treatment system. The NH_3 emission rate on 12/7/2006 was 0.80 g/s. However, 3 months after starting the new treatment system, the NH_3 emission rate increased to 2.64 g/s, because the air temperature along with the wind speed were much higher. In addition, it was too short period of time to observe the impact of the new treatment system on lagoon water quality (the lagoon renovation capacity with treated effluent was 1.2 lagoon volumes per year or hydraulic residence time, HRT = 0.8 years). After observing the NH_3 emission flux from the lagoons was comparable to that from conventional swine lagoons without any treatment (**Figure 4** top), NH_3 emission rate was not measured for the rest of 2007 to give more time for the new manure treatment system fully impacting the total farm emission. In 2008, NH_3 emission rates were monitored in relatively cold (4/4/2008), mild (9/16–9/17/2008), and hot days (7/24/2008 and 8/20/2008). Regardless the the wide variation of air temperatures and wind speeds, in the second year, downwind NH_3 PICs were all below the MDL (i.e., 8.1 μL L^{-1}-m) of TDL. Below-detection-limit emission rates of these days were estimated by assuming all PICs had the MDL concentration of 8.1 μL L^{-1}-m (**Table 3**). These below-detection emission rate ranges from 0.04 to 0.15 g/s, more than an order of magnitude lower the initial emission rates. These data clearly demonstrated that the new treatment system substantially reduced the NH_3 emission from the swine farm.

The NH_3 emissions rates obtained prior and during initial operation of the new wastewater treatment in this full-scale study were compared to emissions rates from other full-scale studies with conventional and converted lagoons in North Carolina. Initially with lower air and lagoon water temperatures (December 2006), the estimated live weight (LW) based emission rate of 0.80 g s^{-1} [1.19 kg N wk^{-1} (1,000 kg $LW)^{-1}$] was similar to the winter combined house-lagoon NH_3 emission rate of 1.06 kg N wk^{-1} (1,000 kg $LW)^{-1}$ from a conventional swine farm with similar number of pigs for a 5,784-head finisher farm using anaerobic lagoon technology (Aneja et al., 2008a). The emission rate obtained immediately after beginning the new treatment system in February 2007 was 2.64 g s^{-1} [3.92 kg N wk^{-1} (1,000 kg $LW)^{-1}$], due to very high wind speed at that day (8.33 m/s compared to 2.67 m/s in 12/7/2006) while the water temperatures were similar. The emission rate was almost linearly increased

with wind speed. Note that during this initial startup period, the effects of the new treatment system on lagoon water quality were minimal.

After 1.5 years of operation the total emissions (combining animal houses, treatment plant, and lagoons) of the treatment plant were <0.15 g s^{-1} [0.22 kg N wk^{-1} (1,000 kg LW)$^{-1}$] for April 2008 (**Table 3**). Astonishingly, even for hot days in July and August 2008, the downwind NH_3 concentrations were below its detection limit. Comparing to swine lagoon NH_3 emission rates with similar water temperature of 30.2°C [2.4 kg N wk^{-1} (1,000 kg LW)$^{-1}$, (Szogi et al., 2006)], this reduction in total NH_3 emission was indeed remarkable.

Compared to the average of the first two emissions for the periods of December 2006 and February 2007 (1.72 g s^{-1}), total NH_3 emissions from the April 2008 to September 2008 periods were reduced by 94%. In comparison, the new treatment plant removed an average of 96.5% of the soluble NH_4-N contained in the raw flushed manure with most of the removal (84%) occurring at the biological N treatment step (Vanotti et al., 2018). Concentrations of NH_4-N in the lagoons were also reduced significantly during the emission evaluation period from 371 to 485 mg L^{-1} in 2006 to lower than 65 mg L^{-1} in 2008 (Vanotti et al., 2018).

Low NH_3 emission rates similar to those recorded in 2008 were also found in earlier studies (Aneja et al., 2008b) of a first generation version of the same wastewater treatment system (Vanotti et al., 2007) that was retrofitted in a 4,360-finishers production unit and removed 98.7% of the soluble NH_4 from liquid waste. According to Aneja et al. (2008b), the NH_3 emissions for this first-generation wastewater treatment plant were 0.02 kg N wk^{-1} (1,000 kg LW)$^{-1}$ in the warm season and 0.0004 kg N wk^{-1} (1,000 kg LW)$^{-1}$ in the cold season. These low NH_3 emissions represented reductions of 94.4% for the warm season and 99.0% for the cool season with respected to a conventional lagoon system (Aneja et al., 2008a). On a separate study of the same first-generation wastewater treatment system, Szogi et al. (2006) found that total annual NH_3 emission from the converted lagoon was 1,210 kg N y^{-1} and equivalent to 0.10 kg N wk^{-1} (1,000 kg LW)$^{-1}$. In contrast the NH_3 emissions from the conventional lagoon totaled 12,540 kg N y^{-1} [1.22 kg N wk^{-1} (1,000 kg LW)$^{-1}$]. Compared with the conventional lagoon, annual NH_3 emissions from the converted lagoon were reduced 90% (Szogi et al., 2006).

The NH_3 concentration in the air inside the houses was also reduced as a result of recycling cleaner water for pit recharge under the animal houses (Szogi and Vanotti, 2008). Compared with the previous conventional lagoon management, the new treatment system lowered NH_3 concentrations in the house exhaust air by an average of 75.1%. Even though the wastewater treatment had instant effect on reducing NH_3 in the manure, and the NH_3 in the recycled water used for flushing the barns, the beneficial effects on emissions at the farm level were not seen immediately; the dirty liquid in the former lagoons needed time to be cleaned up. Actual lagoon 1 volume was 9,565 ± 750 m^3 and received 11,552 m^3 per year of the clean plant effluent (Vanotti et al., 2018). In this study, one year of continuous operation of the wastewater treatment plant was necessary to observe marked differences in NH_3 emissions at the farm level.

SUMMARY

The NH_3 emissions from a 5,145-head finishing swine farm before and after the new manure treatment system implementation were measured using both micrometeorological VRPM and static chamber techniques. The NH_3 emission flux from the lagoons decreased from 32.8 to 7.1 kg-N ha^{-1} d^{-1}. The reduction in the total farm NH_3 emission was even more dramatic: All downwind NH_3 concentrations 1.5 year after starting up of the new treatment system were all below MDL. The dramatic decrease in total ammoniacal nitrogen in the lagoon validated this exceedingly low NH_3 emission from the farm.

AUTHOR CONTRIBUTIONS

KR designed and conducted the emission experiments, collected and post-processed data, and wrote the draft. MV, AS, JL, and PM conducted water quality work, data summarization and processing. All authors participated in writing of the manuscript.

Biogas plant

ABSTRACT

The paper deals a case study of solid-liquid separation (SLS) approaches for swine manure biogas recovery in a system configured to treat solid fraction on Continuous Stirred Tank Reactor (CSTR) and liquid fraction on Covered lagoon biodigester (CLB) in a large scale. At the same time, scale down reactors on laboratory scale were operated under same conditions. Biogas productivity of full-scale CSTR showed an average of 0.65 ± 0.23 $NL_{biogas}\ L^{-1}{}_{reactor}\ d^{-1}$, while CLB was around 0.18 ± 0.05 $NL_{biogas}\ L^{-1}{}_{reactor}\ d^{-1}$. The results of lab-scale can predict digestion capability and methane recovery for full-scale system. Economy in biogas plant construction and operation, biogas generation constantly and digestate treatment system implementation are the mainly benefits to use SLS followed different reactor configurations. Biological desulfurization process was dependent of biogas retention time. By the way, operational improvements made on large scale have allowed an advance in the productivity and biogas quality.

1. Introduction

Swine farming has changed from small family farms to large concentrated animal feeding operations (CAFO's) to increase swine production at lower cost and sanitary benefits (Moses and Tomaselli, 2017; Wang et al., 2019). It is an important activity for Brazil's economy, being result of work in development, modernization, and intensification this sector. Brazil appears as 4th largest in global majors' producer of swine meat, with 4.1 million tons annually (USDA, 2021).

Considering the large production and consequently huge amounts of swine manure, anaerobic digestion (AD) is considered an environmentally friendly technology that combines biogas production and sustainable waste management, being a key process in any swine manure treatment system (Tápparo et al., 2020). Besides, due to large volume of swine manure produced in a restricted area, traditional methods of disposal, like land application, posed pressure on the environment. This situation represents a risk to the expansion of swine farming and consequently as an economic activity (Kunz et al., 2009b).

AD has intensified in Brazil in view of the low cost, easy operation, high efficiency in reducing odors by using covered lagoons biodigesters (CLB) and energy use of biogas. However, these biodigesters have limitations, such as work better for liquid manure with less than 3% total solids, low organic loading rate (approximately 0.5 $kg_{VS}{\cdot}m^{-3}d^{-1}$) (Wu, 2013), biogas production varies seasonally, because reactors are not heated and depend of ambient temperatures (Khanal et al., 2019). Furthermore, microorganisms and liquid have limited contact since there is no agitation, biogas yield (0.36 $m^3{\cdot}kg_{VS}^{-1}$) is lower than others technologies and periodic cleaning is necessary due to fixed solid accumulation (Cantrell et al., 2008; Yu and Schanbacher, 2010).

In contrast, others different reactor models were developed, and its use is emerging. One example is the continuous stirred tank reactor (CSTR) that is widely used to substrates with high solids concentration, especially for the treatment of high-strength liquid animal manure (Mao et al., 2015). Microorganisms are suspended due to complete mixing in CSTR and this condition offers good substrate-sludge contact, increasing mass transfer resistance and consequently AD occurs swiftly (Tauseef et al., 2013; Wei et al., 2019). Combined with temperature control (mesophilic and thermophilic), this design provides higher biogas

productivity (>1.5 m^3_{biogas} $m^3_{reactor}$ d^{-1}), that in comparison to CLB the increase is over 10-fold (Cantrell et al., 2008). The feed should contain 3 to 10% total solids and short retention time (< 20 days) for swine manure. Nevertheless, this reactor design own relatively high capital, energy consumes, and need mechanical parts maintenance (Kress et al., 2018) and these drawbacks decrease the use in development countries.

On the other hand, because the low concentration of volatile solids of swine manure (between 1 and 5%) and high volume the maintenance of temperature a CSTR is difficult and consequently the energy recovery would be affected (Yang et al., 2015). Increasing solid concentration of substrate, through co-digestion (Tápparo et al., 2018) or using preliminary SLS are options to swine manure large-scale plants economic feasibility using of CSTR (Vu et al., 2016).

Previous studies evidence that using SLS processes, such mechanical separations, screens, gravity settling are ways for improve biogas generation. Additionally, the fractions of solid-liquid separation have different methane yields and afford more effective options for reactor design and operational conditions for swine wastewater treatment (Amaral et al., 2016; Chen et al., 2015; Yang et al., 2016).

Considering this background, the goal of this study is evaluating the process performance and biogas production of one combined system where after a solid-liquid separation unit, the solid fractions of swine manure are forwarded to CSTR and the liquid fraction directed to CLB comparing in lab and full-scale.

2. Material and methods

The research was conducted at a full-scale swine manure treatment system, localized in Videira, Santa Catarina – Brazil (27°02′S 51°05′W) and in laboratory of Embrapa Suínos e Aves, Concórdia, Santa Catarina – Brazil (27°18′S 51°59′W). The swine farm is a farrow to wean unit, with 5320 breeder sows. Swine manure treatment system consist in one solid-liquid separation unit (SLS), include a sieve with rotating brushes (2 mm sieves) and a settling tank (40 m^3), followed by one biodigester module where the liquid fraction is forwarded to a CLB and the solid fraction to a CSTR reactor. The configuration of the manure treatment system follows the Brazilian Patent of SISTRATES (PI1100464-9 A2) (Kunz et al., 2015). Data collection were in the years of 2018 and 2020. A flowchart of treatment system is shown on Fig. 1.

2.1. Biochemical biogas potential (BBP)

BBP was measured on samples of solid retained in sieve (SRS), settling tank sludge (StS), CLB sludge (CLBS), and supernatant (SN). Sampling was carried out on different seasons, respectively, summer (1), autumn (2) winter (3) and spring (4). Experiments were conducted in triplicate using 250 mL batch reactors bound to 500 mL eudiometer tubes. The system was maintained at a mesophilic temperature (37 °C). The biogas yield was evaluated until it became stable, which was indicated when the daily biogas production was less than or equal to 1% of the total biogas that had been produced, according to (VDI 4630, 2016). Inoculum containing mesophilic anaerobic microorganisms was prepared and used according to (Steinmetz et al., 2016). All samples were analyzed for total nitrogen (TKN), total carbon (TC), K, TP, total solids (TS), and volatile solids (VS).

2.2. Lab-scale reactors

The CSTR used was made of acrylic, had a working volume of 21 L and was jacketed, allowing water circulation for temperature control. Temperature was controlled by means of a thermostatic bath (JULABO, Model M8) kept in mesophilic range (37 °C ± 1). The daily feed was composed by a mixture of approximately 7% of CLBS, 10% of SRS and 83% of StS. The composition of CSTR feed was response of SLS module and necessity of CLB sludge discard.

CLB was made of acrylic, had a working volume of 17 L, without temperature control. Feed composition of this reactor was the supernatant after the SLS module as described in Fig. 1. Both reactors were manually fed intermittently once a day and biogas production was measured using Milligascounter (model MGC-1 V3.3 PMMA, Ritter, Germany). Methane concentration was evaluated using BIOGAS 5000 (Geotech, UK). The strategy for CLB start-up used 20% of working

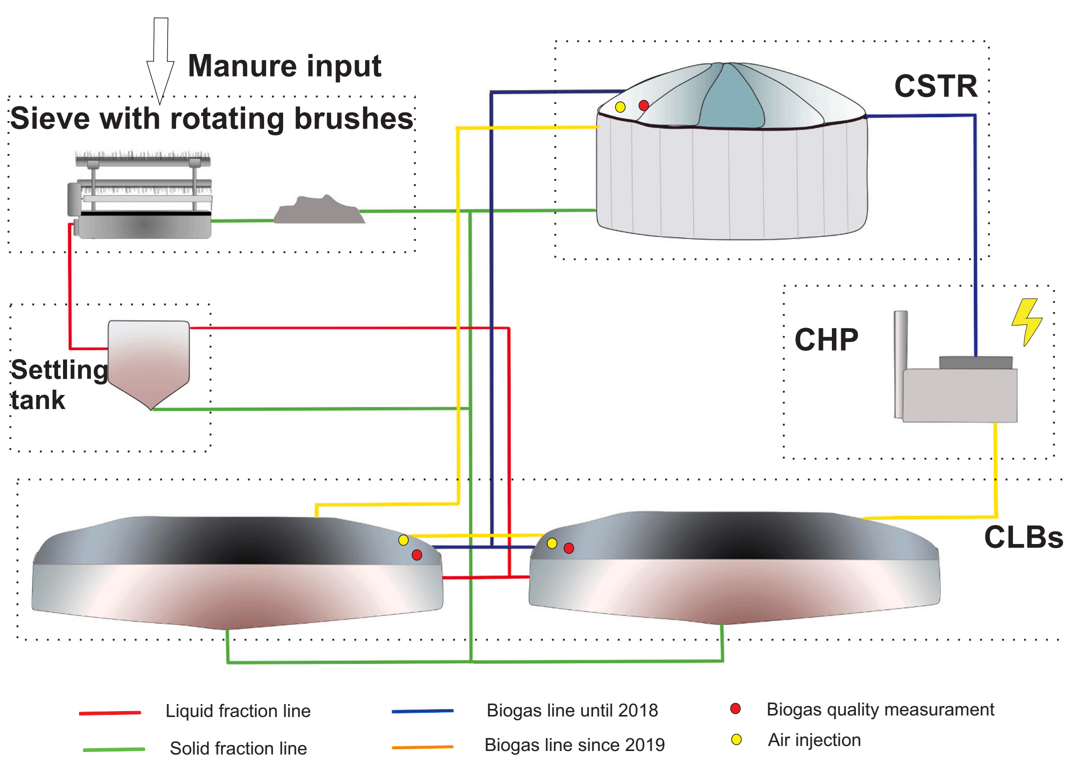

Fig. 1. Schematic of solid-liquid separation unit and biodigesters fed.

volume (3.4 L) of sludge and 80% (13.6 L) of effluent from a CLB reactor fed with swine manure from a commercial farm. The CSTR was started with 12 L of effluent (digestate) from a full-scale CSTR fed with solid fraction from a solid-liquid process unit installed in a swine manure treatment process from a commercial farm.

2.3. Full-scale reactors

The full-scale CSTR has a working volume of 700 m^3 and is operated under mesophilic conditions and built in concrete. The heating system was assembled to use the heat losses of a 300 kVA CHP unit used for electrical energy generation. CSTR mixing was performed by a side shaft, mixing took place for 5 min on every 30 min. The two CLB were built using a PEAD geomembrane and has a volume of 2500 m^3 each one, its flow is divided equally for these digesters. The CLBs are operated without heating system.

Thermal mass flow meters, model FT2 (Contech®, Brazil) were used for biogas quantification of both biodigesters. Biogas composition (CH_4, CO_2, O_2 and H_2S) was measured every 2 h using AwiFLEX (Awite®, Germany). The biogas analyzer includes the biological desulfurization module "AwiDESULF" (Awite, Germany), which automatically doses ambient air based on the measurements of H_2S and O_2 in the biogas. The system uses a combination of artificial intelligence (Fuzzy Logic) and conventional PI-control to regulate oxygen concentration in the biogas between 0.2 and 1%. As the digester headspace is used to achieve biological desulfurization by micro-aeration, no additional constructions are needed to use the system. For both reactors, feed conditions were the same as described for lab-scale reactors.

2.4. Analytical methods

TC was determined by CNHS elemental analyzer (model Flash 2000, Thermo Fisher Scientific, (Massachusetts, USA) following the manufacturer's instructions. Total phosphorus was determined using spectrophotometric molybdovanadate method on a spectrophotometer Cary 50 (Agilent, Santa Clara, USA). TKN was measured by Kjeldahl method on a digester and distillation unit model Kjeltec 8100 (Foss, Hilleroed, Denmark). The correlation between volatile fatty acids (VFA) and alkalinity (TA) was determined according Liebetrau and Pfeiffer (2016) by titration with sulfuric acid 0.05 mol L^{-1} in an automatic titrator, (model 848, Titrino plus, Metrohm, Switzerland), previously, samples were centrifuged (5488*g* for 7 min). TS, VS, pH and K were determined according Standard Methods (APHA, 2012).

3. Results and discussion

3.1. Samples characteristics and BBP assays

The characteristics of SRS, StS, CLBS and SN feedstock showed variation in all parameters, and in particular in BBP and CH_4 concentration in all collections due to temporal and seasonal changes (Table 1). Amaral et al. (2016) demonstrated that the methane potential of the StS fraction was approximately two times higher than the methane potential of the SN fraction. In the present work it was observed that 1 ton of StS fraction could produce about 16.2 ± 5.2 Nm^3 of biogas, while for SN fraction this production was reduced to 4.3 ± 1.4 Nm^3 (Table 1) and while for CLB the production was 3.0 ± 1.5 Nm^3. The SRS present the highest biogas production per fresh matter, around 96 ± 17 Nm^3. Despite the SN fraction showing a low methane production (fresh matter) and VS concentration, comparing with StS, it presents higher bioavailable carbon (Amaral et al., 2016). The swine manure characteristics and consequently biogas generation is linked with the inherent fluctuations of production process. The water consumption by swine's, animal number in the installations, swine growing phase, nutritional aspects and manure storage time directly influence concentration and biodegradability of manure (Amaral et al., 2016; Kunz et al., 2009a).

The differences in biodegradability and biogas potential of swine manure fractions enables the use of different reactors to recover biogas of each fraction. Due SRS and StS are produced in smaller volumes than SN it is easier to increase temperature and assure operation in mesophilic range. The settling process is an interesting strategy to improve biogas production, because using concentrated manure as a feedstock a smaller size digester is required to produce the same volume of biogas than it would need when using the raw swine slurry. Thus, the costs with reactor construction and heating system are lower (Deng et al., 2014). Moreover, sedimentation is an attractive option because of lower cost and simpler technology compared to others SLS, like centrifugation and pressurized filtration (Hjorth et al., 2011; Hollas et al., 2019).

The substrates that feed the CSTR reactor in this work concentrate the most part of nutrients (e.g. N, P, K) (Table 1), which consequently are preserved in digestate, producing high-quality organic fertilizer compared with digestate of swine manure. Therefore, CSTR digestate has a high agronomic value compare to the swine manure digestate.

3.2. Lab-scale reactors performance

The performance parameters of CSTR and CLB are presented in

Table 1
Swine manure samples characteristics. Volatile solids, biogas yield, N, P K and C each fraction.

Samples		BBP (NL_{biogas} kg_{VSadd}^{-1})			CH_4 (%)	TS (g kg^{-1})	VS (g kg^{-1})	TKN (g kg^{-1})	K (g kg^{-1})	TP (g kg^{-1})	TC (g kg^{-1})

Fig. 2A and B, respectively. Table 2 summarizes digestate analyses for lab-scale and full-scale digestion processes.

CSTR biogas productivity showed 0.61 $NL_{biogas}\ L^{-1}{}_{reactor}\ d^{-1}$, and biogas yield was around 0.46 $NL_{biogas}\ g^{-1}_{vsadd}$, while the BBP (based on Table 1) is approximately 0.32 $NL_{biogas}\ g^{-1}_{vsadd}$. The methane concentration ranged from 59 to 68%. In contrast CLB presented 0.2 $NL_{biogas}\ L^{-1}{}_{reactor}\ d^{-1}$ and 0.9 $NL_{biogas}\ g^{-1}_{vsadd}$ (BBP was 0.7 $NL_{biogas}\ g^{-1}_{vsadd}$) in stationary period with 70% of methane concentration. Due to SLS process, the manure forwarded to CLB contains only between 0.5 and 1% of VS (Table 1). This low concentration of solids and high bioavailability of carbon present in this fraction explains the higher biogas yield of CLB compared to CSTR, that is fed with food residues, nondigested fed and pig hair residues, that present low biodegradability (Amaral et al., 2016; Zhang et al., 2014).

The BBP predictions (Table 1) with lab results for CSTR and CLB biogas yield showed that experimental values were 43% and 28% higher than predicted values, respectively. Notwithstanding, for CSTR, the mixture of this substrates probably had shown a synergic effect, when compared with digestion of individual samples. As shown in Table 2, the pH for both reactors remained between 7.26 and 7.86 and VFA/TA ratio did not rise above the critical value of 0.4, indicating good process stability. Biogas yield and productivity showed an initial transitory state, attributed to the star-up to the process establishment with a balance between hydrolytic, fermentative bacteria and methanogenic archaea (Bouallagui et al., 2010).

3.3. Full-scale reactors performance

CSTR feeding consist in a mixture of SRS, StS and CLBS, as aforementioned. The flow rate was 20 ± 5 $m^3\ d^{-1}$ with a VS concentration of 60.6 ± 10.8 kg m^{-3}. Until operational day 152, the OLR was 1.69 ± 0.34 $kg_{\ VSadd}\ m^{-3}\ d^{-1}$, biogas productivity showed 0.65 ± 0.23 $NL_{biogas}\ L^{-1}{}_{reactor}\ d^{-1}$, and biogas yield was 0.38 ± 0.14 $NL_{biogas}\ g^{-1}_{vsadd}$. Between 121 and 155 operation days a maintenance in agitation system was performed and the reactor was opened. For this maintenance it was necessary to reduce about 33% of reactor volume and this occurred during winter time, causing the decrease of temperature in the biodigester up to 10 °C. During this time biogas production was not registered, after the maintenance conclusion the process was restarted. Biogas productivity decreased to 0.48 ± 0.18 $NL_{biogas}\ L^{-1}{}_{reactor}\ d^{-1}$ and biogas yield to 0.29 ± 0.10 in an OLR of 1.68 ± 0.24 (Fig. 2 C). This difference was attributed to the decrease in biodigester temperature. Already, CLB was feeding with the SN, in a flow rate of 76 ± 29 $m^3\ d^{-1}$ (each biodigester), with VS concentration of 11 ± 2.5 kg m^{-3}. Biogas productivity was 0.18 ± 0.05 $NL_{biogas}\ L^{-1}{}_{reactor}\ d^{-1}$ and 0.56 ± 0.27 $NL_{biogas}\ g^{-1}_{vsadd}$ with OLR 0.35 ± 0.16 $kg_{VSadd}\ m^{-3}\ d^{-1}$ (Fig. 2 D). A decrease in biogas yield between the days 165–184, was due to the temperature decline of 5 °C. A decrease in the biodigester internal temperature had impact on degradation efficiency and consequently in biogas production, a decline of 7 °C could reduce up to 30% the biogas production (Schmidt et al., 2019). One of the main CLB characteristics is the absence of heat systems, consequently a variation on biogas production is expected. This reactor configuration is indicated to geographical regions with moderate or elevated year-round temperatures. However, due to the economy in construction and operational simplicity, its use justifies the lowest AD efficiency compared with others configuration (Yu and Schanbacher, 2010).

3.4. Lab-scale versus full-scale results

The comparison of results for continuous reactors (CSTR and CLB) showed that the lab-scale predict full-scale biogas yield and biogas productivity. The variability of biogas yield and biogas productivity are attributed to the lack in heating and HRT fluctuations in the AD system, that can be attributed to manure composition and volume. This is caused by limitations of large-scale process control, leading to fluctuations in operating parameters (e.g. variations in HRT, biodigester external temperature influence and variations in substrate composition). In the lab-scale reactors a higher process control was provided comparing to full-scale, thus allowing to predict the operating parameters of the full-scale reactor.

Moreover, must be highlighted that the HRT and solids retention

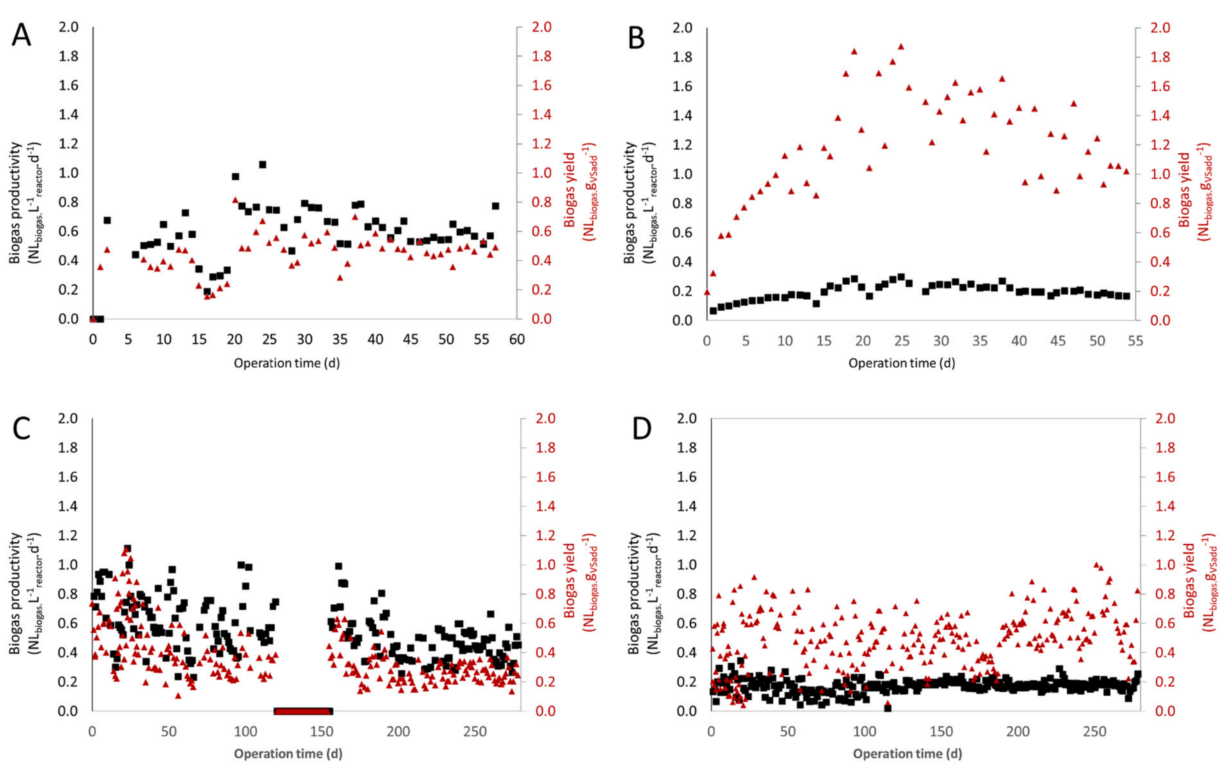

Fig. 2. Biogas yield and productivity of reactors studied. A. CSTR lab-scale. B CLB lab-scale. C. CSTR full-scale. D. CLB full-scale.

Table 2
CSTR and CLB reactor performance and efficiency on volatile solid reduction from full and lab scale.

		pH			HRT (d)			OLR ($kg_{vsadd}\cdot m^{-3}{}_{reactor}\cdot d^{-1}$)			T (°C)			VS removal (%)			VFA/TA ($mg_{HAC}\cdot mg_{CaCO3}^{-1}$)		
Lab Scale	BLC	7.46	±	0.22	30	±	0	0.165	±	0	24	±	1.2	71	±	7	0.289	±	0.064
	CSTR	7.76	±	0.20	36	±	1.5	1.340	±	0.09	37	±	1.0	58	±	7	0.117	±	0.009
Full Scale	BLC	7.37	±	0.17	28	±	11	0.356	±	0.163	23	±	3.5	63	±	8	0.330	±	0.116
	CSTR	7.72	±	0.26	38	±	8	1.618	±	0.418	34	±	4	55	±	4	0.122	±	0.045

time is different in CLB. Therefore, the inoculum used in start-up of lab-scale reactor can be contributed with biogas production, and maximizing the biogas yield, since the inoculum is from a covered lagoon biodigester operating for 13 years. Nevertheless, around 55 to 60% and 60 to 70% of the VS for CSTR and CLB, respectively, were degraded to biogas in both digester scales. Lower VFA/TA ratios and high pH stability were also observed which means that anaerobic production efficiency of biogas in a lab-scale was reproduced in full-scale digester.

Furthermore, based on CSTR full-scale stability, the OLR could be increased, without process failure, increasing global biogas production and energy conversion. The Fig. 3 shows the global biogas production of the full-scale system where it could be observed that in approximately one year of monitoring 370,000 m^3 of biogas were produced, being used in the CHP unit. SRS and StS represented 10% of the volume of initial wastewater and contained around 27% of organic materials, methane and nutrients and contributed with around 30% of global biogas generation.

3.5. Learning with large-scale biological desulfurization

Desulfurization is required to avoid damages to combustion equipment. H_2S in combination with humidity can form corrosive acids, which is besides its toxicity the main reason to remove it, before the gas is used. The injection of small amounts of oxygen or ambient air into the biodigester headspace is a well-known and comparatively cheap way to reduce the H_2S concentration significantly. To avoid formation of sulfuric acid (H_2SO_4) and other compounds, like SO_2, as acid rain precursor, it is important limit the oxygen content in biogas. In addition, it is known that excess of oxygen and the generation of sulfide inhibits methanogenesis (Hilton and Oleszkiewicz, 1988). Over the period of full-scale monitoring, it was possible to identify daily variations in the quality of biogas influenced by operational variations of the system. The high data resolution (biogas sampling every 2 h) allowed a better understanding of H_2S generation and to make decisions regarding changes in the plant to benefit the microaerobic desulfurization system.

One of the perceptions was the direct influence of the biogas residence time (BRT) on the biodigester headspace in the H_2S concentration. The Fig. 4a shows H_2S concentration at biogas headspace in the CLB that would occur daily during the operation of the electric generator group (CHP unit). At some periods, the generation of electric energy occurred in a discontinuous way (around 8 to 12 h d^{-1}) according to the biogas availability. In these periods, the flow variation of biogas consumption oscillated between zero (when CHP turned off) to 55 $m^3\ h^{-1}$ (when CHP turned on) and this produced an H_2S concentration increasing effect approximately from 50 to 500 ppm.

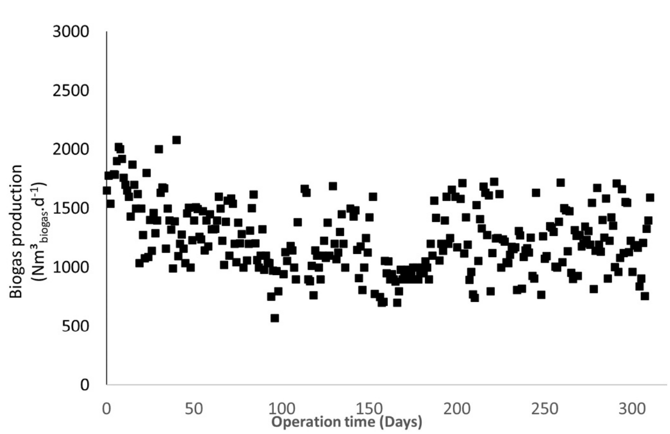

Fig. 3. Global biogas production of swine manure anaerobic digestion.

Another possible explanation for the growth of H_2S during the day could related to the manure loading in the digesters, since the operational management of the manure and cleaning of the swine facilities occurs manually during the morning period. It is known that the generation of H_2S is dependent on the organic loading in the digester, since the generation of the component gases of biogas is dependent on the of substrate composition (Hilton and Oleszkiewicz, 1988; Stams et al., 2003).

However, the Fig. 4a shows a strong correlation between H_2S and BRT. The concentration changes at the same moments when the consumption of biogas increases (CHP turn on) indicating that the BRT is the most important condition for the process control. The efficiency of biological desulfurization is dependent on the contact time of the sulfide oxidizing microorganisms with the biogas with oxygen levels below 1%. There is also a dependency on headspace homogeneity and microorganism abundance, but usually for a H_2S removal efficiency higher than 90% the BRT must be longer than 5–10 h (Khoshnevisan et al., 2017).

This BRT influence in the gas composition can also be observed by comparing the periods in which there was an inversion of the biogas flows. In the period prior to December 1, 2018, the biogas pipeline has been connected following the flow CLB ➔ CSTR ➔ CHP unit. The CSTR headspace volume is 530 m^3 resulting in an estimated BRT of 7–10 h. The CLB biogas capacity is 5600 m^3 that corresponding to the BRT of 66–100 h. After December 1, the flow changed to the sequence CSTR ➔ CLB ➔ CHP unit. The Fig. 4b present the temporal concentration of H_2S (gray line) and CH_4 (black line) at the CHP intake in the period between January 31, 2018 and March 31, 2020. The inversion of the flow allowed an increase in stability, resulting in a decrease in the average concentration of H_2S from 763 ± 823 to 457 ± 379 mg L^{-1} and an increase in the CH_4 concentration from 61.5 ± 2.4 to 65.2 ± 1.9%. This increase in the concentration of methane was expected, as it is already known that the better stability on sulfur oxidizing bacteria activity promotes a lower concentration of H_2S in the digester and thereby reduces competition with methanogenic microorganisms (Hilton and Oleszkiewicz, 1988; Mulbry et al., 2017; Ramos et al., 2014a, 2014b; Stams et al., 2003).

The robustness and efficiency of the desulfurization process was also observed. Fig. 4c shows the H_2S profile over 120 h of operation in which there happens an electric power failure to the desulfurization equipment and interrupted oxygen supplementation in the headspace of the CLB. Immediately the concentration of H_2S increased from 14 to 4388 ppm in a 56-h interval. After correcting the operational problem that generated the power interruption to the desulfurizer system, the H_2S concentration returned to the previous level after 32 h. Although a maximum stable value was not verified, it is possible to infer that the biological desulfurization presented an efficiency of H_2S removal above 98%. This is similar of the efficiency reported by Mulbry et al. (2017) that shown 99% removal efficiency for similar micro-aeration system in plug-flow reactor for dairy manure.

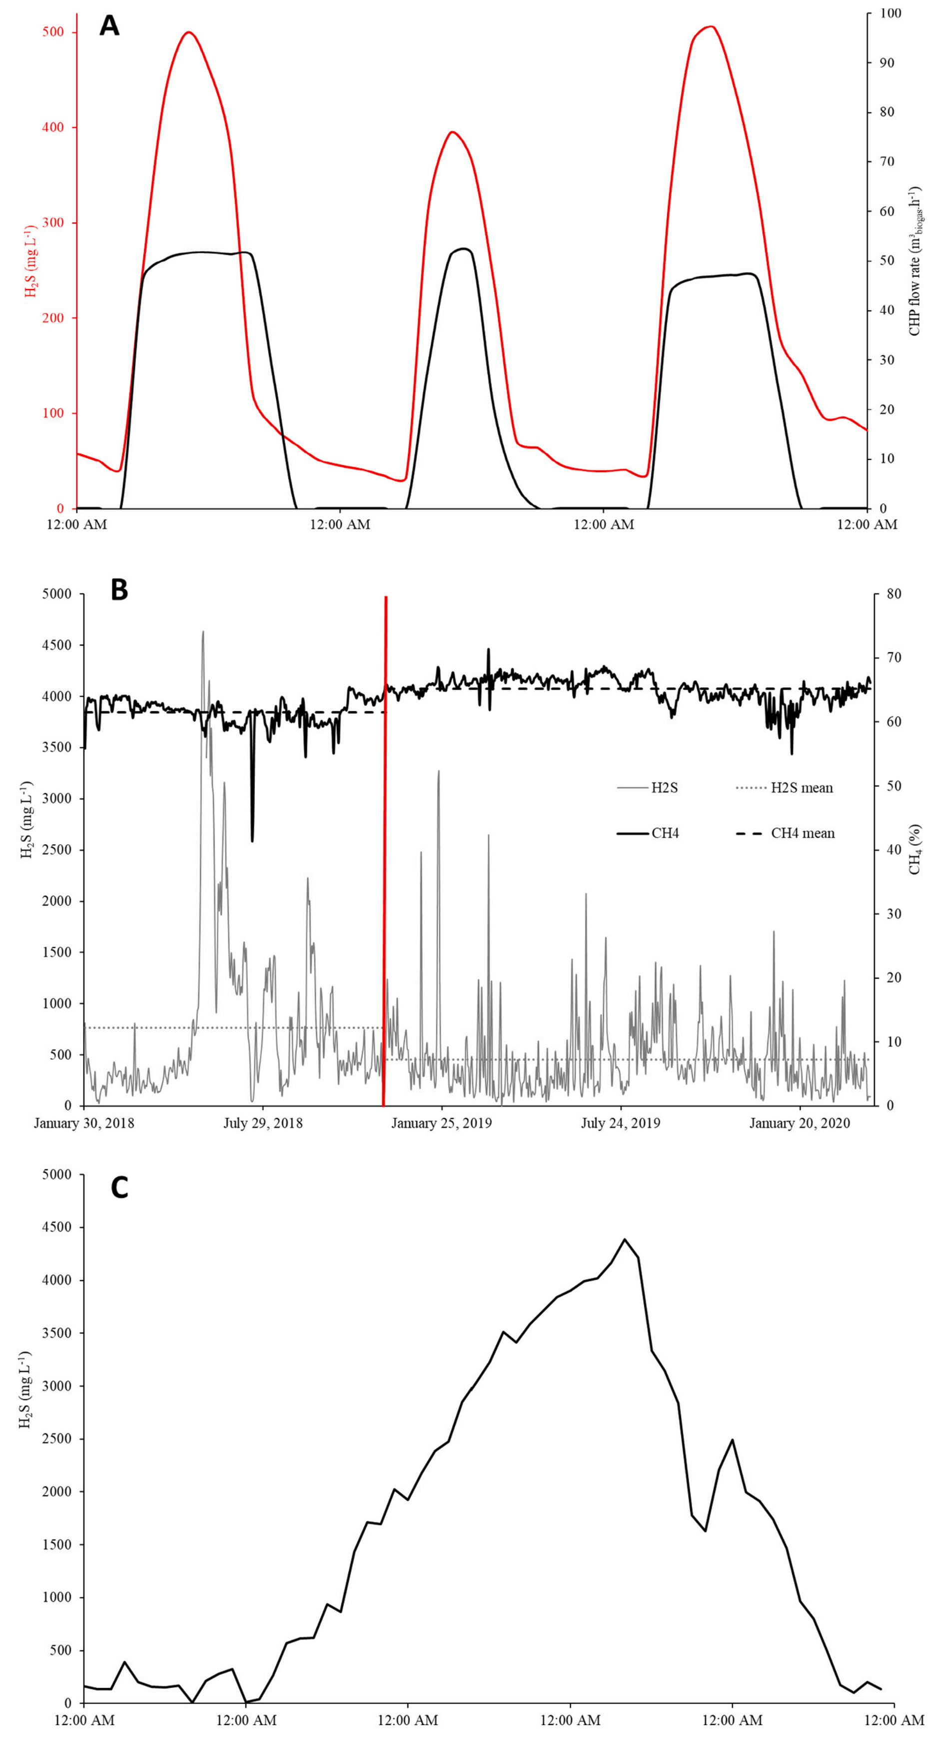

Fig. 4. Desulfurization process monitoring. A. Variations in the H_2S content at biogas headspace in the CLB in relation of electric generator group (CHP unit) operation. B. temporal concentration of H_2S (gray line) and CH_4 (black line) at the CHP intake from January 2018 to March 2020. C. hydrogen sulfide profile over 120 h during interrupted oxygen supplementation in the headspace of the CLB.

4. Conclusion

The SLS as a pre-treatment is an interesting alternative to enable the treatment of swine manure fractions using different reactor configurations. The main benefits are: 1) CSTR size reduction 2) Stability in biogas generation in CSTR reactor, treating the solid fraction 3) Solid over loading reducing effect for CLB improving biogas generation 4) Possibility to implement a digestate treatment system for CLB that presents more diluted effluent due to previous SLS. Moreover, the biogas monitoring allowed a better understanding to gas production and concentration variation. The gas concentration and H_2S removal was BRT dependent.

Summary – The generation of energies from the biomethane fuel generated by the anaerobic bio-digestion process of animal effluents has received special attention in Brazil as a promising alternative and sustainable source of energy. However, technical and economic limitations persist in the process, mainly regarding the correct recycling of effluents. This prospective study analyzes the technical and economic feasibility of five alternatives available in the national market for the correct treatment and disposal of effluents generated in a biogas plant to be installed in the Southern region. The results obtained from the estimation of technical performance and use of production inputs and factors and consequent net present value (LPV) for the technologies were accounted for in order to estimate the respective economic impacts on the central biogas plant. The information generated can support the energy sector and the production chain of pig farming, as well as the formulation of public policies for renewable energies from biogas.
Keywords: agribusiness, biomethane, costs, prospecting, economic viability.

Effluent wastewater treatment from biogas plants

Abstract – Biomethane production from the anaerobic digestion of animal wastes has regained popularity in Brazil and therefore is receiving especial attention lately. Biomethane is an alternative source of renewable energy that can contribute to local agribusiness economy whereas decreasing our dependency on petroleum. Therefore, large scale biogas plants have been considered toincrease methane productivity to volumes that can make it commercially competitive. Despite the fact that biogas plants technologies are well established, little effort has been placed on how to treat the final wastewater adequately in order to maintain the sustainability of the process without

jeopardizing its economic feasibility. The aim of this case-study was to determine the economic impacts of five most conventional wastewater treatment approaches available at local market on a specific pilot-scale biogas plant designed to operate in Southern Brazil. The benefits and technical limitations of each wastewater treatment approach were taken into consideration during analyses. The economic analyses were estimated based on net present value (NPV). Overall, the information gathered in this case-study can serve as guidance to decision makers during the development of newer biogas plants. Moreover, the results can assist public policies towards the development of sustainable agribusiness that is capable of producing biomethane as promising and profitable source of renewable energy.
Keywords: agribusiness, biomethane, costs, prospecting, economic feasibility.

Introduction

The generation of energy from the production of biogas with animal waste has grown in the world and in Brazil (DEUBLEIN; STEINHAUSER, 2011; PLANO..., 2012), with great potential to generate additional income and reduce agricultural and agro-industrial costs. There is also growing interest from governments, technology institutions, energy companies (electricity and gas), suppliers of machinery and equipment and specialized technical consulting services. Biogas also emerges as a potential solution to reduce greenhouse gas (GHG) emissions in agribusiness. Therefore, the projects in this area align with the Brazilian government's agenda for mitigating the effects of agricultural activities on climate change and is placed as an alternative to initiatives aimed at sustainable rural development, also attracting the interest of institutions with local action, such as the municipal governments and the technical assistance and rural extension agencies.

Although the use of biogas as an alternative source of energy is not recent, technical and economic limitations still persist in the process, especially with regard to the correct destination of the final effluent. Although they are conventionally considered a reliable source of fertilizers, effluents can promise the quality of water resources in regions with high herd concentration and little availability of agricultural area – in the case of many producing regions in the South of the country. In recent years, many viable initiatives have emerged for the production and use of animal waste biogas. One of these initiatives foresees the implementation of a central biogas plant in the South and with the participation of a public company in the energy sector, a foreign agency of international technical cooperation and the local city council.

This prospective study analyzed the technical and economic feasibility of five treatment routes and final disposal of effluents produced by a biogas plant for the Southern region, available in the market. The realization occurred under the technical cooperation contract between Embrapa Swine and Poultry and the German International Cooperation Agency (GIZ). The original project foresees the installation of a central power generation plant with a power of 500 kW to 1 MW with the biogas of pig, cattle and broiler manure waste from 78 agricultural establishments (BLOCK, 2011; OAK, 2011). Figure 1 shows the schematic design of the proposal, which provides as a strategy for the management of effluents (A and B) its transport for application as a biofertilizer and the composting and drying of silt, and it is up to the municipal government to bear the transport costs (from waste to the plant and effluents to agricultural areas).

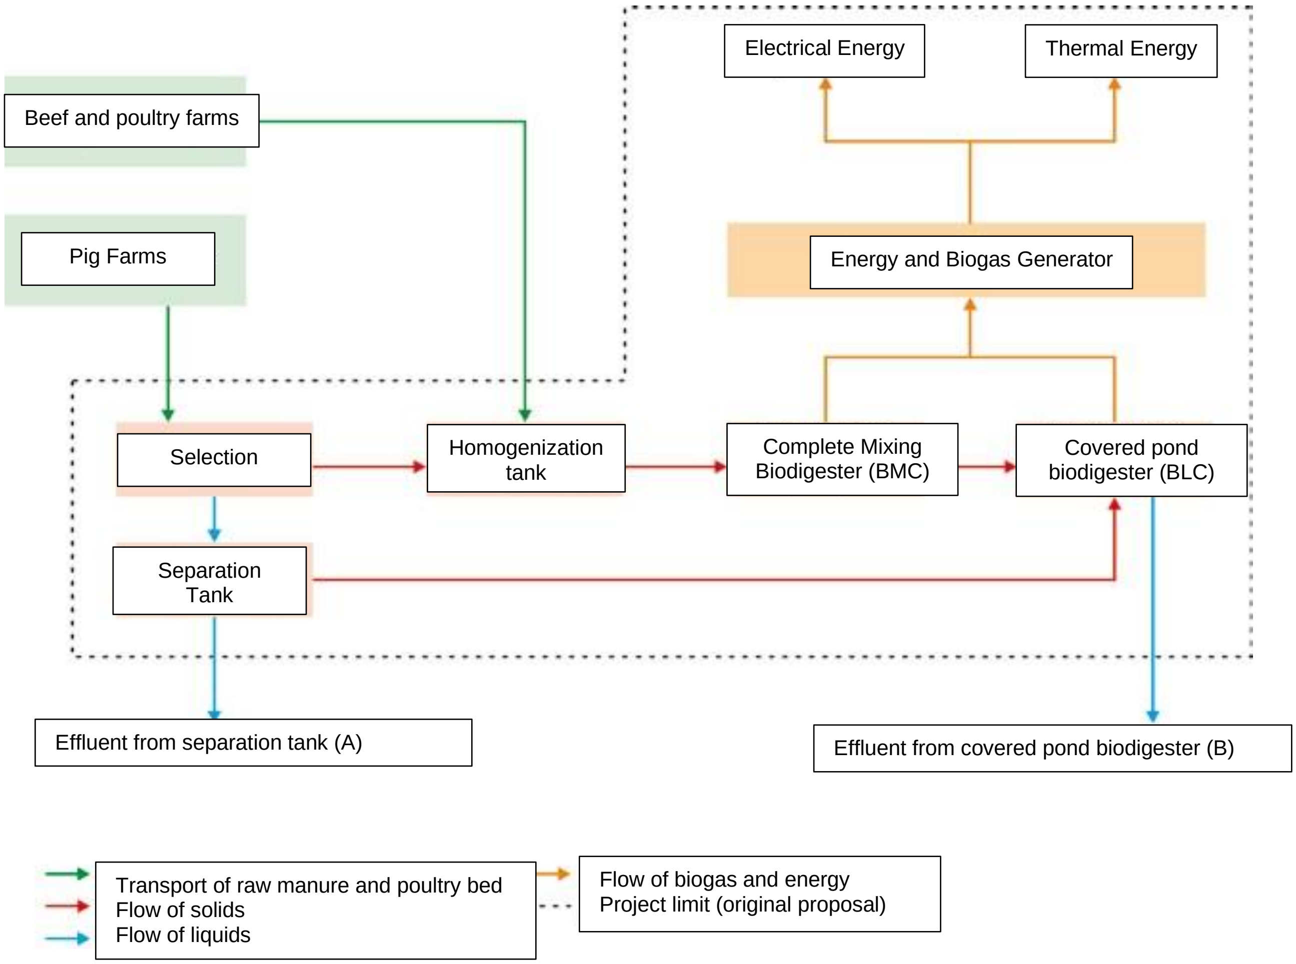

Figure 1. Schematic design of the biogas plant implementation project.
Source: Block (2011) and Carvalho (2011).

Scope of the study and technologies considered

The study did not propose to analyze the overall viability of the project, but only the impact of the five effluent treatment routes on the economic value generated by the plant. The treatment technologies are as follows:

1) Transport of effluents for application in the soil as liquid biofertilizer.
2) Separation of silt with decanter, transportation of liquid effluent for application in soil as biofertilizer and drying of silt with the use of raphyus bags for sale of the by-product (solid organic fertilizer).
3) Swine Effluent Treatment System (Sistrates) with disposal of effluents treated in water bodies (or reuse) and drying of silt of the phosphorus module and use of raphyus bags for sale of the by-product in the form of calcium phosphate.
4) Separation of silt with sand filter, followed by treatment of the liquid by reverse osmosis and subsequent disposal in water bodies (or reuse), transport of untreated liquid effluents for application in soil as biofertilizer

and drying of sand filter silt using raphyus bags for sale of the by-product – solid organic fertilizer, for example.

5) Use of effluents in place of water supplied by the public network or artesian well in the process of manufacturing fluid fertilizers and subsequent sale of the product in the fertilizer market. This is not exactly an alternative, but a new business.

A flowchart of technological alternatives is presented in Figure 2. The use of liquid effluents (A and B in Figure 1) for composting was discarded because of the absence of carbon as substrate for the biological process (HIGARASHI, 2012). The drying of the effluent with the heat from the plant's generators was also discarded because this process does not present technical feasibility (BLOCK, 2012a).

Methodology

The methodology used is prospective and allowed estimating the technical performance and the use of production materials and factors (capital and labor) to calculate the net present value (LPV) of the five technological alternatives analyzed. Following the concept of incremental cash flow, the NPV of the technological alternatives should be counted in the value generated by biogas plants (GALESNE et al., 1999)[10]. A qualitative evaluation was also developed for each alternative, addressing the benefits, actions, disadvantages and potential risks. The case study concludes with considerations focused on public policy and the challenges for innovation in projects of this nature.

To estimate the annual input volume of waste, dry matter and nutrients, the following information was used: a) initial analysis of the herd volume of the 78 producers planned to participate in the project (BLOCK, 2011); b) average dry matter value of liquid waste

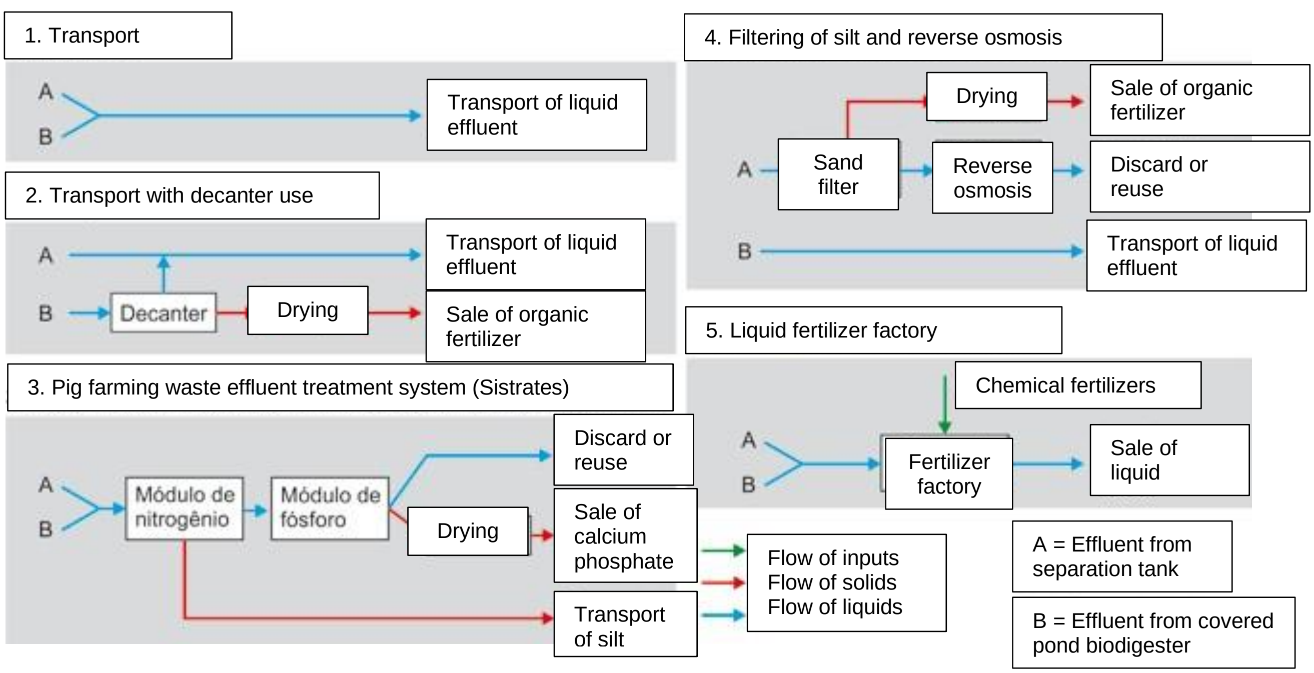

Figure 2. Technological alternatives for the treatment and final disposal of effluents from a central biogas plant in the South region.

[10] Discount rate of 10% per year or 0.797% per month, project life of 120 months and residual value of investments of 10%.

of pigs equal to 3.46%, obtained from the survey of 23 samples (RAMME, 2011); and c) consultation with previous surveys carried out by Embrapa Swine and Poultry (OLIVEIRA et al.,1993) and the Soil Chemistry and Fertility Commission of Rio Grande do Sul and Santa Catarina states (MANUAL..., 2004) to establish the concentration of nitrogen nutrients (N), phosphates (P_2O_5) and potassium (K_2O).

The volume and characteristics of the effluents were estimated based on the technical performance coefficients projected for the plant (BLOCK, 2011). The characteristics of effluents, silt and by-products of alternative technologies were estimated by means of technical information obtained in the development of swine effluent treatment systems, such as Sistrates[11] (KUNZ et al., 2009; MIELE et al., 2011) and reverse osmosis (BLOCK, 2012b). For the liquid fertilizer plant, field technical data (COZZO, 2012) were used. Table 1 presents the characteristics of effluents, used to determine the use of inputs and production factors by volume of effluent to be treated and estimate the initial investment necessary for the implementation of each alternative.

The fertilizer value was calculated from the concentration of nutrients in effluents, silt and by-products, and from the market price of fertilizers. Urea was considered to contain

Table 1. Characteristics of effluents, slides and by-products of the central biogas plant and the technological alternatives analyzed.

Effluent, silt and by-products	**Daily volume**	**Dry material (%)**	**N (kg/m³)**	**P_2O_5 (kg/m³)**	**K_2O (kg/m³)**

[11] The Patent of Sistrates was filed in February 2011 with the INPI (PTO), as PI (Application for Invention), protocol no. 012110000133.

44% N; triple superphosphate contains 42% P_2O_5; and potassium chloride (KCl) contains 60% K_2O. It is emphasized that this value is a “shadow price” given to effluents, silt and by-products, because they have no market price (except fluid fertilizer). Thus, they are illustrative values that allow comparing effluents and by-products on the same basis (value in NPK) and do not necessarily constitute revenue, sales price or production cost. The economic benefit provided by effluents is equal to the fertilizer value when they are applied in their own areas. When applied in third-party areas, they have an equal value to the sales price, which can suffer deductions of up to 100%.

The study considered as a baseline for the comparison of technological alternatives the cost of transporting effluents from the central plant to the crops of the region for application in the soil as a biofertilizer (Figure 2, alternative 1), deducing the economic benefit generated by these effluents. This cost is determined by the equipment used, by the price of the inputs (diesel, tires and maintenance, labor and truck value) and mainly by the average distance traveled. To estimate the average distance, a model was developed based on the supply and demand of nutrients in the plant's implantation region and in the 127 municipalities with distance of up to 150 km, in addition to the willingness of farmers in the region to accept the effluents from the plant. The data sources and information used were: data from the Municipal Livestock Survey (PPM) (IBGE, 2012b) to size the pig herd; b) estimation of the supply of manure and nutrients (NPK) by pig herds from the average concentration of 3.46% of dry matter, average daily excretion of 8.6 L/head/day and average nutrient concentration of 3.13 kg/m³ for N, 2.68 kg/m³ for P_2O_5 and 1.63 kg/m³ for K_2O (MANUAL..., 2004; OLIVEIRA et al., 1993; RAMME, 2011)[12]; c) data from the Municipal Agricultural Survey (PAM) (IBGE, 2012a) to size the planted area (ha) of the main crops; d) estimation of nutrient demand (NPK) based on fertilization recommendations for maintenance and correction of nutrient contents in the soil as a function of NPK extraction capacity by agricultural crops cultivated in the region, considering the critical phosphorus element (NICOLOSO; CORREA, 2012); e) the willingness of farmers in the region to accept the effluents of the plant and the consequent percentage of the available area. As they are unknown variables, a simulation was made with several levels of acceptance (from 100% to 10% of the planted area). The estimated unit cost of effluent transport (R$/km and R$/m³) was based on Miele et al. (2011) and Sandi et al. (2011, 2012), being considered only 165 working days without rain per year (NATIONAL INSTITUTE OF METEOROLOGY, 2012) – the application of effluents cannot be performed on rainy days. Table 2 shows the market prices used in this study.

Baseline to compare alternatives: effluent transport

Alternative no. 1, transportation of effluents from the biogas plant for application in the soil as a biofertilizer of crops, is the one of lowest technological complexity and greater flexibility (MAYERLE, 2011)[13] and represents the first strategy for management of swine manure in Brazil and is also the management strategy of the effluents proposed by the project (CARVALHO, 2011). Therefore, this option was considered the main baseline for comparison with the other alternatives.

The benefits of this alternative are the use of nutrients contained in waste and effluents (NPK) and its important role as a soil conditioning agent (carbon and other nutrients), reducing farmers’ expenses

[12] Since ppm data do not discriminate the rearing system and the type of pig herd, it was decided to use daily excretion and the average concentration of herd nutrients.

[13] Logistic setup with centralized production of biogas and electricity and decentralization in waste collection and effluent distribution (MAYERLE, 2011).

Table 2. Market prices used in this study.

Item	Unit	Price[1]
Organic fertilizer from decanter[2]	R$/t	16.27
Organic fertilizer from rapid sand filter[2]	R$/t	170.91
Purchased electricity	R$/kWh	0.264
Electricity sold	R$/kWh	0.140
Liquid fertilizer (00-10-10)	R$/t	519.82
Solid fertilizer (00-25-25)	R$/t	1,214.54
Calcium phosphate from Sistrates[2]	R$/t	28.84
Freight of the inputs to the liquid fertilizer plant	R$/t	35.47
Liquid fertilizer freight (100 km one way)	R$/t	58.000
Freight of by-products sold (35 km one way)[3]	R$/t	15.85
Calcium hydroxide	R$/kg	0.50
KCl	R$/t	1,262.22
MAP	R$/t	1,491.00
Diesel oil	R$/L	2.12
Polymers	R$/kg	25.00
Raphyus bags for drying silt	R$/bag	10.00
Operator salaries (includes charges)	R$/month	1,353.00
Triple superphosphate	R$/t	1,328.74
Tannins	R$/L	1.85
Urea	R$/t	1,197.13

[1] Average values for the period of Jan./2011to May/2012, updated by IGP-DI for Jun./ 2012.

[2] FOB price calculated, considering 60% of dry matter and discount of 74% in relation to fertilizer value, according to discount verified in the aviary market.

[3] For the sale of organic fertilizer and calcium phosphate, we considered the distance of 35 km from the plant's installation site to the neighboring municipality where it is cooperative that produces and markets organic fertilizers by composting agro-industrial waste.

Source: prepared with data from the National Agency of Petroleum, Natural Gas and Biofuels (2012), Cozzo (2012) and Santa Catarina (2012)

with mineral fertilizers and also positively impacting crop productivity[14]. In situations in which the effluent is applied in its own areas, it can be affirmed that the effluent holder will benefit from its fertilizer value equivalent to the reduction of expenses with chemical fertilizers. However, when the effluent is applied in third-party areas, the benefit will be equivalent to the selling price, not the fertilizer value. The selling price is very variable, but can suffer deductions of up to 100% in relation to fertilizer value. In the marketing of poultry for consumption, the deductions vary from 66% to 92% in relation to the fertilizer value. The main limiting factor of this alternative is the high concentration of pig herds and other confined farms in relation to the low availability of nearby agricultural areas for the recycling of waste in an environmentally correct manner. This situation does not occur in all producing regions, but is particularly characteristic of the traditional swine production areas of Southern Brazil, in the case of the region chosen for the plant installation.

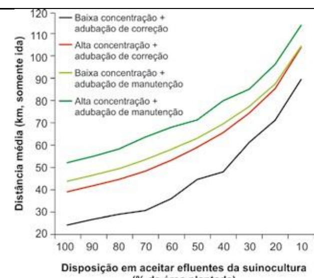
[14] This economic analysis did not consider the positive effects on soil quality and crop productivity, only their fertilizer value (reduction of chemical fertilizer expenses) or their sales price when applicable.

The soils of the region and its surroundings are characterized by the low aptitude for mechanized agriculture (high slope and rocky), which limits the agricultural area available for biofertilizer application, and by high natural fertility. Given this and the need for the enterprise (plant) to be sustainable in the long term, the nutrient demand had to be calculated based on the recommendations of fertilization to maintain the nutrient contents in the soil as a function of the capacity of NPK extraction by agricultural crops cultivated in the region. As there is no up-to-date and available information on the level of soil fertility in the region, the fertilizer demand in the first years of the project was considered to be potentially higher than that used in this study, given the need to correct soil fertility. However, over the lifetime of the project, fertilizer demand should fall to the estimated levels necessary for soil maintenance, keeping the agricultural scenario of the region unchanged and correctly following agronomic recommendations.

In addition to the supply of NPK via biofertilizers of the plant, it is also necessary to compute the supply of biofertilizers in the municipalities potentially receiving the effluents of the plant, so that the problem of excess nutrients is not only transferred to the other municipalities. In view of the recommendations for fertilization (correction vs. maintenance), the variability of nutrient concentration of effluents and the levels of willingness of farmers to accept the effluents of the plant, great variability and uncertainty should be predicted in relation to the distance traveled for the transport of effluents. Figure 3 shows the simulation of the model described above, which predicts that the distance for the transportation of effluents from the central biogas plant can vary from 24 km to 115 km (one way)[15].

Average distance (km, one way)

Low concentration + corrective fertilizer
High concentration + corrective fertilizer
Low concentration + maintenance fertilizer
High concentration + maintenance fertilizer



Willingness to accept effluents from pig farming (% of planted area)

Figure 3. Weighted average distance to transpose the effluents of the central biogas plant as a function of the willingness to accept the effluents of swine culture, the concentration of nutrients in the effluents and the agronomic recommendation for fertilization.

The large range of distances covered (Figure 3) is reflected in the cost of transport of effluents, which may present great variability. These projections are aligned with the transportation costs of liquid pig waste with the use of tanker trucks that participated in the surveys by Sandi et al. (2011, 2012) in municipalities in the South region. It is important to compare the distance required to meet the agronomic recommendation as a function of the willingness in accepting the effluents (Figure 3) with the maximum distance that guarantees the viability of the transport as a function of the condition of the effluent appraisal. The transport and subsequent application of effluents in third-party areas are only feasible at distances lower than that necessary to meet the agronomic recommendation, even when the availability to accept effluents is 100% of the planted area (Table 3).

[15] The study did not consider the supply of manure or NPK by the bovine herd because most of it is not reared in confinement – waste is absorbed by grazing areas. It was also not considered the herd of broilers or other birds because the poultry bed can be marketed at greater distances than pig manure, being, in many cases, acquired by organic fertilizer factories. If the supply of NPK by these herds were considered, a significant increase in the average distance covered should be predicted.

Table 3. Distance required to meet the agronomic recommendation due to the willingness to accept effluents, maximum distance for economic viability of transportation due to the condition of effluent stocking and respective transport costs.

Criteria	Average distance (Km, one way)	Transportation Cost	
		R$/km	R$/m^3
Distance to meet the agronomic maintenance recommendation using 100% of the planted area	44	3.72	16.32
Distance to meet the agronomic recommendation of maintenance and high acceptance of effluent (70% of the planted area)	54	3.64	19.55
Distance to meet the agronomic recommendation of maintenance and low acceptance of effluent (30% of the planted area)	78	3.53	27.50
Economically viable distance for application in own area (cost = fertilizer value)	73	3.55	26.01
Economically viable distance for application in third-party area (cost = market price with average discount of 74% on fertilizer value)	15	4.52	6.96

Based on these considerations, it is believed that these are the most likely conditions of removal of effluents from the central biogas plant: a) predominance of good quality soils requiring only maintenance fertilization; b) low concentration of nutrients in waste; c) low willingness to accept effluents from the biogas plant; d) great variability and uncertainty regarding the distance traveled for the transport of effluents (Figure 3) and, consequently, in transport costs (Table 3); e) application in a third-party area, with high discount on its fertilizer value, also subject to great variability and uncertainty[16].

The main consequence for the baseline of this study is that the net cost[17] of effluent transportation will most likely be positive (cost of transport > economic benefit), subject to great variability, which can be one of the main sources of uncertainty of a project with such characteristics. Since it is not possible to determine the standard value, we chose to use two scenarios for the analysis:
a) scenario 1, of low net transport cost, of 1.50 R$/m^3 (defined from consultation with pig producers in the Southern region with large scales of accommodation and which does not have an agricultural area); b) scenario 2, of high net transport cost, of 2.71 R$/m^3, which would represent an increase of 80% over scenario 1.

Both scenarios were considered conservative (underestimating the net cost of transportation) given the characteristics described above, the trends observed in the relationship between herd and agricultural area (IBGE, 2012a, 2012b) and also the future behavior of prices (especially diesel oil). It is also important to highlight the possibility of biogas generated being used as a fuel source to move the truck fleet, which could be an attractive alternative for reducing costs and atmospheric emissions (GHGs). At the moment, this technology is still incipient and commercially unavailable in Brazil. In addition, a reduction in the plant's biogas supply is expected, which would consequently reduce project revenues.

[16] The high volatility of exchange rates and the price of fertilizers on the international market also directly impacts this variable.

[17] The net cost of transporting the effluent is equivalent to the transport cost deducted from the fertilizer value of the effluent when it is applied in its own areas or minus the sales price of the effluent when it is applied in third-party areas.

Results

Alternative no. 1, of effluent transport, requires the lowest initial investment, of R$ 357,000, a value that refers to the construction of a wastewater storage pond with a volume of 30,900 m³, for a period of 80 days[18]. Investments in its own fleet were not accounted for, assuming that the enterprise would outsource freight services[19]. Thus, the main component of the cost are freight expenses (Tables 4 and 5). In Scenario 1, it is the lowest cost option of approximately R$2.08/m³ of effluent (Tables 4 and 6), as well as the lowest impact on the value generated by the central biogas plant, with a reduction in the LPV of the plant of R$ 1.8 million in ten years (Table 7). Scenario 2 presents a cost of R$3.29/m³ of effluent (Table 6), with a negative impact on the value generated by the plant, estimated at R$ 2.9 million over ten years (Table 7).

The main benefit of this alternative is the possibility of using biofertilizer, given its low cost and greater flexibility of use for small distances. However, it can present disadvantages when contributing to GHG emissions and by detaining large agricultural areas of their own to benefit from fertilizer value. It would also present high cost when considering greater transport distances.

Alternative no 2, transport with separation of silt with decanter, was considered a variant of the alternative no 1, not being properly a distinct technological option. This option requires the second lowest investment

Item	**Transport**	**Transport + Decanter**	**Sistrates**	**Filtering + Reverse Osmosis**	**Liquid Fertilizer Factory**
Investment required	357,115	585,288	917,571	1,547,157	4,256,422

[1] Discount rate of 0.797% per month, project life of 120 months and residual investment value of 10%.

R$ 585,000, a value that refers to the construction of a wastewater storage pond with a volume of 27,300 m³, for a period of 80 days, and the installation of a decanter equipment (flow of 15 m³/h) for separation of silt from the covered pond biodigester. Investments with their own fleet were also not considered. The use of a decanter implies higher expenses with chemical and maintenance, but has shown little effectiveness in reducing freight expenses. This option was the one with the highest cost and the greatest negative impact on the value generated by the project. The revenue that could be obtained from the sale of by-products (organic fertilizer) has little importance in relation to costs and does not change these results (Tables 4, 5, 6 and 7).
Effluent treatment alternatives require greater initial investment compared to transport alternatives – Sistrates requires R$ 918,000 in investments, while reverse osmosis requires R$ 1,547,000. In addition to being more costly in terms of equipment, this latter option also requires the construction of a storage pond of the portion of untreated effluents for a period of 80 days, with a volume of 16,400 m³. The main components of the cost of treatment in Sistrates are chemical and electric energy, which account for almost half of the total costs and reduce the supply of energy to the market. Reverse osmosis equipment, although more energy efficient, has higher costs with depreciation and amortization of capital and maintenance expenses (especially in filter replacement), which together account for more than half of total costs (Tables 4 and 5). It is important to highlight that the reverse osmosis equipment does not treat the entire effluent, but only the effluent of the separation tank (A in Figure 2 and Table 3), with up to 2% organic dry matter, limit for this technology (BLOCK, 2012b). A significant portion of the cost (at least 20%) occurs because of the transport of untreated effluent (effluent from the covered pond biodigester, B in Table 1), which presents more than 2% of organic dry matter.
Sistrates presented treatment costs lower than the reverse osmosis option in the two scenarios analyzed (Tables 4, 5 and 6), as well as lower negative impact on the value generated by the central biogas plant (Table 7)[20]. In relation to the baseline, Sistrates has the lowest cost of scenario 2, approximately R$3.18/m³ of effluent (Table 6) and the lowest negative impact on the value being generated by the plant, approximately R$ 2.8 million in 10 years without obtaining revenue stemmed from the sale of by-products, and R$ 2.4 million with revenues (Table 7). The recipe that can be obtained from the sale of by-products (calcium phosphate and organic fertilizer) changes little the performance of these alternatives, especially in the case of Sistrates. It is important to note that in all options, except in Sistrates, there is a significant impact by the increase in the value of effluent removal freight in the total costs (scenario 1 x scenario 2).
Among the main benefits of Sistrates are the possibility of reducing GHG emissions, reuse of water or release in receiving bodies and the use of the generated by-product (calcium phosphate) as an input for fertilizers and feed. The advantages of this system are the efficiency of nutrient removal and the reduction of the area necessary for the application of animal production residues and consequent reduction of transport costs. As disadvantages, it presents high initial investment value, high operating cost and consumption of electricity and chemical inputs. The removal of N and P makes this technology less attractive because it reduces the supply of nutrients for agriculture. In addition, it is a technology still in the validation phase and is subject to fluctuations in the price of electricity and phosphate.
Reverse osmosis has characteristics similar to those of Sistrates. Its main

[20] This condition is maintained even when electricity tariffs practiced in the market (R$ 264.00/MWh) are considered instead of the cost of selling the energy used in this study (estimated at R$ 140.00/MWh).

benefits are the possibility of reducing GHG emissions, the production of clean water (about 40% of the total effluent) and the generation of organic fertilizer, being able to access value-added markets. The advantages of this system are the reduction of the volume of effluent transported, the reduction of the area necessary for the application of animal production waste and also the availability of clean water. However, it has the same disadvantages as Sistrates, besides not treating the entire effluent of the biogas plant (62%).

The alternative that requires the greatest investment is the implementation of a fluid fertilizer plant, with a projected total value of R$ 4.3 million and the capacity to produce 240,000 t/year. This option includes facilities and equipment in the amount of R$ 3.7 million and the construction of a wastewater storage pond for a period of 120 days, with a volume of 46,300 m^3 and a value of R$ 536 thousand, necessary because of the seasonality of demand due to the calendars of agricultural harvests.

It should be considered that this is not exactly a treatment alternative, but a new business in the fertilizer segment, which can be located in central biogas plants, using bio digestion effluents in industrial processes in place of clean water[21]. Therefore, the costs of the fluid fertilizer plant were not compared to those of the other treatment alternatives. Chemical inputs for the manufacture of fluid fertilizers (MAP, Urea and KCl) represent 99% of production costs (Tables 5 and 6) and 89% of costs when considering freight to the rural producer.

This option is extremely sensitive to the freight costs of the products sold. Because there is no return freight (specialized transport), one should charge the round-trip routes, unlike the case of solid fertilizer. In addition, this is a product intended for farmers with an area of more than 50 ha (COZZO, 2012).

These limitations also make the option of the liquid fertilizer plant dependent on the area of crops around the plant. Considering the formulation that uses the largest amount of effluent[22, it] would be necessary to produce 215,000 tons per year, which would require an area of 537,000 hectares of crops in establishments with more than 50 hectares. For the economic viability of the project, this area should therefore be at a distance of up to 50 km, or 100 km round trip (COZZO, 2012), which is not the case in the project region (IBGE, 2006, 2012a). The unfavorable logistics of the region chosen for the project and the low availability of agricultural areas directly impact the expected return of a fluid fertilizer plant (COZZO, 2012). This conclusion is maintained even in the situation in which resources from the central biogas plant to the fertilizer plant equivalent to the expenses with transportation of effluents occur (subsidy from one project to another). The advantage of this alternative that provides the sale of fluid fertilizers is to add value to the effluent, enabling transportation to greater distances (up to about 50 km). However, it requires high investment and operational cost with chemical and electricity. In addition, its priority audience is producers with areas greater than 50 ha and specific machinery is needed for the application of fertilizer in the soil.

Environmental legislation, cost-sharing and co-responsibility

In view of the differences in scale, it should be considered that the posture of environmental agencies in relation to central biogas plants will be guided by greater caution and a degree of requirement (release, supervision and monitoring and technological standard, for example) significantly more restrictive than with small and medium geographically dispersed pig farmers. As pointed out, the predominant option of

[21] It takes 565 L to 647 L of water (or effluent) to produce one ton of fluid fertilizer, depending on the formulation.
[22] Formulation 00-10-10 requires 647 L of effluent for each ton of fertilizer produced

management of pig waste in Brazil is its transport for later application as biofertilizer in crops. The cost is borne by the swine producers, and there is no co-responsibility of the other actors in the production chain (especially agro-industries), and in many producing regions there is a significant contribution of public resources to subsidize the transport of waste (SANDI et al., 2011, 2012)[23]. It is understood that the entry of new sectors in the biogas segment, such as energy, should be guided by the internalization of the costs involved in the transport or treatment of effluents. The original proposal to divide tasks in this plant project in the South region does not solve the problem. On the contrary, it increases the impacts on the municipal budget. In a survey conducted in the municipality, the subsidy reached 74.6% of the cost of distribution of waste in farms that needed to transport at distances greater than 8 km (SANDI et al., 2012), which represents annual expenditure for the municipal budget of R$ 111,000.

The public incentive to implement central biogas plants should consider that it is not possible to enable new ways of generating value on pig production (from meat to energy and fertilizer) without reserving part of this added value to the correct management of effluents, preferably considering the reduction of GHG emissions and pressure on water resources. The regulatory framework of auctions for the purchase of energy from renewable sources should consider such issues. In this sense, the scope of the project should be expanded to include the transport or treatment of effluents.

From the point of view of the agricultural establishment, it is important to reinforce that the producer will incur costs to participate in a project of this nature and magnitude, especially labor and investments to reduce the volume of water in waste and the length of their stay in the facilities (RAMME, 2011). Initiatives of this nature, taken in the agricultural establishment and affecting the resources of the producer, not only increase the efficiency of the plant in the generation of biogas but reduce the costs of transport or treatment of effluents. For this to happen, incentives should be established or explained, through financial remuneration or the possibility of increasing the herd through technical analysis on a case-by-case basis. It is understood that it would be convenient and promising to develop a contractual arrangement, similar to the integration of production with agro-industries, for the determination of standards and delivery volumes and, mainly, to determine economic advantages for the pig farmer from quality parameters of the supplied waste (especially in terms of volatile solids and dry matter).

Final considerations

The option of replacing small biodigesters of covered pond, geographically dispersed by rural properties, with central biogas plants allows significant gains in technical efficiency (CANTRELL et al., 2008). However, this option represents an increase in transportation costs and, above all, the risks of pollution of water resources, in view of the limitations of inspection and the economic incentive for effluents to be overapplied in areas near the plant. Regarding the alternatives analyzed for the correct management and final disposal of effluents from a central biogas plant, there are also dilemmas to be considered. The transport alternative and its variant, the use of decanter for silt separation, on the one hand provide the agricultural sector with the nutrients contained in pig farming waste[24], reducing costs with chemical inputs and ultimately reducing

[23] In addition, they represent a permanent focus of tensions, such as difficulties in meeting demand, political pressures to prioritize beneficiaries and impact on the budget of small municipalities.

[24] In many cases, the full use of nutrients is impaired because of the way effluents are used in the soil (ammonia loss, leaching and percolation) and the non-observance of agronomic fertilization recommendations.

the country's dependence on fertilizer imports. On the other hand, this option contributes to GHG emissions (ÁLVARES JUNIOR; LINKE, 2002; BRAZIL, 2009), either by emissions in transport (CO2), or by emissions from the use of waste applied to the soil (N2O). Moreover, as pointed out, this alternative increases the risk of pollution of water resources.

Treatment options reduce the polluting potential of pig farming and biogas plants of water resources and GHG emissions (BORTOLI et al., 2012). On the other hand, they reduce the surplus of electricity generated and do not return to the agricultural sector the nutrients contained in the waste (except organic fertilizer and calcium phosphate).

The combined use of central biogas plants with fluid fertilizer plants can be an alternative for the utilization of nutrients contained in waste without impacting water resources. As the effluent starts to make up a product to be sold (liquid fertilizer), that is, there is a price to be paid by the farmer, there is no economic incentive for its excess application, contrary to agronomic recommendations, in the case of the liquid effluent transported. However, a fertilizer plant consumes electricity and generates GHG emissions through transportation (ÁLVARES JUNIOR; LINKE, 2002; BRAZIL, 2011), and another limitation of this alternative is its maximum radius of activity, up to 50 km. Thus, even in regions with low herd/area ratio there is a limit of fertilizer production scale, which limits the scale of the central biogas plant to half or one third of the size proposed in the project.

Another issue that should be analyzed in projects of central biogas plants, which permeates all the alternatives described here, refers to the sanitary implications, which should be evaluated and discussed with the multiple actors of the process, as well as agricultural defense and control agencies and agro-industries.

In this study, quantitative data and qualitative questions were presented and discussed to prospect the technical and economic feasibility of various effluent treatment routes for the project of implementation of a biogas plant in the South region. What is evident is that the viability of the plant goes through the logistics strategy adopted and the stocking of effluents, but, above all, it passes through the dimensioning of the scale of the central plant, which should consider the availability of agricultural areas or the adoption of treatment technologies. Unfavorable logistics and low availability of agricultural areas limit their scale or raise the costs with the correct destination of effluents. Under the energy business's focus, this negatively affects profitability and LPV and prompts the change of project location to more favorable regions. Already under the focus of local public policy focused on rural development, it is possible that environmental demands and tensions in agriculture require interventions to deal with effluents from animal production, even if they have to operate with lower profitability than that accepted by the market.

Finally, it should be considered that the biogas segment has been characterized by accelerated and increasing incorporation of innovations, which tend to increase efficiency or reduce the costs of the technological alternatives analyzed. These innovations should also expand the range of options available, such as the use of biogas as a substitute for diesel oil in the transport of effluents or the development of modern and efficient physical-chemical and biological systems for the treatment of effluent from biodigesters. In both cases, significant implications for the results of this study can be expected.

DIGESTATE MANAGEMENT

OUR SOLUTIONS

Benefits & Impacts

Reduce digestate handling costs, improve gas production and digester throughput, concentrate nutrients, and reclaim clean water for reuse or discharge.

ULTRAFILTRATION (UF)

- Recover 65-85% of digestate as a transparent filtrate free of pathogens and suspended solids with very low levels of phosphorus and organic nitrogen
- Filtrate is ideal for high-volume application to fields and will not clog irrigation systems
- Concentrate is rich in undigested volatile solids and bacteria that can be recycled to the digester to increase solids retention time, thereby boosting gas production and allowing higher volumetric throughput of feedstock
- Concentrate is also a phosphorus-rich slurry that can be cost effectively transported to fields further away or used to produce value-added composts and fertilizers

TWO-STEP REVERSE OSMOSIS (TSRO)™

- UF filtrate is converted into clean water for reuse or discharge and a concentrated liquid fertilizer
- Water reclamation reduces digestate hauling, spreading, and lagoon storage requirements while decreasing freshwater consumption

FACILITY BENEFITS

- Use UF to create low-phosphorus filtrate for cost-effective land application or sewer discharge
- Increase daily loading rates to boost tip fee revenues while maintaining efficient gas production
- Reduce digestate disposal costs
- Reduce regulatory and operating risks of land application

HOW IT WORKS

Technology & Performance

ULTRAFILTRATION

- Proven, polymer-free membrane technology with demonstrated results at commercial digester
- Stainless steel tubular design handles high temperatures, high solids, high viscosities, and extremes in pH
- Designed to last 10-15 years in challenging applications with little downtime, maintenance, or repair
- Cleans quickly and automatically using standard cleaning solutions
- Can operate in batch or continuous modes and be mounted horizontally or vertically

TWO-STEP REVERSE OSMOSIS

- Unique combination of Forward Osmosis (FO) and Reverse Osmosis (RO) membrane technologies can reduce UF filtrate volume by 65-90%
- Highly reliable, non-biological, and polymer-free solution to purify UF filtrate
- Produces clean water ready for reuse or discharge and a value-added product high in ammonia nitrogen and potassium
- Highly automated design requires minimal operator attention with demonstrated results at commercial digester

UF Equipment

TSRO Equipment

We will help you...

- Reduce digestate disposal costs
- Boost revenues by processing more feedstock and making more biogas
- Increase digester efficiency and throughput

JUST ASK OUR CUSTOMERS...

"Ultrafiltration is a useful tool for biogas developers and digester operators. We believe it can be used to concentrate feedstocks like manure prior to digestion, thereby reducing hauling costs, and concentrate volatile solids and bacteria in digestate that can be returned to the digester to enhance gas production while minimizing hydraulic residence time. This means we can digest manure from more cows through the same size digester, reducing the capital costs and footprint for digestion facilities."

- Dan Nemke, CTO at Dynamic Group

EXPLORING Filtration

Call to learn how a Digestate Filtration System can help your facility. We will assess your current situation and recommend the best solution for you.

TESTING Filtration

We will pilot test your feedstock at our facility in Michigan and provide a thorough report and proposal for a full-scale system.

IMPLEMENTING Filtration

We deliver, install, and commission your new filtration system and teach employees how it works, ensuring it meets your expectations.

MAINTAINING Filtration

The filtration system will become an integral part of your facility, allowing you to streamline operations, significantly reduce costs, and increase your revenues.

(57) **ABSTRACT**

A process for removing phosphorus from solid poultry or animal wastes involving (a) mixing solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher than about 3.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue (having a N:P ratio of at least more than 4 expressed on an elemental basis), (b) separating the liquid extract from the washed solid residue to form separated liquid extract and separated washed solid residue, (c) mixing the separated liquid extract with an alkaline earth base to a pH of about 8.0 to about 11.0, (d) mixing the liquid extract with a flocculant to form (i) precipitated phosphorus solids with P_2O_5 content greater than about 10% and (ii) a liquid, and (e) separating the precipitated phosphorus solids from the liquid to form separated phosphorus solids and separated liquid. The process is conducted at a temperature greater than about 5° C. and less than about 50° C. The solid poultry or animal wastes are not pretreated prior to mixing the solid poultry or animal wastes with water and acid; such pretreatments include those that may cause the complete or partial loss of oxidizable organic carbon and nitrogen.

PROCESS FOR REMOVING AND RECOVERING PHOSPHORUS FROM ANIMAL WASTE

REFERENCE TO RELATED APPLICATION

This application claims the benefit of U.S. patent application Ser. No. 12/026,346, filed 5 Feb. 2008, which is incorporated herein by reference in its entirety.

FIELD OF THE INVENTION

The invention relates to a process for extracting and recovering phosphorus from animal wastes.

BACKGROUND OF THE INVENTION

Animal production, a major component of the U.S. agricultural economy, is at risk because of both real and perceived environmental problems. Dramatic advancements are required to protect the environment, save this vital industry, and maintain food security. Municipal and agricultural waste disposal is a major problem. For agricultural animals, the animals are confined in high densities and lack functional and sustainable treatment systems. Confined livestock produce approximately 1329 million pounds of recoverable manure phosphorus annually with about 70% (approximately 925 million pounds) in excess of on-farm needs. This livestock production system was developed in the early and mid 20^{th} century prior to the current trend in high concentrated livestock operations. One of the main problems in sustainability is the imbalance of nitrogen (N) and phosphorus (P) applied to land (Edwards, D. R., and T. C. Daniel, Bioresource Technology, 41: 9-33 (1992)). Nutrients in manure are not present in the same proportion needed by crops, and when manure is applied based on a crop's nitrogen requirement, excessive phosphorus is applied resulting in phosphorus accumulation in soil, phosphorus runoff, and eutrophication of surface waters (Sharpley et al., J. Soil Water Conserv, 62: 375-389 (2007); Heathwaite, L., et al., J. Environ. Qual., 29: 158-166 (2000); Sharpley, A., et al., J. Environ. Qual., 29: 1-9 (2000); Edwards and Daniel, Bioresource Technology, 41: 9-33 (1992)).

Phosphorus build up in soils to excessively high levels due to animal manures often results in eutrophication and pollution of surface waters due to intense application of animal manures to land (Edwards and Daniel, 1992; USEPA, 1992; Heathwaite et al., 2000; Sharpley et al., 2000). This is a national problem affecting dairy, poultry, and swine production systems. Consequently, a substantial amount of manure phosphorus needs to be moved at least off the farms and some needs to be transported longer distances beyond county limits to solve accumulation and distribution problems of this nutrient (USDA-ERS, Agricultural Outlook, September 2000, p. 12-18). Manure nutrients in excess of the assimilative capacity of land available on farms are an environmental concern often associated with confined livestock production. The ability to extract-phosphorus from manure will be critical to poultry and livestock producers to accomplish manure utilization through land application without elevating soil phosphorus levels when land is limited. In addition, the aspect of phosphorus reuse is becoming important for the fertilizer industry because the world phosphorus reserves are limited (Smil, V., Annu. Rev. Energy Environ., 25(1):53-88 (2000)). According to the Potash and Phosphate Institute, the United States annual consumption of inorganic phosphorus for crop production is about 3700 million pounds (Potash and Phosphate Institute, 2002, Plant nutrient use in North American agriculture, Technical Bulletin 2002-1). On the other hand, for the U.S. as a whole, confined livestock produces about 1,329 million pounds of recoverable manure phosphorus annually with about 70% (about 925 million pounds) in excess of on-farm needs (Kellogg, R. L., et al., Manure nutrients relative to the capacity of cropland and pastureland to assimilate nutrients: Spatial and temporal trends for the United States, NRCS and ERS GSA Publ. No. nps00-0579. Washington, D.C., 2000). Therefore, reuse of phosphorus recovered from animal waste could substitute about 25% of the phosphorus now obtained from mining.

Farmers obtain nutrients for their crops from inorganic commercial fertilizers and from organic sources such as animal manure and biosolids from wastewater treatment plants. Inorganic nitrogen and phosphorus compounds are water soluble and readily available to plants. Most organic nutrient sources contain both inorganic forms of nutrients and forms that must first be mineralized or decomposed to become available to plants. The movement of nitrogen and phosphorus through soil are different. If nitrogen is converted to the highly water soluble nitrate-nitrogen form, and it is not used during plant growth, it can move through the soil-water system and be vulnerable to leaching into groundwater. Soil amended with large quantities of organic or inorganic phosphorus may generate significant amounts of soluble phosphorus that can be readily transported by surface and subsurface runoff and groundwater leachate.

A further problem with the management of human and animal waste is the loss of nutrients. Phosphates and nitrates are fundamental nutrients which determine the possibility for plant and animal life to occur. They are taken up by plants and the plants are eaten by animals. Subsequently they should return to the soil as manure in a normal agricultural cycle, but in the present situation in most cases they end up washed into the sea, whether they are simply dumped in a river or go through a municipal wastewater treatment

The lack of closure of the nutrient cycle is a major environmental problem, especially in the case of phosphates which, at present, are considered a mineral resource to be extracted. Excess of phosphates in the seas causes eutrophication. The depletion of the mineral phosphate resources is a problem which will become important in the near future (Scrivani et al., Solar trough concentration for fresh water production and waste water treatment, Desalination, 206: 485-493 (2007))

In livestock operations, the crop acreage is typically calculated to allow for uptake by the crops of the applied nitrogen from the soil, thus minimizing movement of nitrogen in ground and surface water beyond the farm's boundaries.

Unlike carbon and nitrogen, phosphorus cannot volatilize from the system. Crops typically take up less phosphorus from the soil than that applied in the manure because the acreage has been calculated for nitrogen removal, which requires less acreage. The soil absorbs phosphorus but over time reaches saturation. Additional application of phosphorus can cause release of phosphorus to surface waters beyond the farm's boundaries, risking oxygen depletion of water organisms. Measures for reducing phosphorus content of manure must be considered.

Phosphorus inputs accelerate eutrophication when it runs off into fresh water and has been identified as a major cause of impaired water quality (Sharpley et al., 2000). Eutrophication restricts water use for fisheries, recreation, industry, and drinking due to the increased growth of undesirable algae and aquatic weeds and resulting oxygen shortages caused by their death and decomposition. Also many drinking water supplies throughout the world experience periodic massive surface blooms of cyanobacteria. These blooms contribute to a wide range of water-related problems including summer fish kills, unpalatability of drinking water, and formation of trihalomethane during water chlorination. Consumption of cyanobacteria blooms, or water-soluble neuro- and hepatoxins released when these blooms die, can kill livestock and may pose a serious health hazard to humans. Recent outbreaks of the dinoflagellate *Pfiesteria piscicida* in near-shore waters of the eastern United States also may be influenced by nutrient enrichment. Although the direct cause of these outbreaks is unclear, the scientific consensus is that excessive nutrient loading helps create an environment rich in microbial prey and organic matter that *Pfiesteria* and menhaden (target fish) use as a food supply. In the long-term, decreases in nutrient loading will reduce eutrophication and will likely lower the risk of toxic outbreaks of *Pfiesteria*-like dinoflagellates and other harmful algal blooms. These outbreaks and awareness of eutrophication have increased the need for solutions to phosphorus run-off.

Past research efforts on phosphorus removal from wastewater using chemical precipitation have been frustrating due to the large chemical demand and limited value of by-products such as alum sludge, or because of the large chemical demand and huge losses of ammonia at the high pH that is required to precipitate phosphorus with calcium (Ca) and magnesium (Mg) salts (Westerman and Bicudo, Tangential flow separation and chemical enhancement to recover swine manure solids and phosphorus, ASAE Paper No. 98-4114, St. Joseph, Mich., ASAE, 1998; Loehr et al., Development and demonstration of nutrient removal from animal wastes, Environmental Protection Technology Series, Report EPA-R2-73-095, Washington, D.C., EPA, 1973). Other methods used for phosphorus removal include flocculation and sedimentation of solids using polymer addition, ozonation, mixing, aeration, and filtration (see U.S. Pat. No. 6,193,889 to Teran et al). U.S. Pat. No. 6,153,094 to Craig et al. teaches the addition of calcium carbonate in the form of crushed limestone to form calcium phosphate mineral. The patent also teaches adsorbing phosphorus onto iron oxyhydroxides under acidic conditions.

Continuing efforts are being made to improve agricultural, animal, and municipal waste treatment methods and apparatus. U.S. Pat. No. 5,472,472 and U.S. Pat. No. 5,078,882 (Northrup) disclose a process for the transformation of animal waste wherein solids are precipitated in a solids reactor, the treated slurry is aerobically and anaerobically treated to form an active biomass. The aqueous slurry containing bioconverted phosphorus is passed into a polishing ecoreactor zone wherein at least a portion of the slurry is converted to a beneficial humus material. In operation the system requires numerous chemical feeds and a series of wetland cells comprising microorganisms; animals, and plants. See also U.S. Pat. Nos. 4,348,285 and 4,432,869 (Groeneweg et al); U.S. Pat. No. 5,627,069 to Powlen; U.S. Pat. No. 5,135,659 to Wartanessian; and U.S. Pat. No. 5,200,082 to Olsen et al (relating to pesticide residues); U.S. Pat. No. 5,470,476 to Taboga; and U.S. Pat. No. 5,545,560 to Chang.

One of the main problems in sustainability of poultry production is the imbalance between nitrogen and phosphorus in the waste (Edwards and Daniel, USEPA, 2001). Nutrients in manure are not present in the same proportion needed by crops. The mean N:P ratio in manure is generally lower than the mean N:P ratio taken up by major grain and hay crops (USDA, 2001). To solve the problem of a phosphorus buildup in soil and increased potential for phosphorus losses through runoff and subsequent eutrophication of surface waters, efforts are being made to immobilize phosphorus or find alternative uses for poultry litter such as burning and gasification and transport to agricultural lands with low levels of phosphorus. Current methods for handling phosphorus in waste include immobilization, see for example U.S. Pat. No. 6,923,917; gasification (Sheth, A. C., and A. D. Turner, Trans. ASAE, 45(4):1111-1121 (2002)), precipitation, see U.S. Pat. No. 7,005,072; litter transport to agricultural lands with low levels of phosphorus (Jones, K., and G. D'Souza, Agric. Resour. Econ. Rev., 30(1):56-65 (2001); Kelleher, B. P., et al., Bioresour. Technol., 83(1) 27-36 (2002); Keplinger, K. O., and L. M. Hauck, Impacts of livestock concentration and application rate restrictions on manure utilization, ASAE/CSAE Meeting Presentation, Paper No. 042204. ASAE, St. Joseph, Mich., 2004); anaerobic digestion by combustion (USDOE-NREL, 2000, Biomass co-firing: A renewable alternative for utilities, NREL/FS-570-28009, DOE/GO-102000-1055, U.S. Department of Energy, National Renewable Energy Laboratory), etc.

While various systems have been developed for treating solid animal waste for the removal of phosphorus, there still remains a need in the art for a more effective treatment system for the phosphorus. The present invention, different from prior art systems, provides a system for extracting phosphorus from solid animal manure using a selective extraction and subsequent recovery.

SUMMARY OF THE INVENTION

In accordance with the present invention, there is provided a process for removing phosphorus from solid poultry or animal wastes involving: mixing the solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher than about 3.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue, wherein the washed solid residue has a N:P ratio of at least more than 4 expressed on an elemental basis and contains no more than about 40% of the total phosphorus in the solid poultry or animal wastes; separating the liquid extract from the washed solid residue to form separated liquid extract and separated washed solid residue; mixing the separated liquid extract with an alkaline earth base to a pH of about 8.0 to about 11.0; mixing the liquid extract with a flocculant to form (i) precipitated phosphorus solids with P_2O_5 content greater than about 10% and (ii) a liquid; and separating the precipitated phosphorus solids from the liquid to form separated phosphorus solids and separated liquid.

Also in accordance with the present invention, there is provided a material produced by a process involving: mixing solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher than about 3.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue, wherein the washed solid residue contains a N:P ratio of at least more than 4 expressed on an elemental basis and contains no more than about 40% of the total phosphorus in the solid poultry or animal wastes; separating the liquid extract from the washed solid residue to form-separated liquid extract and separated washed solid residue; mixing the separated liquid extract with an alkaline earth base to a pH of about 8.0 to about 11.0; mixing the liquid extract with a flocculant to form (i) precipitated phosphorus solids with P_2O_5 content greater than about 10% and (ii) a liquid; and separating the precipitated phosphorus solids from the liquid to form separated phosphorus solids and separated liquid. The material is the separated phosphorus solids and contains greater than

about 10% P_2O_5, greater than about 10% Ca, less than about 5% N, and less than about 5% K as K_2O.

Still in accordance with the present invention is a material produced by a process involving: mixing solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher than about 3.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue; and separating the liquid extract from the washed solid residue to form separated liquid extract and separated washed solid residue. The material is the separated, washed solid residue and contains a N:P ratio of at least more than 4 expressed on an elemental basis and contains no more than about 40% of the total phosphorus in the solid poultry or animal wastes.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a schematic drawing of the step **1** of the quick wash process of poultry litter showing phosphorus extraction showing an extraction tank **20** as described below.

FIG. **2** is a schematic drawing of the quick wash process showing: (1) mixing solid poultry or animal wastes with water and acid to perform a selective hydrolysis for phosphorus extraction in an extraction tank **20** to form a separated liquid extract and separated washed solid residue; (2) treatment of separated liquid extract with lime and flocculant in a phosphorus removal tank **30**, and to form precicpitated phosphorus solids (3) in removal tank **30** as described below.

FIG. **3** is a schematic drawing of the field prototype system for solid manure quick wash showing a field prototype system for a solid manure quick wash process including an extraction tank **20**, and a phosphorus removal tank **30** as described below.

FIG. **4** is a graph showing particle size distribution of homogenized broiler litter used in field prototype experiments as described below. Each data point is the mean of three replicates.

FIG. **5** is a graph showing extraction of phosphorus from poultry liter using acids at seven concentration levels as described below.

FIG. **6** is a graph showing the pH on total phosphorus extracted from broiler litter as described below. Total phosphorus concentration increased with decreasing pH of mineral and organic acids extracting solutions; more than about 50% of total phosphorus was extracted with respect to initial total phosphorus content in broiler litter at pH lower than 5 of the extracting acid solutions. The % phosphorus extracted from solids corresponds with values in FIG. **5**. Variables in regression line $y=-11x+107$ are x=pH and y=% phosphorus extracted from solids.

FIG. **7** is a graph showing effect of stirring time on total phosphorus concentration in the extract as described below. Broiler litter was extracted with citric acid solution at pH about 4.5 (step **1**). Data show that total phosphorus concentration stays stable in supernatant liquid with stirring time between about 20 and 60 minutes. Data points are average concentrations of two separate runs using the field prototype.

FIG. **8** shows effect of citric acid treatment on the ratio of percent total phosphorus extracted to percent total nitrogen extracted from poultry litter as described below. For purposes of the present invention, selective hydrolysis is defined as any hydrolysis reaction that, relative to the initial phosphorus and nitrogen contents in the solid poultry or animal wastes, allows extraction of at least twice as much of the phosphorus (in percentage terms) than the nitrogen (y-axis≥2.0, preferably >2.0); in other words, allows extraction of at least twice as much of phosphorus (in percentage terms) than nitrogen (e.g., 55% phosphorus and 25% nitrogen extracted).

FIG. **9** (another version of FIG. **6**) is a graph showing the pH on total phosphorus extracted from broiler litter as described below. Total phosphorus concentration increased with decreasing pH of mineral and organic acids extracting solutions; more than about 50% of total phosphorus was extracted with respect to initial total phosphorus content in broiler litter at pH lower than 5 of the extracting acid solutions. The % phosphorus extracted from solids corresponds with values in FIG. **5**. Variables in regression line $y=-11x+107$ are x=pH and y=% phosphorus extracted from solids.

DETAILED DESCRIPTION OF THE INVENTION

Land application of large amounts, of solid animal wastes is an environmental concern often associated with excess phosphorus in soils and potential pollution of water resources. Recovery of phosphorus from solid waste was developed for extraction and recovery of phosphorus from solid poultry or animal wastes (e.g., aminal solid manures and poultry manure). The term solid poultry or animal wastes includes any materials containing a mixture of poultry or animal urine, feces, undigested feed, and optionally bedding material. The invention can use different types of poultry manure such as litter (manure mixed with bedding material) or cake (manure with minimal bedding material). The invention can also use different types of animal wastes such as manure mixed with bedding materials (such as in deep bedding systems for pig or cow rearing) or animal wastes with minimal bedding material (such as scraped or centrifuged manure or manure collected with belt systems).

The process generally includes three steps: (1) phosphorus extraction, (2) phosphorus recovery, and (3) phosphorus recovery enhancement. In the first step (FIG. **1**), solid poultry or animal wastes (e.g., animal solid manures or poultry manure) is washed by mixing it with water and acid in a reactor vessel at a pH lower than about 5.0 (e.g., lower than 5.0) and higher than about 3.0 (e.g., higher than 3.0); preferably at a pH of about 3.1 (e.g., 3.1) to about 5.0 (e.g., 5.0), preferably at a pH of about 3.1 (e.g., 3.1) to about 4.5 (e.g., 4.5) to form a liquid extract and a washed solid residue. The washed solid residue is settled and is dewatered to prevent unnecessary carbon and nitrogen oxidation and digestion; the washed solid residue contains the oxidizible organic carbon and nitrogen fraction that would be digested and oxidized if the animal solid manure or poultry manure had been instead washed by mixing it with water and acid at a low pH (e.g., below 3.0) or that would be lost by ignition (or that would be lost if the animal solid manure or poultry manure had been incinerated before being mixed with water and acid at a low pH (i.e., below 3). The first step extracts at least 60% (e.g., at least 60%) of the phosphorus contained in the original solid poultry or animal wastes (in other words, no more than 40% of the original phosphorus remains in the washed solid residue while the balance is in the liquid extract), preferably at least about 65% (e.g., at least 65%), preferably at least 67%, preferably at least 68%, preferably at least 81%; and the first step extracts no more than about 30% (e.g., 30%) of the nitrogen contained in the original solid poultry or animal wastes (in other words, no more than 70% of the original phosphorus remains in the washed solid residue while the balance is in the liquid extract), preferably no more than 22.0%, preferably no more than 26.8%, preferably no more than 27.4%. The washed solid residue has a N:P ratio (expressed on an elemental basis) of at least more than about 4 (e.g., more than 4; preferably at least 4.1, more preferably at least 4.3, preferably at least 4.4, preferably at least 5.5, preferably at least 9.8, preferably at least 11.1). The washed solid residue contains no more than about 40% (e.g., no more than 40%) of the total phosphorus (P and/or P_2O_5) in the original untreated waste (preferably no more than 37.3%, preferably no more than 35.2%, preferably no more than 29.9%, preferably no more than 26.9%, preferably no more than 26.7%, preferably no more than 26.3%, preferably no more than 25.9%, preferably no more than 25.7%, preferably no more than 24.7%, preferably no more than 22.5%, preferably no more than 18.4%, preferably no more than 17.6%, preferably no more than 16.7%, preferably no more than 16.6%, preferably no more than 16.1%, preferably no more than 15.9%, preferably no more than 15.7%, preferably no more than 15.5%, preferably no more than 14.1%, preferably no more than 13.4%); based on Table 10: the washed solid residue contains less than about 5% (e.g., less than 5%) P_2O_5, preferably less than 4%, preferably less than 3%, preferably less than 2%, preferably no more than 1.15%, preferably no more than 1.06%, preferably no more than 0.96%; the washed solid residue contains less than about 5% (e.g., less than 5%) P, preferably less than 4%, preferably less than 3%, preferably less than 2%, preferably less than 1%, preferably no more than 0.52%, preferably no more than 0.50%, preferably no more than 0.46%, preferably no more than 0.42%, preferably no more than 0.40%. The washed solid residue contains about 100% (e.g., 100%) of the carbon in the original untreated waste; based on Table 10: the washed solid residue contains about 34% to about 42% carbon. The washed solid residue contains at least about 60% (e.g., at least 60%) of the nitrogen in the original untreated waste, preferably at least 66.1%, preferably at least 68.7%, preferably at least 74.9%, preferably at least 77.4%, preferably at least 78.3%, preferably at least 80.4%, preferably at least 81.1%, preferably at least 82.5%, preferably at least 83.4%, preferably at least 83.7%, preferably at least 85.4%, preferably at least 85.8%, preferably at least 86.7%, preferably at least 87.0%, preferably at least 88.2%, preferably at least 88.6%, preferably at least 89.9%, preferably at least 97.8%; based on Table 10: the washed solid residue contains less than about 5% (e.g., less than 5%) N, preferably less than 4%, preferably less than 3%, preferably no more than 2.16%, preferably no more than 2.10%, preferably no more than 1.96%, preferably no more than 1.82%, preferably no more than 1.76%. The washed solid residue contains no more than about 20% (e.g., no more than 20%) of the potassium in the original untreated waste, preferably no more than about 15% (e.g., no more than 15%), preferably no more than 14.6%, preferably no more than 14.4%, preferably no more than 13.8%, preferably no more than 13.3%, preferably no more than 13.0%; based on Table 10: the washed solid residue contains, less than about 5% (e.g., less than 5%) K, preferably less than 4%, preferably less than 3%, preferably less than 2%, preferably less than 1%, preferably no more than 0.50%, preferably no more than 0.48%, preferably no more than 0.44%, preferably no more than 0.39%, preferably no more than 0.38%. The washed solid residue contains no more than about 20% (e.g., no more than 20%) of the K_2O in the original untreated waste, preferably no more than about 15% (e.g., no more than 15%), preferably 14.7%, preferably no more than 14.5%, preferably no more than 13.8%, preferably no more than 13.2%, preferably no more than 12.9%; based on Table 10: the washed solid residue contains less than about 5% (e.g., less than 5%) K_2O, preferably less than 4%, preferably less than 3%, preferably less than 2%, preferably less than 1%, preferably no more than 0.59%, preferably no more than 0.57%, preferably no more than 0.52%, preferably no more than 0.47, preferably no more than 0.45%. This first step produces a liquid extract containing low suspended solids of less than about 3.5 g/L (e.g., less than 3.5 g/L; preferably less than about 3 g/L (e.g., less than 3 g/L)) and extracted soluble phosphorus (e.g., generally more than about 600 mg/L (more than 600 mg/L); preferably at least about 613 mg/L (at least 613 mg/L)); the liquid extract contains the phosphorus in the original material less the phosphorus in the washed solid residue. The washed solid manure residue is subsequently separated from the liquid extract and dewatered; unnecessary carbon and nitrogen oxidation and digestion are prevented by dewatering the residue.

The liquid extract is transferred to a second vessel where phosphorus is recovered in steps **2** and **3** (FIG. **2**). In step **1**, organically bound phosphorus is first converted to soluble-P by selective, hydrolysis reactions using mineral or organic acids. This process hydrolyzes organic phosphorus-containing compounds rapidly in order to extract the phosphorus; more phosphorus goes into solution than nitrogen under the acidic conditions utilized (e.g., 3>pH<5). This step also releases phosphorus from insoluble inorganic phosphate complexes. Therefore, for purposes of the present invention, selective hydrolysis is defined as any hydrolysis reaction which allows extraction of at least twice as much of phosphorus (in percentage terms) than nitrogen (Table 2 and FIG. **8**; see also Table 11). The selective hydrolysis and solubilization of phosphorus compounds is obtained by using organic acids such as citric, oxalic, malic, etc., mineral acids such as hydrochloric or sulfuric, for example, or a mixture of both mineral and organic acids or their precursors. The acids used in the process can be produced using different acid precursors that consist of organic substrate including animal waste transformed into acid compounds by bacterial, yeast, or fungal microorganisms for example, such as *Thiobacillus* sp., *Arthrobacter paraffineus, Candida* sp., and *Aspergillus niger*. Furthermore, any mineral acid or organic acid can be used in the selective hydrolysis step. Although the preferred acids for quick wash are those acids which do not add phosphorus or nitrogen, the use of acids such as nitric, ethyldiamintetracetic, sulfuric or phosphoric may be used during the process of the present invention to fortify the final extracted product with nitrogen, sulfur or phosphorus.

In step **2**, phosphorus is precipitated by addition of an alkaline earth base, such as for example lime (calcium hydroxide), magnesium hydroxide, calcium oxide, magnesium oxide, and mixtures thereof, to the liquid extract to a pH range of not less than about 8.0 (e.g., not less than 8.0) to not more than about 11.0 (e.g., not more than 11.0), preferably not less than about 9.0 (e.g., not less than 9.0) to not more than about 11.0 (e.g., not more than 11.0), to form an alkaline earth metal-containing phosphorus compound.

In step **3**, an organic flocculant is added into the second vessel to enhance precipitation and phosphorus grade of the precipitated product (steps **2** and **3** may occur simultaneously or sequentially; preferably sequentially). After a settling period, of less than about 30 minutes (e.g. less than 30 minutes) the precipitated phosphorus-rich solid is removed from the bottom of the second vessel while the supernatant liquid is recycled back into the quick wash system or land applied. The flocculant is a poly-electrolyte and is added at less than about 10 ppm (e.g., less than 10 ppm) to increase the yield of filtering. One example of a filtering device is a 0.84 m×0.84 m×0.13 sieve box with a 0.6 wire mesh bottom and a commercial polypropylene non-woven fabric (Dupont E.I. de Nemours, N.J.). One of ordinary skill in the art could readily determine any other filter that would be useable in the process of the present specification. The present invention produces a phosphorus fertilizer material (i.e., the precipitated phosphorus-rich solid after steps **2** and **3**) that contains: (1) greater than about 10% P_2O_5 (e.g., more than 10%; preferably 10.91% or more; preferably 10.95% or more; preferably 11.06% or more; preferably 1.1.16 or more %; preferably at least 11.21%); (2) greater than about 4% P (e.g., more than 4%; preferably 4.57% or more; preferably 4.61% or more; preferably 4.70% or more; preferably 4.79% or more; preferably at least 4.83%); (3) less than about 5% N (e.g., less than 5% N; preferably less than 4.5%; preferably less than about 4% (e.g., less than 4%); preferably 3.64% or less; preferably 3.61% or less; preferably 3.54% or less; preferably 3.47% or less; preferably no more than 3.44%); (4) less than about 5% K as K_2O (e.g., less than 5%; preferably less than about 4.5% (e.g., less than 4.5%); preferably less than about 4.0% (e.g., less than 4.0%); preferably less than about 3.5% (e.g., less than 3.5%); preferably less than about 3.0% (e.g., less than 3.0%); preferably less than about 2.5% (e.g., less than 2.5%); preferably less than about 2.0% (e.g., less than 2.0%); preferably less than about 1.5% (e.g., less than 1.5%); preferably less than 1.188%; preferably less than 1.164%; preferably less than 1.128%; preferably less than 1.08%; preferably no more than 1.068%); (5) less than about 4% K (e.g., less than 4%; preferably less than about 3.5% (e.g., less than 3.5%); preferably less than about 3.0% (e.g., less than 3.0%); preferably less than about 2.5% (e.g., less than 2.5%); preferably less than about 2.0% (e.g., less than 2.0%); preferably less than about 1.5% (e.g., less than 1.5%); preferably less than 0.99%; preferably less than 0.97%; preferably less than 0.94%; preferably less than 0.90%; preferably no more than 0.89%); (6) less than about 40% C (e.g., less than 40%; preferably less than 36.26%; preferably less than 36.11%; preferably less than 35.90%; preferably less than 35.60%; preferably no more than 35.54%); (7) more than about 10% Ca (e.g., more than 10%; preferably more than 10.27%, preferably more than 10.54%; preferably more than 11.22%; most preferably more than 11.89, preferably at least 12.117%); (8) less than about 2% Na (e.g., less than 2%; preferably less than about 1% (e.g., less than 1%); preferably less than 0.34%, preferably less than 0.33%, preferably less than 0.31%, preferably less than 0.29%, preferably no more than 0.28%); (9) less than about 2% Mg (e.g., less than 2%; preferably less than about 1.5% (e.g., less than 1.5%); preferably less than 0.70%, preferably less than 0.69%, preferably no more than 0.68%). Furthermore, this phosphorus product is only about 15% (e.g., 15%) of the initial volume of the poultry litter.

In addition, the remaining washed solid residue has a more balanced nitrogen to phosphorus ratio that is environmentally safe for land application and use by crops. As an alternative, washed litter residue can be digested for methane production or utilized as bedding especially in areas where bedding material is in short supply.

The process is generally conducted at an ambient temperature greater than about 5° C. and less than about 50° C. (e.g., greater than 5° C. and less than 50° C.; preferably greater than about 10° C. and less than about 45° C. (e.g., greater than 10° C. and less than 45° C.); greater than about 10° C. and less than about 40° C. (e.g., greater than 10° C. and less than 40° C.); greater than about 10° C. and less than about 35° C. (e.g., greater than 10° C. and less than 35° C.); greater than about 10° C. and less than about 30° C. (e.g., greater than 10° C. and less than 30° C.); in other words the process does not require heat and the process is not exothermic.

Poultry litter used in the following experiments consisted of wood chip bedding plus manure accumulated during bird production. Broiler litter for Examples 1 and 2 below was collected from a 27,400-bird broiler house in Sumter County, South Carolina. At the time of sampling, the litter was being used by the fifth consecutive flock (approximately 6.5 flocks per year). Two composite litter samples were taken in approximately two 12-meter transects covering the width of the house. Composite samples were placed in 20-liter plastic sealed containers and stored in the freezer until preparation for laboratory experiments.

Broiler litter used for field prototype experiments was collected from a 25,000-bird broiler house. At the time of sampling, the house was empty and between the second and third flock (5 flocks per year). Two large composite litter samples were taken in two transects along the house, in its center section between water lines, and placed in 160-L containers. The containers were sealed, transported and placed in cold storage of about <2 degrees centigrade. Two 15.2 kg samples were prepared for field prototype experiments. In average, the two samples contained approximately 28.6 (±0.6) % moisture, approximately 26.2 (±0.04) mg/kg TKN, and approximately 15.5 (±3.8) mg/kg total phosphorus (Table 1 below). Prior to field prototype tests, broiler litter was ground and homogenized using a chipper (Yard Machines 5HP model, MTD LLC, Cleveland, Ohio). Average particle size distribution of chipped poultry litter is shown in FIG. **4**.

Analysis of supernatant liquid was, performed according to Standard Methods for the Examination of Water and Wastewater (APHA, 0.1998, Standard Methods for the Examination of Water and Wastewater, 20th edition. Washington, D.C., American Public Health Association, American Water Works Association, and Water Environment Federation). Total phosphorus and Total K nitrogen were determined in liquid and solid samples using the automated ascorbic acid method (Standard Method 4500-P F) and the phenate method (Standard Method 4500-NH_3 G) adapted to digested extracts (Technicon Instruments Corp., 1977, Individual/simultaneous determination of nitrogen and/or phosphorus in BD acid digests (dialyzer), Industrial method 337-74W/B, Tarrytown, N.Y.), respectively. Total nitrogen is the sum of total K nitrogen plus nitrate-nitrogen. Nitrate nitrogen was also determined using Standard Method 4500-NO_3^-F; it represented less than about 3% of total nitrogen. The pH of the supernatant liquid was measured electrometrically using a combination pH electrode. Total suspended solids (TSS) were determined by retaining solids on a glass-fiber filter (Whatman grade 934AH, Whatman Inc., Clifton, N.J.) dried to approximately 105° C. (Standard Method 2540 D). Moisture in solids was determined using a microwave moisture analyzer (Omnimark Instrument Corp., Tempe, Ariz.). Elemental analysis of recovered phosphorus-rich solids for total carbon and nitrogen was done by dry combustion (Leco Corp., St. Joseph, Mich.) and for phosphorus, calcium, magnesium, potassium, and sodium by inductively coupled plasma (ICP) from nitric acid plus H_2O_2 digested extract (Peters, J., et al., Recommended methods of manure analysis, University of Wisconsin-Extension Publication A3769, 2003).

The process can be carried out in batch mode using a single vessel to do the mixing and settling in step **1** or steps **2** and **3** (FIG. **2**) or adapted for continuous operation using two separate vessels, to do the mixing first and then the settling (FIG. **3**).

The following examples are intended only to further illustrate the invention and are not intended to limit the scope of the invention as defined by the claims. Unless defined otherwise, all technical and scientific terms used herein have the same meaning as commonly understood by one of ordinary skill in the art to which the invention belongs. The term "about" is defined as plus or minus ten percent; for example, about 100° F. means 90° F. to 110° F. Although any methods and materials similar or equivalent to those described herein can be used in the practice or testing of the present invention, the preferred methods and materials are now described. Poultry litter is used as a model for solid animal or poultry manure to demonstrate the invention.

Example 1

Organic and inorganic acids were tested for their potential to extract phosphorus from poultry litter. Poultry litter samples were prepared by grinding and passing through a sieve of about 5.8 mm. Aqueous solutions of acetic, citric, and hydrochloric acids were added to about 2.00 grams of ground and sieved poultry litter samples in a ratio of about 1:2.5 w/v at concentration levels of about 0, 2.5, 5, 10, 20, 40, and 80 mmoles/liter. The solutions and litter were mixed in a reciprocating shaker at about 135 oscillations/minute at ambient temperature of about 23° C. for approximately 1 hour. Subsequently solids and liquid were separated by centrifuge at about 2000×g for about 5 minutes. The liquid supernatant was decanted and analyzed for pH, total phosphorus (TP), and total Kjeldahl nitrogen (TKN). Solids were air dried at about 40° C. and analyzed for total Kjeldahl and total phosphorus. The experiment was repeated and the treatment control consisted of extraction with distilled water. Treatment efficiency of the various acid treatments was established by comparison of phosphorus extraction relative to initial phosphorus content in untreated poultry litter (Technicon Instruments Corp., 1977), respectively. The ground and sieved poultry litter contained approximately 17.1±0.2% moisture, approximately 35.10±0.02 mg/kg of total kjeldahl nitrogen, and approximately 19.2±0.2 mg/kg total phosphorus (Table 1).

Both mineral and organic acids extracted phosphorus from poultry litter (FIG. **5**). During extraction, a significant portion of total phosphorus in poultry litter was released from the manure solids. Total phosphorus extraction rates increased with increasing acid concentrations. At approximately 40 mmol/L concentration of acid, about 81% of the initial total phosphorus content in broiler litter was extracted. In contrast, the distilled water (control) extracted only about 20%. In addition to the concentration of acid, the type of acid made a difference. Citric acid was surprisingly more efficient at extracting phosphorus than HCl or acetic acid at similar molar applications (approximately 2.5 to 40 mmol/L). High extraction efficiencies (>70%) were also possible with HCl, but required molar rates that were double (approximately 80 mmol/L).

Even though phosphorus extraction surprisingly increased from approximately 17% to approximately 81% with increased citric acid treatment in the range of approximately 0 to approximately 40 mmol/L, nitrogen extraction was surprisingly not greatly affected (Table 2). Nitrogen contained in litter was extracted much less efficiently than phosphorus. For instance, about 81% of initial total phosphorus in litter was extracted in treatment 5 at about pH 3.8 (approximately 40 mM citric acid) but only about 27% of nitrogen was extracted (Table 2). Thus, the litter wash residue surprisingly resulted in a nitrogen:phosphorus ratio of approximately 9.8. This is surprisingly about 5-fold higher than the nitrogen:phosphorus ratio of the untreated litter (nitrogen:phosphorus ratio of about 2.1). Furthermore, this is in the range of nitrogen:phosphorus ratio required for balanced fertilization of crops for both nitrogen and phosphorus.

The percentage of phosphorus extracted from solids increased linearly with decreasing pH ($y=-11x+107$, $R^2=0.87$, $n=19$, $P<0.0001$, FIGS. **6** and **9**). Using the equation one can estimate a range of percent phosphorus extracted; for example where pH=3.1, $y=(-11)(3.1)+107=73\%$, or where pH=5.0, $y=(-11)(5.0)+107=52\%$. The pH required to extract % P from solids decreased linearly with increasing phosphorus extraction ($x=(y-107)/-0.11$, $R^2=0.87$, $n=19$, $P<0.0001$, FIGS. **6** and **9**). Using the equation one can estimate the pH required to extract a percentage of phosphorus extracted from solids; for example, where % P extracted from solids is 55%, $x=(55\%-107)/-11=4.73$, or where % P extracted from solids is 60%, $x=(60\%-107)/-11=4.27$. Although the quick wash process consistently extracted more than about 50% of total phosphorus when the pH of the acid solution-broiler litter mixture was lower than 5 units, similar percentages of phosphorus from broiler litter were extracted at different acid concentrations (FIG. **5**). Thus, the amount of acid added in the process to extract a specific amount of phosphorus can be controlled by setting a specific end point pH using a pH controller. The process includes any pH range along the curve shown in FIG. **6** or **9** (or defined by the above equation); for example pH range of 3.1 to 4.0, or 3.2 to 4.1, or 3.3 to 4.2, etc. The process also includes any % P extracted from solids range along the curve shown in FIG. **6** or **9** (or defined by the above equation); for example 50-60%, or 51-61%, or 52-62%, etc.

Although other mineral and organic acids can be used for the present invention, such as for example, sulfuric, malic, oxalic, phosphoric, nitric ethyldiamintetracetic, etc., the preferred acids are those that do not add phosphorus or nitrogen during the process of extracting phosphorus. Therefore, the use of acids such as phosphoric nitric, or ethyldiamintetracetic is not recommended.

The treated litter (washed solids; washed solid residue) left at the end of the process can now be used for land application at rates based on the nitrogen crop requirements without accumulation of excess phosphorus in the soil. Using data from Edwards and Daniel (1992), a nitrogen:phosphorus ratio of 5.2:1 would be needed to match Kentucky bluegrass specific nutrient uptake needs, which can be delivered with a phosphorus extraction at pH 4.5 (nitrogen:phosphorus=5.5). Higher nitrogen:phosphorus ratios needed for cotton (6.2:1), corn (7.5:1) or wheat (10.7:1) can be obtained at pH<4.5 (Table 2).

TABLE 1

Broiler litter characteristics.

Experiment	Moisture %	Total Phosphorus g/kg	Total Nitrogen g/kg	Nitrogen: Phosphorus Ratio
Examples 1 and 2 Sample 1	17.6	19.4	34.6	1.8

Example 2

To demonstrate the removal and recovery of phosphorus from the liquid extract, which includes steps **2** and **3** of the process, generated by litter washing (step **1**) (FIG. **2**), approximately 64 grams of poultry litter, as prepared in Example 1, was mixed with approximately 1.6 liters of 20 mM citric acid solution in a ratio of 1.25 w/v and stirred for about one hour with a magnetic stirrer. After the mixture settled for about 20 minutes, the liquid extract was separated from washed litter by decantation and transferred to separate laboratory vessels. To one half of the vessels, hydrated lime ($Ca(OH)_2$) was added, to the other half, lime and flocculant was added. Hydrated lime in water was added in various amounts until the pH of the mixed liquid reached set points of approximately 6, 7, 8, 9, 10, or 11 units (Treatments 1-6, respectively); a control treatment with no lime addition was included (Treatment 0). The recovery of phosphorus was enhanced by adding an organic flocculant to clump the fine particles of the phosphorus precipitate (Step **3**). The organic flocculant was an anionic polymer (polyacrylaminde) Magnafloc 120 L with an approximately 34% mole charge and approximately 50% active ingredient (CIBA Specialty Chemicals Water Treatment, Inc., Suffolk, Va.). This flocculant was added at a rate of approximately 7.0 mg/L (active ingredient). For both lime only and lime plus flocculant addition, the liquid supernatant was decanted and analyzed for pH, total phosphorus, and total Khejdahl nitrogen. Solids were air dried at about 40° C. and analyzed for total Khejdahl nitrogen. Treatment efficiency of the various lime and flocculant treatments was expressed as percentage of phosphorus extraction relative to initial phosphorus content. All tests were conducted in duplicate.

A 20 mmol/L citric acid extract solution was selected for step **1** to further recovery of phosphorus with hydrated lime. This liquid extract contained a high total phosphorus concentration of about 600 mg/L at about pH 4.7 (Table 3, Treatment 0) and low total suspended solids (approximately 2.1 g/L) after liquid-solid separation by decantation. In step **2**, total phosphorus was removed from solution by precipitating soluble phosphorus compounds under alkaline conditions. Addition of hydrated lime decreased total phosphorus until a pH of approximately 8.0 units was obtained (Table 3).

Subsequent addition of a flocculant improved the percentage of total phosphorus removed at pH higher than 8.0 (Table 4). A small amount of an organic flocculant was added at a rate of about 7 mg/L (active ingredient) to all treatments to enhance thickening and phosphorus grade of the precipitated product (Step **3**). Results in Table 4 surprisingly show an increase of the amount of phosphorus extracted and higher phosphorus grade of the precipitate by addition of hydrated lime followed by flocculant enhancement. The highest phosphorus recovery rate and grade in the precipitate (about 18.8% P_2O_5) was surprisingly obtained when the pH reached a value of about 10.0 units.

The enhancing effect of organic flocculant addition on total phosphorus content of the precipitate is summarized in Table 5 at three hydrated lime levels (pH approximately 8, 9, and 10) with and without application of polymer after citric acid (approximately 20-mM) extraction. From these results, surprisingly more than 65% of total phosphorus in poultry litter can be recovered by the addition of hydrated lime and small amounts of organic flocculant (Steps **2** and **3**).

TABLE 3

Quick wash process (Step 2), hydrated lime application for recovery of extracted soluble phosphorus from broiler litter. Data show total phosphorus concentration in liquid extract and corresponding percentage of total phosphorus removed by increasing pH with hydrated lime after phosphorus extraction (Step 1) with citric acid solution (1:25).

Treatment[1]	pH	$Ca(OH)_2$ applied g/L liquid	Total phosphorus mg/L	Total phosphorus removed from liquid extract[2] %
0	4.7	0.0[3]	613	0
1	6.0	1.4	381	39
2	7.0	2.0	299	51
3	8.0	2.6	215	65
4	9.0	3.1	251	59
5	10.0	3.7	303	51
6	11.0	4.1	236	62

[1]Treatment of the liquid was done by addition of hydrated lime (2% $Ca(OH)_2$ in water) to obtain a specific pH.
[2]Total P Removed = P recovered from liquid fraction relative to initial P concentration in liquid extract (613 mg/L).
[3]Data are the average of two replicates.

TABLE 4

Quick wash process (Steps 2 and 3), hydrated lime and flocculant application for recovery of extracted soluble phosphorus from broiler litter. Data show total phosphorus recovered per unit weight of broiler litter and phosphorus grade of the recovered phosphorus. Step 1 (P extraction), was carried out using citric acid solution (1:25 w/v).

Treatment[1]	pH	$Ca(OH)_2$ applied g/L liquid	$Ca(OH)_2$ applied g/kg litter	Total phosphorus recovered[2] g/kg litter	Total phosphorus recovered[2] %	Phosphorus grade in precipitate % P_2O_5
0	4.7	0.0[3]	0.0	0.5	2.8	1.4
1	6.0	1.4	36	6.5	33.6	14.9
2	7.0	2.0	50	8.1	42.3	11.9
3	8.0	2.6	65	11.7	61.0	17.6

[3]Anionic polyacrylamide, 37% charge, applied at a constant rate (7 mg/L active ingredient).
[4]Data are the average of two replicates.

Example 3

A field prototype system was developed to evaluate the process of the present invention to extract and recover phosphorus from poultry litter. The system included two connected reactor vessels (FIG. **3**). The extraction vessel **20** in the sequence was the phosphorus extraction reactor that consisted of an approximately 378-liter tank with a conical bottom **22**, a mixer **24**, and a pH controller (not shown). Once liquid reacted with solids, stirring was stopped to let solids settle. After settling of solids, the supernatant from tank **20** was pumped to a second vessel, a phosphorus removal tank **30**. The tank **30** in the sequence was the phosphorus recovery reactor that consisted of a second about 378 liter tank with a conical bottom **32**, mixer (not shown) and pH controller (not shown). The unit was completed with a smaller 115 gallon tank (not shown) with a mixer and pump used to stir and inject the hydrated lime solution into the tank **30**. Solid and liquid sampling was done in duplicate. Phosphorus extraction was performed by adding citric acid, approximately 10% w/w to a stirred mixture of approximately 15.2 kg of broiler litter, prepared as in Example 1, and water in a ratio of approximately 1:25 w/v inside the extraction reactor **20**. Addition of citric acid stopped when the pH of the mixture reached a set point of approximately 4.5. The extraction mixture was sampled about every 10 minutes during about a sixty minute, stirring period to determine the minimum stirring time required to reach a stable total phosphorus concentration in the extraction liquid; total phosphorus was determined in supernatant after about a 24 hour settling of unfiltered samples. The treated litter solids were removed from the bottom of the phosphorus extraction tank **20** after, about a twenty minute-settling period and further dewatered through a filter. The filter was a 0.84 m×0.84 m×0.13 sieve box with a 0.6 wire mesh bottom and a commercial polypropylene non-woven fabric (Dupont E.I. de Nemours, N.J.).

The supernatant from the phosphorus reactor was pumped into the phosphorus recovery reactor tank **30** and hydrated lime; about 10% $Ca(OH)_2$, was injected and mixed pH controller (not shown) stopped the lime injection when the pH of the mixed liquid reached a set point of about 9.0 in the first experiment or about 10 in the second experiment. Once the desired pH was reached, about 15 mg/L of anionic polyacrylamide, a flocculant, was injected and mixed to enhance phosphorus recovery. The precipitated solids were removed from the bottom, of the tank-after an approximately 30 minute settling period and dewatered through a filter as described above. The dried P-solids were analyzed for phosphorus, carbon, nitrogen, calcium, magnesium, potassium, and sodium content.

The prototype experiment was based on the acid and alkaline endpoint pH values that were determined in Examples 1 and 2 to extract, and recover more than about 65%, of total phosphorus from poultry litter. This procedure avoided an excessive chemical application. Consequently, in the prototype experiment, phosphorus was extracted from broiler litter using citric acid solution at approximately pH 4.5. The first tested component was the effect of stirring time on amount of phosphorus extracted from the slurry formed by mixing litter and extracting liquid (Step **1**). Extracted total phosphorus concentration remained stable (approximately 300-330 mg/L) at pH of approximately 4.5 with stirring time of about 20 minutes or more (FIG. **7**). From these results, it was confirmed that stirring time of about 20 to about 60 minutes (e.g., 20 to 60 minutes) is sufficient to obtain a stable total phosphorus extracted concentration during extraction process at a pH of approximately less than 5.0.

Phosphorus extraction performance of the prototype system under field conditions (Table 6) was surprisingly consistent with performance obtained in the laboratory (FIGS. **5** and **6**). Phosphorus-extraction efficiencies of approximately 65 to approximately 75% with respect to initial total phosphorus in broiler litter were surprisingly obtained with pH treatment of approximately 4.5 for both runs. As a result of phosphorus extraction, the average nitrogen:phosphorus ratio is better for crop utilization. As an alternative, the dried washed litter could be reused in the broiler house as bedding in geographic areas where bedding materials are in short supply or digested for methane production.

After settling in the phosphorus extraction tank, the supernatant liquid had a low total suspended solids (TSS) concentration of approximately <3.5 g/L, with respect to the total suspended solids concentration of the extraction slurry of approximately 28.7 g/L. This clarified liquid was pumped to the phosphorus recovery tank reactor and treated with hydrated lime and flocculant. This treatment surprisingly recovered approximately 92 to 89% of phosphorus extracted in step **1**. The complete process surprisingly recovered >60% of the initial total phosphorus in broiler litter; higher phosphorus recovery rates were obtained at a pH of approximately 10.0 (Table 6).

Before dewatering, mean initial moisture of the phosphorus sludge was about 96.3% (Table 7). After filtration, the sludge-had a mean moisture content of about 88.8%. The drying process was further accelerated by placing the phosphorus sludge in a greenhouse. The mean moisture content declined to about <10% in the subsequent thirteen days after filtration.

The prototype performance confirmed laboratory results that about >60% of the total phosphorus content of poultry litter can be surprisingly recovered using the quick wash process of the present invention (Table 6). The phosphorus grade of the product obtained in the prototype was lower (about 11.1% P_2O_5=4.85 mg P/100 grams×2.29) than the precipitate obtained in the laboratory (Tables 3 and 8). For example, on a dry matter basis, litter treated in the prototype had a lower mass and lower phosphorus concentration per volume of extracting solution.

In average, the precipitate contained relatively large amounts of phosphorus, carbon (C), nitrogen (N), and calcium (Ca), and small amounts of magnesium (Mg), potassium (K), and sodium (Na) (Table 8). Thus, the resulting molar ratio was about 1:7.0:1.6:1.4 for P:C:N:Ca.

An additional characteristic of the recovered phosphorus product was its surprisingly reduced bulk volume. The recovered phosphorus product (average dry bulk density of about 780 g/dm^3) surprisingly had about 17% of the initial volume of poultry litter. Therefore, the recovered phosphorus product can be transported more economically off the farm for use as a fertilizer material.

TABLE 6

Performance of field prototype to remove phosphorus from poultry litter using the quick wash process.

	Litter Before Wash			Extraction			Recovery		
Run	Total P g/kg litter	N:P Ratio[1]	N:P Ratio Washed Litter	pH	Total P[2] g/kg litter	%	pH	Total P[3] g/kg litter	%
1	12.8	2.0	4.4	4.5	8.3	65	9.0	7.7	60
2	18.2	1.5	4.1	4.5	13.7	75	10.0	12.2	67
Average	15.5	1.75	4.3	4.5	11	70	9.5	10.0	64

[1]Initial N content in litter: 2.59 and 2.65 g/kg for run 1 and 2, respectively.

[2]Total P extracted = P extracted relative to initial P content in litter before wash.

[3]Total P recovered = P recovered in precipitated solids relative to initial P content in litter after flocculant application.

TABLE 7

Percent moisture of phosphorus sludge before and after dewatering.

Sludge Phosphorus Dewatering	Percent Moisture g per 100 g Run 1	Run 2	Mean

[3]Potassium grade expressed as K_2O = % K × 1.20

Example 4

This Example demonstrated that the manure wash treatment was also surprisingly effective to remove P from other animal manure besides poultry litter. A 64-g hog manure sample was mixed with about 1.6 L of 10-mM citric acid solution and stirred for approximately one hour. Similar to Examples 1 and 2 above, after the manure-liquid extract mixture settled for about 20 minutes, the liquid extract was separated from the washed litter by decantation and transferred to separate laboratory vessels. Hydrated lime was added to the vessels in various amounts until the pH of the mixed liquid reached set points of about 6, 7, 8, 9, 10 and 11 units (Treatments 1-6, respectively); the test included a control (treatment 0) with no lime addition. The recovery of P was enhanced (step **3**) by adding the same flocculant as in experiment 2 (7.0 mg L^{-1} active ingredient) to all six lime treatments and control. Liquid supernatant was decanted and analyzed for pH, TP, and TKN; solids were air dried at 40° C. and analyzed for TKN and TP. The tests were conducted in duplicate.

Table 9 shows experimental data supporting that the quick wash process can be surprisingly used for swine manure treatment and other fresh animal manures. In step **1**, phosphorus from fresh manure was extracted at pH 4.5 when mixed with 10-mM citric acid (Table 9, treatment 0). Results in Table 9 show a surprising increase of the amount of phosphorus recovered by addition of hydrated lime (step **2**) and organic flocculant (step **3**). The highest phosphorus recovery rate (6.4 g/kg manure) was surprisingly obtained when the pH reached a value between 9.0 and 10.0 units. Thus, about 90% of total phosphorus in swine manure can be surprisingly recovered by the addition of hydrated lime and small amount of organic flocculant. From this example, we concluded that the quick wash treatment can be used for P extraction and recovery from animal manures other than poultry litter.

TABLE 9

Quick wash process (steps 2 and 3), hydrated lime and flocculant application for recovery of phosphorus from swine manure after phosphorus extraction (step 1) with citric acid solution. Data show phosphorus recovered fresh swine manure by increasing pH with hydrated lime and organic flocculant addition.

		Total P Recovered	
Lime Treatment	pH[1]	g/kg manure	%
0	4.5	0.0	0
1	6.0	2.2	31
2	7.0	4.7	66
3	8.0	6.2	87
4	9.0	6.4	90
5	10.0	6.4	90
6	11.0	6.3	89

[1]Specific pH treatment was obtained by addition of hydrated lime (2% $Ca(OH)_2$ in water). An anionic polymer (polyacrylamide) was added at a rate of 7 mg/L (active ingredient) to all treatments to enhance precipitation.

[2]% Total P recovered = P recovered relative to initial P content in fresh swine manure (7.1 g/kg). Solids content of fresh manure = 30%.

[3]Data are the average of two replicates.

Van Slyke (U.S. Pat. No. 6,916,426) discloses to extract ammonium, phosphorus and potassium from an animal waste slurry to form ureates of potassium and ammonium in crystalline form. Van Slyke further discloses that a substantial amount of potassium is extracted as ureates of potassium using flocculation before they degrade. Therefore, the solid material disclosed by Van Slyke contains substantial amounts of the potassium, nitrogen and phosphorus that was contained in the original animal waste sludge. Our fertilizer phosphorus product material is low in potassium (e.g., potassium content of less than 1% in Table 8) and low in nitrogen (e.g., nitrogen content of less than 4 in Table 8) because the acid treatment that we apply with our process would solubilize and destroy the potassium ureates, and the potassium remains in solution in the liquid extract. Our subsequent alkaline addition to the liquid extract reaching a pH between 8 and 11 does not recover significant amounts of the solubilized potassium that resulted from the destruction of the potassium ureates at acid pH. Therefore, our phosphorus fertilizer product contains low concentrations of potassium (e.g., Table 8, where total potassium is at most 0.97%). In contrast, our process does not involve ureates; there is also no flocculation of our initial animal wastes prior to or during our acid addition and/or lime addition.

Our process does not involve anaerobic digestion, composting, or direct combustion processes as disclosed in Kelleher et al., Bioresource Technology, 83: 27-36 (2002).

The solid poultry or animal wastes utilized by the process of the present invention are not incinerated before or during our process; in other words the present invention does not concern incinerated materials (e.g., incineration ash in JP 2000189927) which are devoid of oxidizable organic carbon and nitrogen and therefore are not solid organic wastes. The present process does not involve the addition of ammonium sulfate nor the production of aluminum phosphates.

The pre-treatment of solids using wet oxidation or fenton oxidation according to Kida (JP 20033200199) destroys the organic matter and solubilizes phosphorus. Nitrogen and organic substances in the sludge are removed by nitrification-denitrification. A wet oxidative pre-treatment to solid poultry or animal waste is contrary to our teaching of removing, phosphorus while conserving most of the carbon and nitrogen in the washed litter residue. In addition, our process does not use nitrification-denitrification to destroy carbon and nitrogen compounds form the solid poultry and animal waste. Furthermore, Kida is different from our process because Kida applies hydrochloric acid to a pH of less than 2 to remove phosphorus only from the ash of the deposit of undigested sludge already separated from supernatant liquid; in contrast, in our process the acid (e.g., at a pH lower than 5.0 and higher than 3.0) is first applied to the entire mass of poultry litter or animal waste to remove phosphorus prior to separation of the formed liquid extract and soluble phosphorus from the washed solid residue.

The process of Higashida (U.S. Pat. No. 5,378,257) is different from our process since it does not form (1) a liquid extract and soluble phosphorus and (2) a washed solid residue, and mixing said liquid extract with an alkaline earth base (e.g., calcium hydroxide). Higashida's process is unrelated to our process of removing phosphorus from solid organic wastes because Higashida does not separate solids from liquid. In Higashida, the Waste material is simply processed by adding nitric acid, crushing the material, adding quicklime, and drying it. In addition, Higashida's process destroys organic matter, which is contrary to the conservation of organic carbon and nitrogen in our process. Higashida teaches that waste matter (e.g., sewage) is oxidized with nitric acid incorporated in it (column 3, lines 30-31; column 4, lines 23-25). Therefore, Higashida's discloses a process that oxidizes, corrodes and destroys the organic matter of organic waste materials. In contrast, our process does not oxidize waste material since our process does not utilize a pH lower than 3.0 where unnecessary carbon and nitrogen digestion would occur which would destroy oxidizable organic carbon and nitrogen.

The method disclosed by Angell (U.S. Pat. No. 5,422,015) adds to solid waste a combination of acid plus a base that produces a strong exothermic reaction that elevates the temperature to at least 70° C. Angell's method has the purpose of disinfecting the waste but not the separation of phosphorus from the waste; phosphorus may even be added for binding heavy metals (see Claim **18**) to produce a material rich in nitrogen, phosphorus, and potassium (Claim **19**). Angell's method is different and unrelated to our process since Angell's method uses the combination of a strong acid and a strong base to create an exothermic reaction when in contact with the waste. In contrast, our process uses acid at such low concentrations that its reaction with the waste does not produce heat. Also, Angell's method requires temperatures of at least 70° C., while our process removes phosphorus from poultry litter and animal waste at ambient temperature of less than about 50° C. Furthermore, Angell's process is an exothermic process developed to kill pathogens but it does not separate phosphorus. Unlike Angell, our process does not involve adding acid and base at the same time and to the same material.

Cabello-Fuentes (U.S. Patent Application Publication No. 2004/0025553) discloses a process for treating sludge involving a first step of disinfecting the sludge by heating the sludge at a temperature of between about 50° C. to 100° C., preferably at 80° C., by means of a heat exchanger, and adding mineral acids in order to decrease the pH of the mass to 3.0 or less, thus guaranteeing that all pathogen microorganisms are destroyed. In contrast, our process does not involve heating solid wastes to a temperature of between about 50° C. to 100° C. and adding acids to decrease the pH of the mass to 3.0 or less.

Our process has, in part, the following advantages: It extracts and recovers phosphorus from organic solid wastes (poultry and animal manures) without the need for destroying the organic carbon as it is usually done during incineration or acid digestion of organic wastes. In addition to conserving the carbonaceous matter, our process conserves most of the nitrogen through a selective hydrolysis reaction. Thus it produces a material with elemental nitrogen to phosphorus ratio (N:P) of more than 4 that is optimal for use in crop production and helps to prevent the eutrophication of surface waters. This washed material contains most of the original carbon, most of the original nitrogen and a reduced amount of the original phosphorus which is more desirable for poultry and livestock producers—such as poultry farmers in the Chesapeake Bay area, Arkansas, and other areas with intensive poultry production—that have problems disposing poultry litter without contaminating soils and water resources with phosphorus. Therefore, poultry producers can use our process to wash the poultry waste to remove only the deleterious constituent for environmental compliance—the phosphorus—and maintaining in the washed residue the desirable constituents that benefit their crops within their operation consisting of the nitrogen with important savings in nitrogen fertilizer cost and the organic carbon which helps to build the organic matter in the soil and improves soil health, water retention, and resistance to drought. Another advantage of our process is that the extracted phosphorus is transferred into a concentrated calcium phosphate fertilizer product that can be easily transported away from areas with excess phosphorus due to intensive poultry and livestock production and be used effectively to substitute for mined phosphate fertilizer used in crop and horticulture production. Another advantage of our process is that heating is not needed and it can be optimally performed at ambient temperatures between 5° and 50° C.

Thus, in view of the above, the present invention concerns (in part) the following:

A process for removing phosphorus from solid poultry or animal wastes comprising (or consisting essentially of or consisting of):

(a) mixing said solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher than about 3.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue, wherein said washed solid residue has a N:P ratio of at least more than 4 expressed on an elemental basis and contains no more than about 40% of the total phosphorus in said solid poultry or animal wastes,

(b) separating said liquid extract from said washed solid residue to form separated liquid extract and separated washed solid residue,

(c) mixing said separated liquid extract with an alkaline earth base to a pH of about 8.0 to about 11.0,

(d) mixing said liquid extract with a flocculant to form (i) precipitated phosphorus solids with P_2O_5 content greater than about 10% and (ii) a liquid, and

(e) separating said precipitated phosphorus solids from said liquid to form separated phosphorus solids and separated liquid;

wherein said process is conducted at a temperature greater than about 5° C. and less than about 50° C., wherein said solid poultry or animal wastes are not pretreated prior to step (a), and wherein steps (c) and (d) are either sequential or simultaneous.

The above process, wherein said process comprises mixing said solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher than 3.0. The above process, wherein said process comprises mixing said solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher or equal to 3.1.

The above process, wherein said process is conducted at ambient temperature.

The above process, wherein said process is conducted at a temperature greater than about 5° C. and less than about 45° C. The above process, wherein said process is conducted at a temperature greater than about 5° C. and less than 45° C. The above process, wherein said process is conducted at a temperature greater than about 5° C. and less than about 40° C.

The above process, wherein said solid poultry or animal wastes are not incinerated before or during said process.

The above process, wherein said-acid is selected from the group consisting of a mineral acid, an organic acid, and mixtures thereof and their precursors.

The above process, wherein said acid is selected from the group consisting of citric acid, oxalic acid, malic acid, hydrochloric acid, sulfuric acid, and mixtures thereof. The above process, wherein said acid is citric acid.

The above process, wherein said alkaline earth base is selected from the group consisting of calcium hydroxide, magnesium hydroxide, calcium oxide, magnesium oxide, and mixtures thereof.

The above process, wherein said steps (c) and (d) are sequential.

The above process, wherein said steps (c) and (d) are simultaneous.

The above process, wherein said washed solid residue contains the oxidizible organic carbon and nitrogen fraction that would be digested and oxidized if said solid poultry or animal wastes had instead been washed by mixing said-solid poultry or animal wastes with water and acid at a pH below about 3.0 or that would be lost if said solid poultry or animal wastes had instead been incinerated before being mixed with water and acid.

The above process, wherein said solid poultry or animal wastes are not pretreated (e.g., incinerated, or treated with flocculant) prior to said mixing said solid poultry or animal wastes with water and acid.

A material produced by a process comprising (or consisting essentially of or consisting of):

(a) mixing solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher than about 3.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue, wherein said washed solid residue contains a N:P ratio of at least more than 4 expressed on an elemental basis and contains no more than about 40% of the total phosphorus in said solid poultry or animal wastes,

(b) separating said liquid extract from said washed solid residue to form separated liquid extract and separated washed solid residue,

(c) mixing said separated liquid extract with an alkaline earth base to a pH of about 8.0 to about 11.0,

(d) mixing said liquid extract with a flocculant to form (i) precipitated phosphorus solids with P_2O_5 content greater than about 10% and (ii) a liquid, and

(e) separating said precipitated phosphorus solids from said liquid to form separated phosphorus solids and separated liquid,

wherein said process is conducted at a temperature greater than about 5° C. and less than about 50° C., and wherein said solid poultry or animal wastes are not pretreated prior to step (a), and wherein steps (c) and (d) are either sequential or simultaneous;

wherein said material is said separated phosphorus solids and contains greater than about 10% P_2O_5, greater than about 10% Ca, less than about 5% N, and less than about 5% K as K_2O.

The above material, wherein said material contains greater than 10% P_2O_5.

The above material, wherein said material contains greater than 10% Ca.

The above material, wherein said material contains less than 4.5% N. The material, wherein said material contains less than 4% N.

The above material, wherein said material contains less than 4.5% K as K_2O. The material, wherein said material contains less than 4% K as K_2O. The material, wherein said material contains less than 3.5% K as K_2O. The material, wherein said material contains less than 3% K as K_2O. The material, wherein said material contains less than 2.5% K as K_2O. The material, wherein said material contains less than 2% K as K_2O.

The above material, wherein said washed solid residue contains the oxidizible organic carbon and nitrogen fraction that would be digested and oxidized if said solid poultry or animal wastes had instead been washed by mixing said solid poultry or animal wastes with water and acid at a pH below about 3.0 or that would be lost if said solid poultry or animal wastes had instead been incinerated before being mixed with water and acid.

A material produced by a process comprising (or consisting essentially of or consisting of):

(a) mixing solid poultry or animal wastes with water and acid at a pH lower that about 5.0 and higher than about 3.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue, and

(b) separating said liquid extract from said washed solid residue to form separated liquid extract and separated washed solid residue;

wherein said material is said separated washed solid-residue and contains a N:P ratio of at least more than 4 expressed on an elemental basis and contains no more than about 40% of the total phosphorus in said solid poultry or animal wastes.

The above material, wherein said material contains less than about 5% (e.g., less than 5%) P_2O_5. The material, wherein said material contains less than 5% P_2O_5. The material, wherein said material contains less than 4% P_2O_5. The material, wherein said material contains less than 3% P_2O_5. The material, wherein said material contains less than 2% P_2O_5.

The above material, wherein said washed solid residue contains the oxidizible organic carbon and nitrogen fraction that would be digested and oxidized if said solid poultry or animal wastes had instead been washed by mixing said solid poultry or animal wastes with water and acid at a pH below about 3.0 or that would be lost if said solid poultry or animal wastes had been instead incinerated before being mixed with water and acid.

Other embodiments of the invention will be apparent to those skilled in the art from a consideration of this specification or practice of the invention disclosed herein. It is intended that the specification and examples be considered as exemplary only, with the true scope and spirit of the invention being indicated by the following claims.

We claim:

1. A process for selectively removing phosphorus from solid poultry or animal wastes containing phosphorus, nitrogen and carbon, said process comprising:

(a) mixing said solid poultry or animal wastes with water and acid at a pH lower than about 5.0 and higher than 3.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue, wherein said washed solid residue has a N:P ratio of at least more than 4 expressed on an elemental basis and contains no more than about 40% of the total phosphorus in said solid poultry or animal wastes,

(b) separating said liquid extract from said washed solid residue to form separated liquid extract and separated washed solid residue,

(c) mixing said separated liquid extract with an alkaline earth base to a pH of about 8.0 to about 11.0,

(d) mixing said liquid extract with a flocculant to form (i) precipitated phosphorus solids with P_2O_5 content greater than about 10% and (ii) a liquid, and

(e) separating said precipitated phosphorus solids from said liquid to form separated phosphorus solids and separated liquid;

wherein said process is conducted at a temperature greater than about 5° C. and less than about 50° C., wherein said solid poultry or animal wastes are not pretreated prior to step (a), wherein said solid poultry or animal wastes are not incinerated before or during said process, and wherein steps (c) and (d) are either sequential or simultaneous.

2. The process of claim **1**, wherein said process comprises mixing said solid poultry or animal wastes with water and acid at a pH of 3.8 to 4.5.

3. The process of claim **1**, wherein said process comprises mixing said solid poultry or animal wastes with water and acid at a pH lower than about 5.0 and higher or equal to 3.1.

4. The process of claim **1**, wherein said process is conducted at ambient temperature.

5. The process of claim **1**, wherein said process is conducted at a temperature greater than about 5° C. and less than about 45° C.

6. The process of claim **1**, wherein said process is conducted at a temperature greater than about 5° C. and less than 45° C.

7. The process of claim **1**, wherein said process is conducted at a temperature greater than about 5° C. and less than about 40° C.

8. The process of claim **1** wherein said acid is selected from the group consisting of a mineral acid, an organic acid, and mixtures thereof and their precursors.

9. The process of claim **1**, wherein said acid is selected from the group consisting of citric acid, oxalic acid, malic acid, hydrochloric acid, sulfuric acid, and mixtures thereof.

10. The process of claim **1**, wherein said acid is citric acid.

11. The process of claim **1**, wherein said alkaline earth base is selected from the group consisting of calcium hydroxide, magnesium hydroxide, calcium oxide, magnesium oxide, and mixtures thereof.

12. The process of claim **1**, wherein said steps (c) and (d) are sequential.

13. The process of claim **1**, wherein said steps (c) and (d) are simultaneous.

14. The process of claim **1**, wherein said washed solid residue contains the oxidizible organic carbon and nitrogen fraction that would be digested and oxidized if said solid poultry or animal wastes had been washed by mixing said solid poultry or animal wastes with water and acid at a pH below about 3.0 or that would be lost if said solid poultry or animal wastes had been incinerated before being mixed with water and acid.

15. The process of claim **1**, wherein said process comprises mixing said separated liquid extract with an alkaline earth base to a pH of 9.0 to 11.0.

16. The process of claim **1** wherein said acid does not add phosphorus or nitrogen during said process.

17. The process of claim **1**, wherein said process is conducted at a temperature of greater than about 10° C. and less than about 45° C.

18. The process of claim **1**, wherein said process is conducted at a temperature of greater than 10° C. and less than 45° C.

19. The process of claim **1**, wherein the percent phosphorus removed from said solid poultry or animal wastes is determined by the following formula: $y=-11x+107$ where x is pH and y is percent phosphorus extracted from said solid poultry or animal wastes.

20. A process for removing phosphorus from solid poultry or animal wastes comprising:

(a) mixing said solid poultry or animal wastes with water and acid at a pH between 3.1 and lower than about 5.0 to form (i) a liquid extract that contains suspended solids of about 3.5 g/L and soluble phosphorus and (ii) a washed solid residue, wherein said washed solid residue has a N:P ratio of 4.1 or more expressed on an elemental basis and contains no more than 40% of the total phosphorus in said solid poultry or animal wastes,

(b) separating said liquid extract from said washed solid residue to form separated liquid extract and separated washed solid residue,

(c) mixing said separated liquid extract with an alkaline earth base to a pH of about 8.0 to about 11.0,

(d) mixing said liquid extract with a flocculant to form (i) precipitated phosphorus solids with P_2O_5 content greater than about 10% and (ii) a liquid, and

(e) separating said precipitated phosphorus solids from said liquid to form separated phosphorus solids and separated liquid.

21. The process according to claim **20**, wherein said acid does not add phosphorus or nitrogen during said process.

[2]*USDA Agricultural Research Service (ARS), Florence, S.C., Matias.Vanotti@ars.usda.gov*

[3]*USDA Agricultural Research Service (ARS), Florence, S.C., Patrick.Hunt@ars.usda.gov*

Abstract – A team of scientists (Drs. Ariel A. Szogi, Matias B. Vanotti, and Patrick G. Hunt) from the Agricultural Research Service (ARS) - Coastal Plains, Soil, Water & Plant Research Center in Florence, S.C., invented a new treatment process, called "quick wash," to extract and recover phosphorus from poultry litter and animal manure solids.[1] This invention led us down the path to an award-winning technology transfer process.[2] As part of this process, a new and unexpected use for the technology emerged that was different from what we had imagined—to the extent that it helped build a new business model for our commercial partner. The purpose of this paper is to describe and illuminate, from the perspective of a principal investigator, what made the process successful and the lessons we learned along the way.

(Keywords: federal laboratory; Department of Agriculture; technology transfer; commercialization; licensing; marketing; technology; principal investigator; business models)

The Inspiration Behind the Effort

Environmental problems, the potential scarcity of phosphorus resources, and the value of recovered phosphorus products were the drivers to developing "quick wash," a method to recover the

[1] Ariel A. Szogi, Matias B. Vanotti, and Patrick G. Hunt. "United States Patent: 8,673,046 - Process for removing and recovering phosphorus from animal waste," March 18, 2014. See http://www.ars.usda.gov/SP2UserFiles/Place/60820500/Manuscripts/2014/pat8673046.pdf.

phosphorus in livestock manure that consists of the rapid removal and recovery of phosphorus in solid form.

Nutrient pollution, caused by too much nitrogen and phosphorus in the environment, is one of America's most widespread, costly and challenging environmental problems, impacting many sectors of the U.S. economy that depend on clean water. The repeated application of untreated manures on soil can cause excess phosphorus accumulation in soils, and its subsequent loss through soil runoff or leaching can result in the pollution of surface waters. For this reason, widespread phosphorus pollution of waterways can occur in regions with concentrated livestock production. As result of phosphorus pollution, algal blooms in drinking water sources can drastically increase treatment costs and generate shortages in water supplies.

Phosphorus, an essential element for life on Earth, is a finite resource since mined phosphates are the main source in the production of phosphorus fertilizers. The demand for mined phosphorus is escalating worldwide due to both increasing food demand and human population. Inevitably, the future demand for mined phosphorus will exceed its supply capacity. Globally, the remaining phosphorus is found in various waste streams. These waste streams include large quantities of effluents rich in phosphorus from municipal, industrial, and livestock production sources. Therefore, phosphorus in these waste streams, if economically recovered, can contribute to a sustainable management of phosphorus resources.

The quick wash process mitigates both of these problems because phosphorus is selectively extracted from solid manure or municipal biosolids prior to land application. In layman's terms, the process takes manure—be it from a chicken or a human—and "washes" it, separating out the phosphorus, but leaving most of the nitrogen behind. This means that both the nitrogen-rich manure and the extracted phosphorus can be more judiciously applied, resulting in more effective fertilizer with less harmful phosphorus runoff as well as surplus phosphorus that can be reused in markets that need it, thus mitigating the shortage. The quick wash process selectively recovers more than 80 percent of the phosphorus from solid waste while leaving most of the nitrogen in the washed solid residue. Consequently, the washed solid residue has a more balanced nutrient composition that is safe for land application and is better balanced to match the specific nutrient needs of crops. Also, fertilizer tests of the recovered phosphate obtained with the quick wash method demonstrated that it is a good plant fertilizer. The concentrated phosphorus material contains more than 90% of its phosphorus in plant available form, which provides a recycled phosphorus source for use as a crop fertilizer on phosphorus-deficient croplands.

Our lab's role in finding a solution to these problems was crucial for more reasons than one. For our agency, it helps meet the objectives of addressing manure management problems that harm the environment and maximizing nutrient recovery.[3,4] For the private sector, we addressed a challenge deemed impossible—to develop a totally new technology capable of meeting multiple and strict environmental standards at a low cost.

Although many similar processes are not profitable, we quickly realized that this one would be profitable. Eventually, economic incentives such as government subsidies, environmental credits, and tipping fees have been considered as possible additional incentives for wide adoption and integration of this new method to reduce phosphorus pollution from animal production activities. Thus, phosphorus recovery in a concentrated, usable form would allow a more economical long-distance transfer of manure nutrients, while reducing agronomic nitrogen and phosphorus imbalances and the adverse effects of soil nutrient losses on the environment.

Lightning in a Bottle: Going Viral

To promote this technology, we made numerous presentations at professional scientific meetings, and two journal papers were published in peer-reviewed engineering journals.[5,6] However, the online ARS news releases were the most effective promotional technique, attracting worldwide attention.

An ARS News & Events story describing the quick wash process, entitled "Mining Manure for Phosphorus,"[7] was released online by the ARS Information Staff. The news release announced ARS's interest in finding business partners to move the product to market. We did not anticipate that when

published in 2008, this technology would become viral. Yet, as a result of this news release we received nine requests for information from entrepreneurs in North America, Europe, and Asia.

The ARS patent application and related information for the quick wash process were provided after signing confidentiality agreements with each interested party. The preparation of these confidentiality agreements was facilitated and overseen by our Technology Transfer Coordinator. (ARS has a Technology Transfer Coordinator at each Area Office; in this case, the Coordinator covered all ARS research units within the southeastern United States).

Within two years after the ARS news release, we had four meetings with individual U.S. entrepreneurs interested in our invention; however, the only one that followed up with additional consultations and meetings with the goal of licensing our invention was Renewable Nutrients, LLC (RN), a small business located in North Carolina.

This interaction led to material transfer agreements, licensing, verification of the technology by independent consultants, and current commercialization.

The Technology Transfer

Initially, a technical consultant working with RN contacted our Research Center at Florence. This consultant read about quick wash from the ARS online news article and called the Florence lab to request more technical information, which was provided upon the signing of a confidentiality agreement.

After this first contact, company representatives attended a meeting at the Florence laboratory, where the technology was showcased. Since RN representatives did not know about ARS technology transfer programs, Florence scientists consulted with the Technology Transfer Coordinator and referred the RN CEO to the Office of Technology Transfer (OTT) at ARS Headquarters in Beltsville, Maryland. Along with technical consultations with the ARS team and the OTT, a Material Transfer Agreement (MTA) was used to determine if wash litter and the recovered phosphorus could be granulated for commercialization. ARS licensing specialists provided instructions regarding how to apply for an exclusive USDA license for the pending patent of the quick wash process.

Upon obtaining the exclusive license, the first step was to advertise in the *Federal Register* the notice of intent to grant exclusive license of the USDA invention to RN. The exclusive license was later granted after 30 days from the date of this published notice since ARS-OTT did not receive any written evidence and argument from other potential investors interested in licensing the invention. The exclusive license was granted five months later once negotiations with the OTT office in Beltsville were completed. In accordance with USDA-ARS policies and procedures, the exclusive license agreement between USDA-ARS and Renewable Nutrients, which was granted August 10, 2010, is confidential because of conflict-of-interest rules.

Finding a New Purpose for Quick Wash

The ARS team worked closely with RN to develop approaches for commercializing this new technology. Our role was to provide innovation, scientific knowledge, and improvement of the technology; RN's role was to design and develop commercial units of the technology. ARS's expectations were to effectively transfer the new technology after verification at pilot scale. RN's expectations were to reach the market with a reliable and proven technology to recover phosphorus that has competitive advantages for commercialization.

Originally we conceived of quick wash as a treatment to be used in the agricultural market with poultry litter, but our research has shown that the approach is equally effective with municipal biosolids (i.e., sewage). In addition to the agricultural market, RN realized the value of this technology for municipal disposal systems and changed its business plan to commercialize quick wash in the municipal wastewater treatment market. For this market, RN's business model now consists of sublicensing the technology to each municipal treatment plant. The technology is being marketed as Quick Wash™.

Bringing Quick Wash to Market

Jeff Dawson, CEO of Renewable Nutrients, worked to secure investors for commercialization. He interacted with local leaders to get the quick wash technology placed on a pilot scale in two municipal treatment plants.

Traditional technologies for phosphorus removal (specifically in the wastewater treatment sector) involve the addition of some form of binding agent to a facility's influent stream. Ferric chloride or aluminum sulfate, for example, are introduced and bind to phosphorus molecules, which then settle with solids material and ultimately depart the facility through its biosolids disposition program. This "chemical" removal of phosphorus can cost a facility anywhere from several thousand dollars to hundreds of thousands of dollars annually, depending upon the facility size and the amount of phosphorus that must be removed. Furthermore, this approach to phosphorus removal only serves to embed this vital nutrient into the facility's biosolids output, and in many areas of the country the biosolids must be transported to disposal sites and landfilled due to land application restrictions for phosphorus.

In recent years, a few technologies have emerged to not just "remove" phosphorus from waste streams, but recover this nonrenewable resource. Quick Wash™, however, has surfaced as the only multi-stream and truly scalable phosphorus recovery methodology in the marketplace. While nearly all of the competitive options for phosphorus recovery concentrate on the liquid side streams of wastewater treatment facilities, Quick Wash™ can remove and recover phosphorus from a facility's side stream or solid stream with recovery rates exceeding 95%. In addition, the system can be effectively deployed in small treatment facilities as well as very large operations, whereas most other nutrient recovery platforms are limited (due to their requisite level of capital investment) to large facility applications.

The following chart provides a net present value (NPV) cost comparison over a 20-year period for various phosphorus removal or recovery options, including Quick Wash™. The NPV cost includes upfront capital expense, annual maintenance fees, labor, and chemical expenses for a typical 11-MGD wastewater treatment facility.

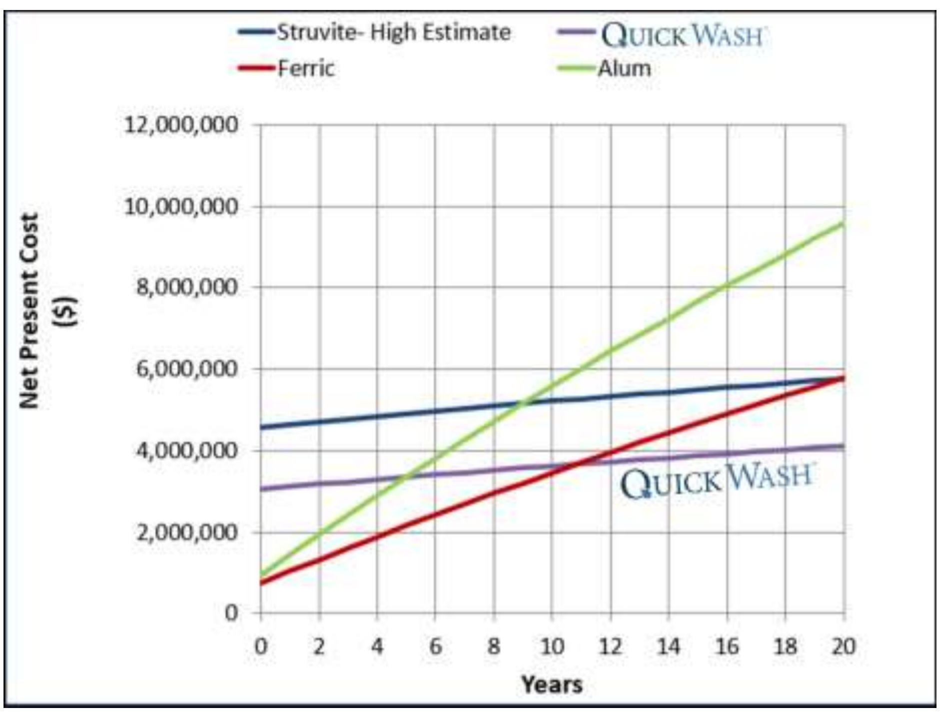

Figure 1. 20-Year NPV Cost Comparison of Phosphorous Removal/Recovery Options

The value proposition of Quick Wash is not simply limited to the removal and recovery of phosphorus. As already mentioned, Quick Wash can replace expensive chemical removal technologies. The system can also significantly reduce the amount of phosphorus in a plant's biosolids output, allowing for land application of the biosolids material and the elimination of transportation and landfill fees. Finally, facilities can sell the recovered phosphorus, a program that can serve as an incremental revenue stream, and participate in nutrient credit trading opportunities.

In the latter half of 2014, Renewable Nutrients designed and constructed a mobile pilot, at a cost of USD $500,000, for its Quick Wash phosphorus extraction and recovery system. The purpose of the mobile pilot was to demonstrate the Quick Wash technology and prove its performance in various scenarios and sizes of wastewater treatment facilities. The pilot was subsequently deployed in early 2015 at the Ephrata Wastewater Treatment Plant in Ephrata, Pennsylvania (a small 2-MGD facility).

Following Ephrata, the Renewable Nutrients team conducted eight additional pilot operations in the Mid-Atlantic, Southeast and Midwest areas, including:

- Westminster, Md.
- Raleigh, N.C.
- Chapel Hill, N.C.
- Greenville, N.C.
- Neoga, Ill. (a large swine production operation).

Currently, RN is marketing Quick Wash™ for the recovery of phosphorus from both animal and human waste through different techniques such as the company website and blog, and exhibiting at national technical conferences for water treatment professionals, such as the Mid-Atlantic Biosolids Association, the Water Environment Federation, and the American Water Works Association.

Our team at the Research Center has hit on a creative marketing technique: We worked with our IT staff to develop a bar code that participants can scan and immediately access a promotional video that RN produced about Quick Wash™.[8] The bar code was included in posters presented at scientific meetings by ARS Florence scientists. We thought it was a good idea to include a link to this video clip because our most recent technical presentations contain results of tests carried out at the request of the licensee. The ARS technology transfer policy permits its inventors, where practicable, to participate

[8] Video, "Renewable Nutrients Quick Wash™ Overview." March 19, 2015. https://youtu.be/VOq2mGh24js.

in the development of their inventions by providing technical assistance to licensees. We have been providing this assistance through monthly conference calls between scientists and RN personnel.

Figure 2. Bar Code Linking to RN Promotional Video

Looking Back: What We Learned

Trust is Key

Renewable Nutrients was the right partner because they trusted the science behind the quick wash project. A mutual trust developed between ARS and RN as a result of reviewing and confirming through technical advisors that the information included in the patent application was a sound scientific approach for phosphorus recovery from animal waste. When RN decided to change its business plan to commercialize Quick Wash™ in the municipal wastewater treatment market, it contacted the ARS Florence scientists to determine if the invention could be used for municipal waste treatment. Once again, we referred the CEO of RN to consult with the OTT office. This time, the ARS patent advisor who prepared the patent application confirmed to RN that the invention also covered use of the quick wash process for recovering phosphorus from municipal waste streams. At RN's request, our team provided technical assistance by performing laboratory tests to demonstrate the feasibility of recovering phosphorus from municipal sludge and biosolids. These lab tests showed that more than 80% of the phosphorus contained in municipal wastes can be recovered using the quick wash process. In addition, the process was tested by a third party—an environmental engineering consulting firm hired by RN—that satisfied RN's expectations of using the process to recover phosphorus from municipal sludge and biosolids. In addition, the consulting engineers developed a marketing program and a mobile pilot plant to test Quick Wash™ onsite at the municipal plant.

Patience Is a Virtue

The major challenge was to maintain the licensee's and scientists' interest in developing the technology during the long time before the technology reached commercialization. It took seven years from the initial ARS news release to start commercialization of the technology. It took the first two of the seven years to license it. Since the technology was licensed while the patent was pending, plus RN's difficulty selling it in the animal waste treatment market, it took RN another four years to redirect its marketing strategy. It is important to mention that RN started to heavily invest in developing and marketing the technology for use in municipal waste treatment once the patent was officially issued in 2014. The commitment of the ARS scientists to provide technical assistance to RN was extremely important in helping RN shift its commercialization plan for the municipal market.

We Could Still Be More Agile

If we could do this tech transfer process over again, we would try to be better prepared to extend the focus of our invention beyond the research laboratory. This could have helped to transfer and commercialize the technology faster. A program for customer discovery and identification of real problems in the different sectors of the waste management industry could have helped ARS have a better idea of the business side of science while helping the licensee to discover an alternative market for the quick wash technology.

In 2015, the ARS started a program called ARS Innovation Corps (I-Corps @ ARS) to help scientists for faster transfer and commercialization of technology. The I-Corps @ ARS pilot consists of a set of activities and programs designed to help ARS scientists broaden the impact of their research by extending their focus beyond the laboratory to the end product of their work. I-Corps @ ARS is based on the NSF I-Corps™ and basically combines experience from established entrepreneurs with a curriculum on market opportunities and innovation.

If we had had this training years ago, we could have learned to be more "agile" with our tech transfer.

About the Authors

Ariel A. Szogi and Mattias B. Vanotti are soil scientists, and Patrick G. Hunt holds the title of collaborator at the Agricultural Research Service's Coastal Plain Soil, Water and Plant Conservation Research Center.

QUICKWASH®

Nitrogen Removal & Ammonia Recovery

Renewable Nutrients is rethinking Nitrogen Removal & Ammonia Recovery with a proprietary system that draws on exclusive patented technology to extract and recover ammonia in either a liquid or gaseous state found in biosolids and other waste streams.

Renewable Nutrients patented Nitrogen Removal & Ammonia Recovery process is disruptive to current technologies as it recovers the ammonia for beneficial use and by its very nature can be operated with no impact to the biological process.

With the Renewable Nutrients patented Ammonia Recovery process in place, an existing facility will:

- Reduce inputs of energy, carbon, alkalinity
- Recover rather than destroy a valuable resource
- Produce a high quality, saleable product
- Improve the quality of the effluent by enhancing existing nutrient removal processes
- Allow the reduction of ammonia alkalinity
- Potentially free existing capacity and allow the rerating of treatment plants in lieu of additional capital investment
- Provide a solution for additional capacity in plants with limited footprint for expansion

Separation of Ammonia and Phosphate Minerals from Wastewater using Gas-Permeable Membranes

WRRI Water Sustainability Through Nanotechnology Symposium
March 15, 2017 – Raleigh, NC

Matias Vanotti

Collaborators: Patrick Dube, Ariel Szogi

United States Department of Agriculture, ARS

Florence, SC

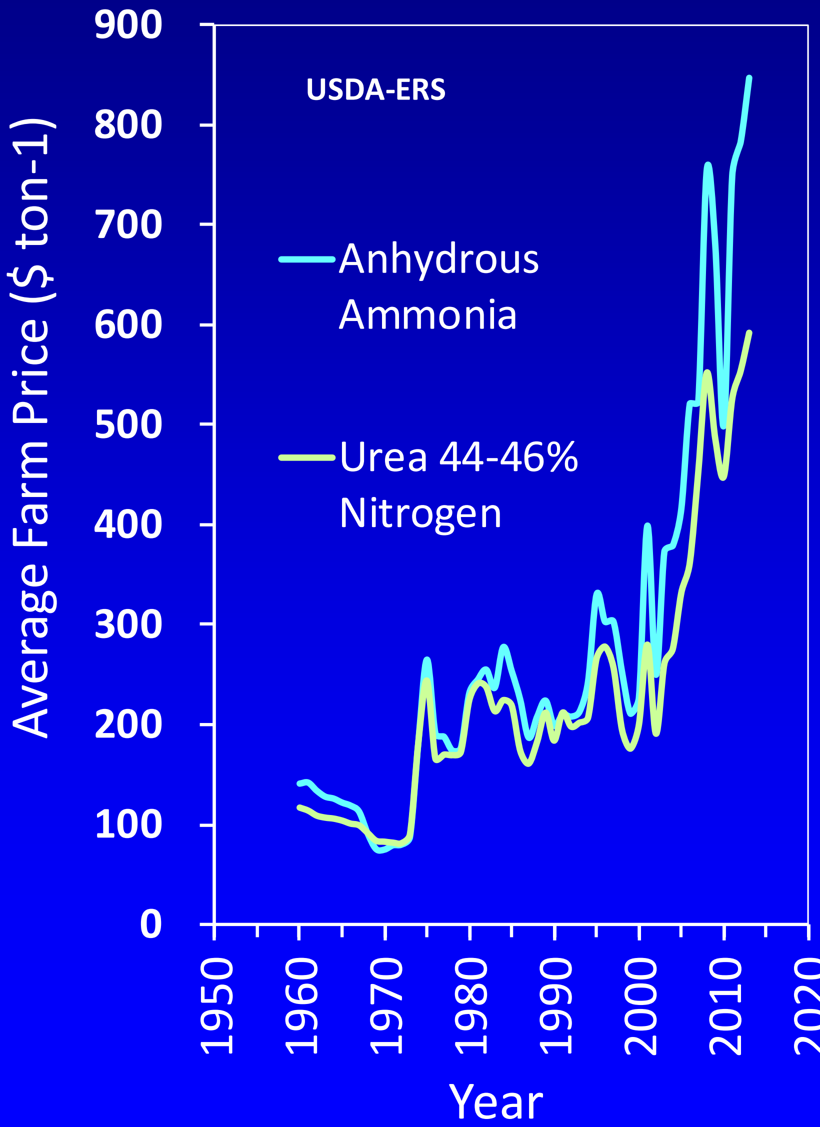
Presentation outline

Recent development at USDA of systems and methods to recover N, P and value-added materials from wastes

- 1. Improved ammonia recovery from liquid with gas-membranes
- 2. Simultaneous N and P recovery with membranes
- 3. Recovery of ammonia without chemicals

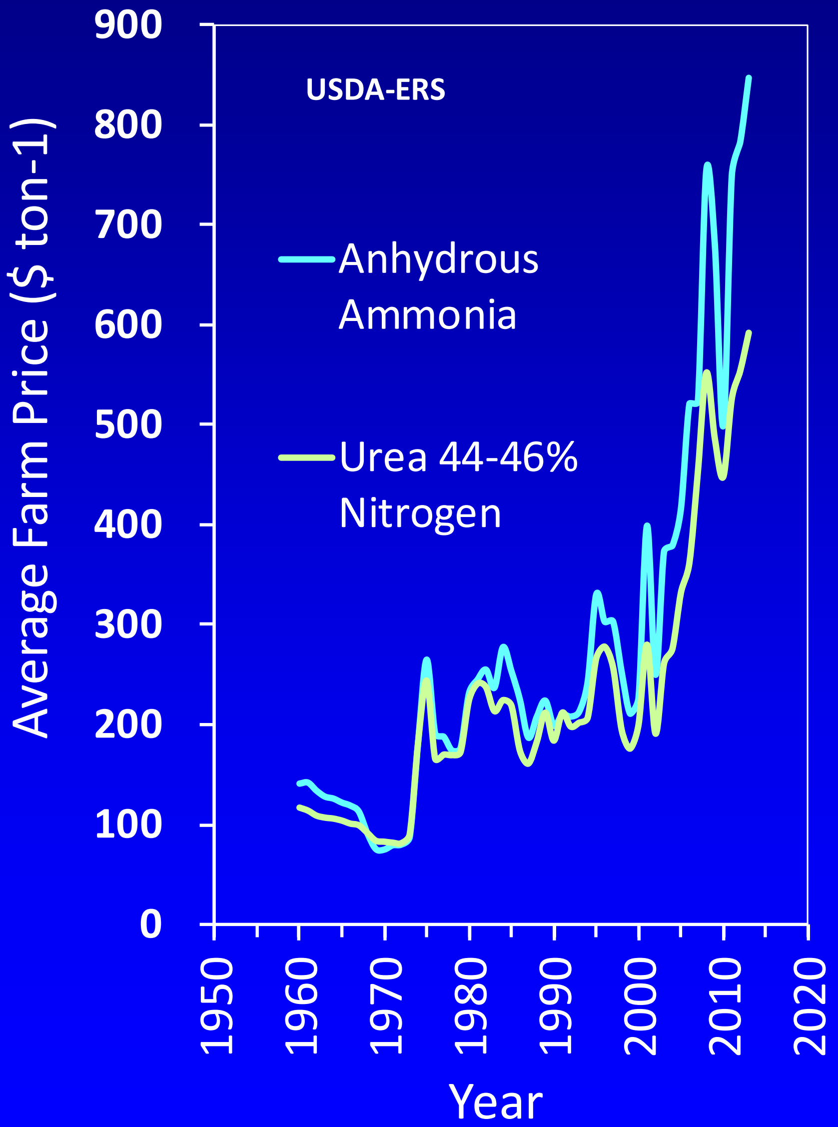
Why recover N?

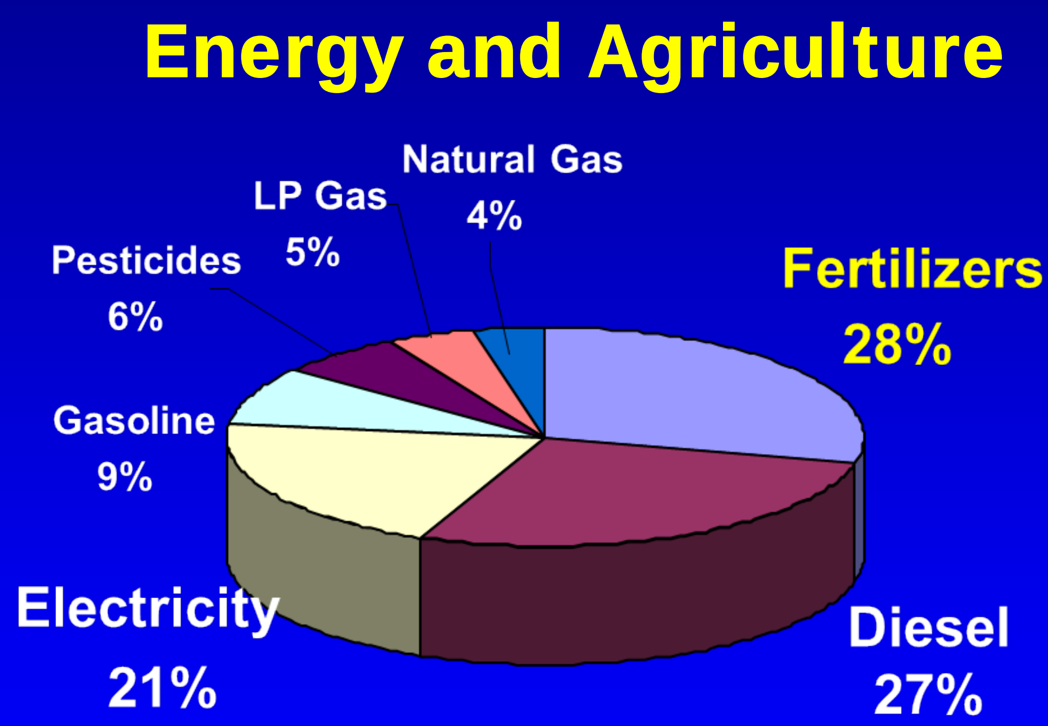
Escalating U.S. Fertilizer Costs



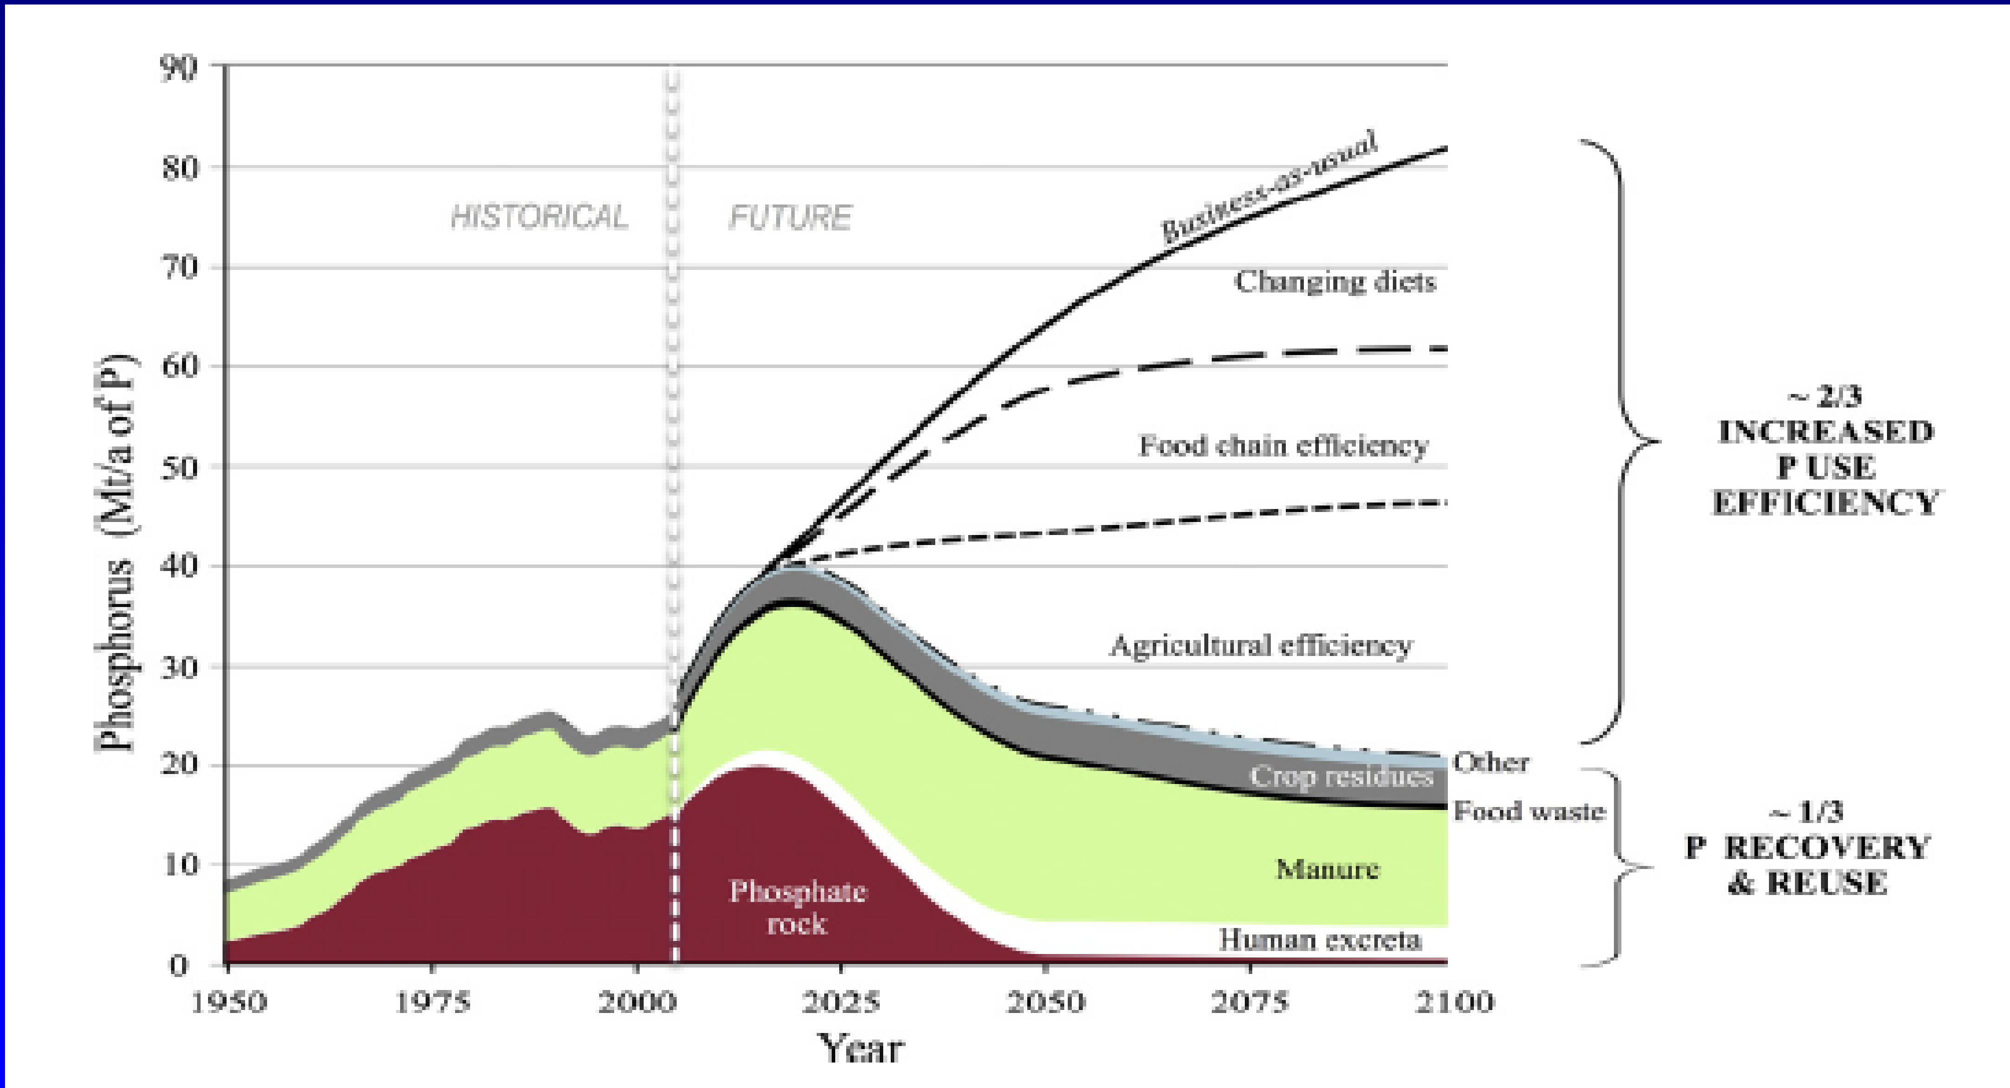
Why recover N?

Escalating U.S. Fertilizer Costs



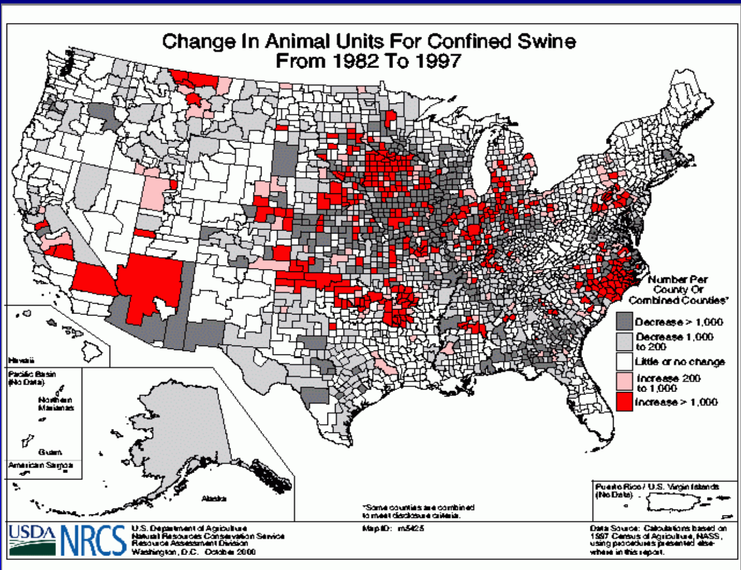


Why recover phosphorus?



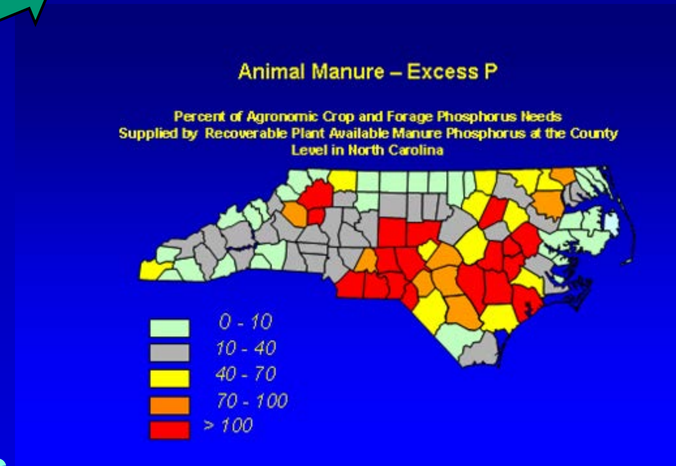
Cordell, D., et al., Chemosphere 84:747-758

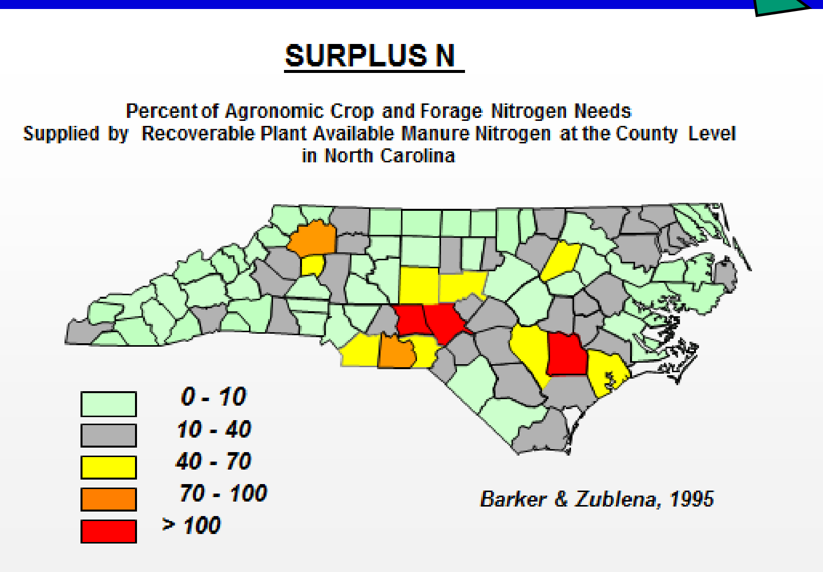
Animal Manure – Surplus N & P , Ammonia emissions in areas of concentrated animal production



North Carolina produces approximately 750 million chickens, 40 million turkeys, 3.5 billion table eggs, and 19 million hogs per year.

Surplus Phosphorus





Ammonia Emissions

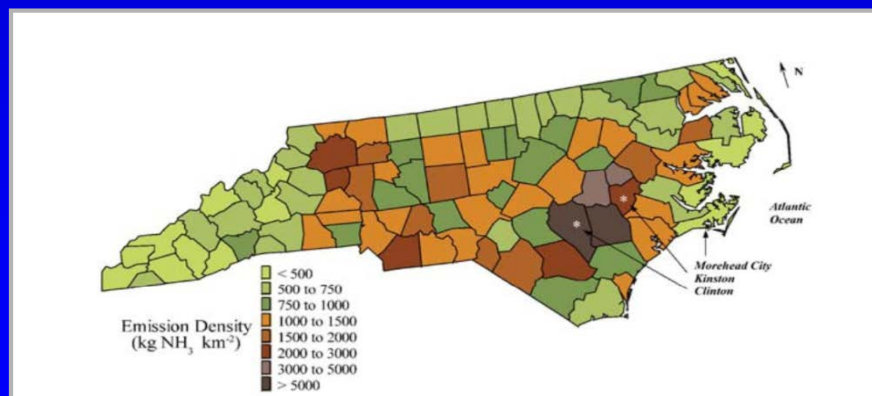


Fig. 1. County scale NH_3 emission density for North Carolina along with measurement sites. Livestock activity data represent 2000 levels. All other activity data represent 1996 levels.

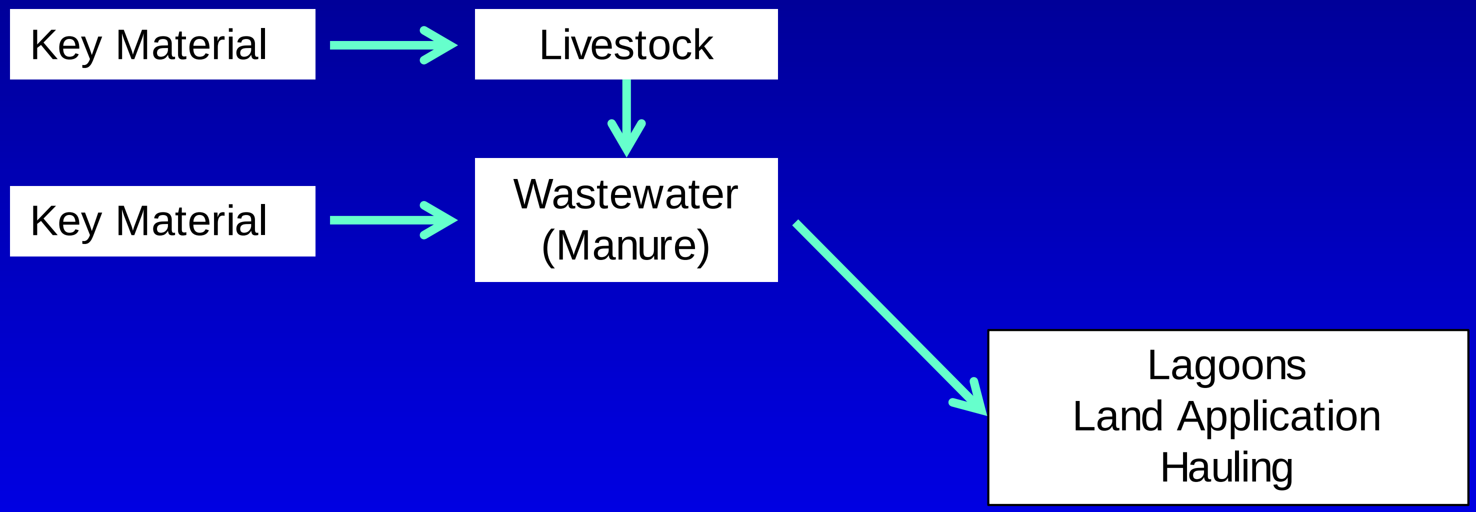
Value Chain without Solution



The Technology

What do you do?

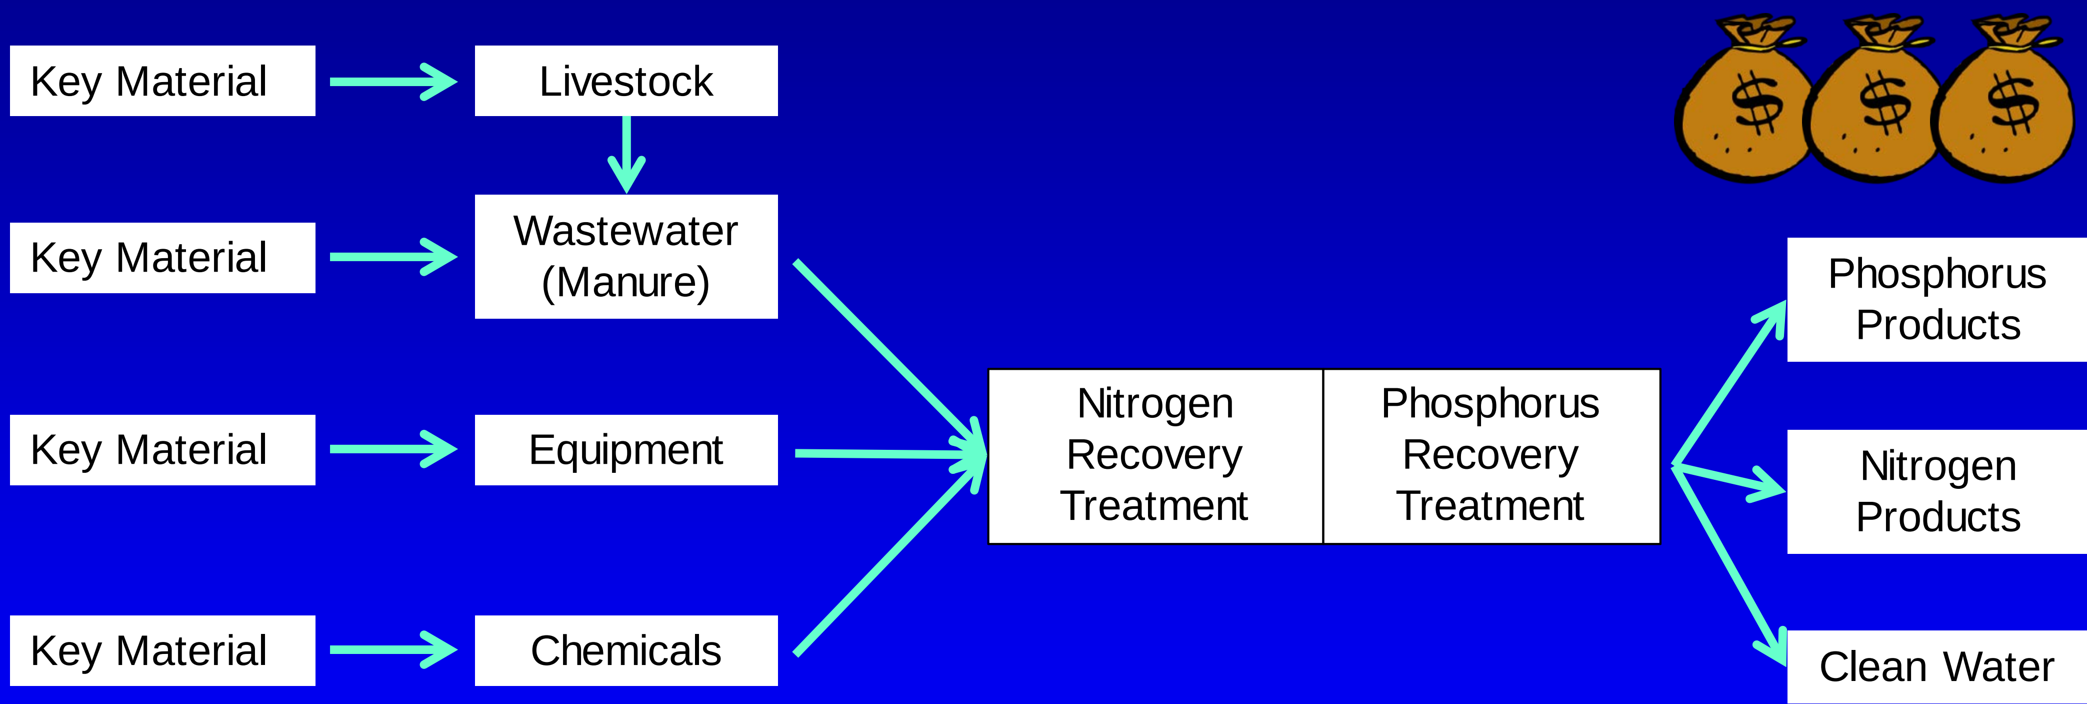
- Our technology simultaneously removes and recovers both nitrogen and phosphorus from manures and wastewaters.

Why do you do it?

- This creates value added products from wastes and helps society with a cleaner environment.

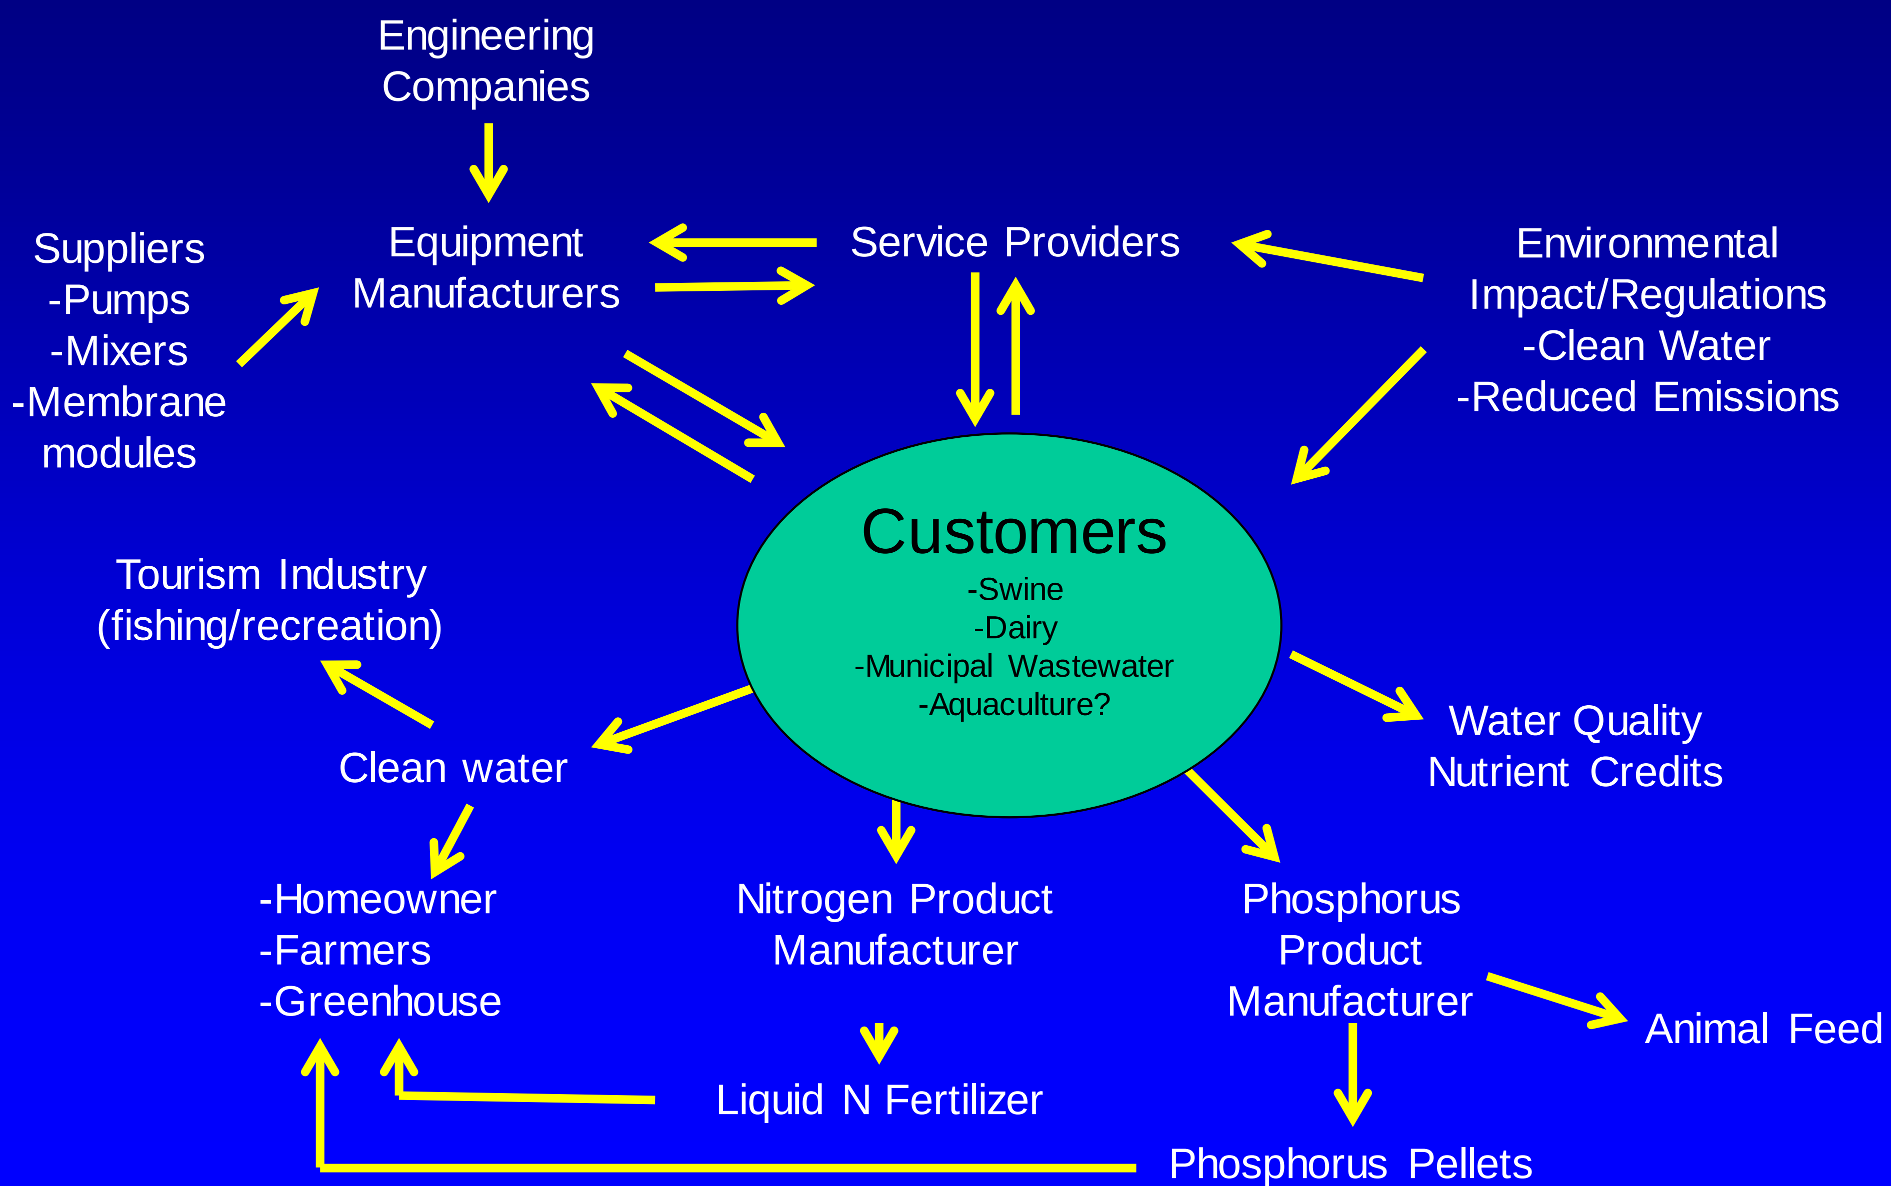
Wastewater (Manure) → Nitrogen Recovery Treatment | Phosphorus Recovery Treatment → Phosphorus Products / Nitrogen Products / Clean Water

Value Chain with Solution

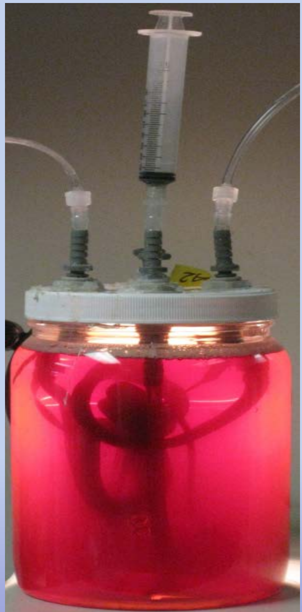


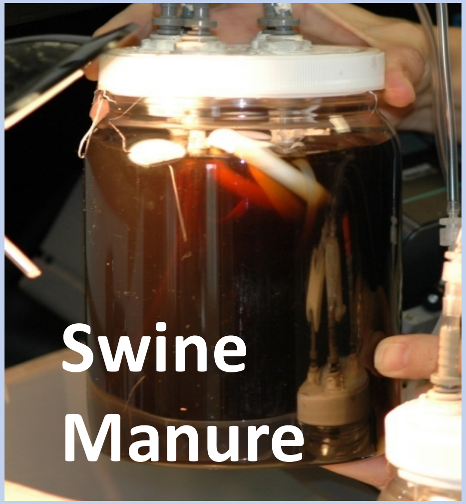
Ecosystem Map With Solution

How your product interacts with the world once it is in the hands of the customer



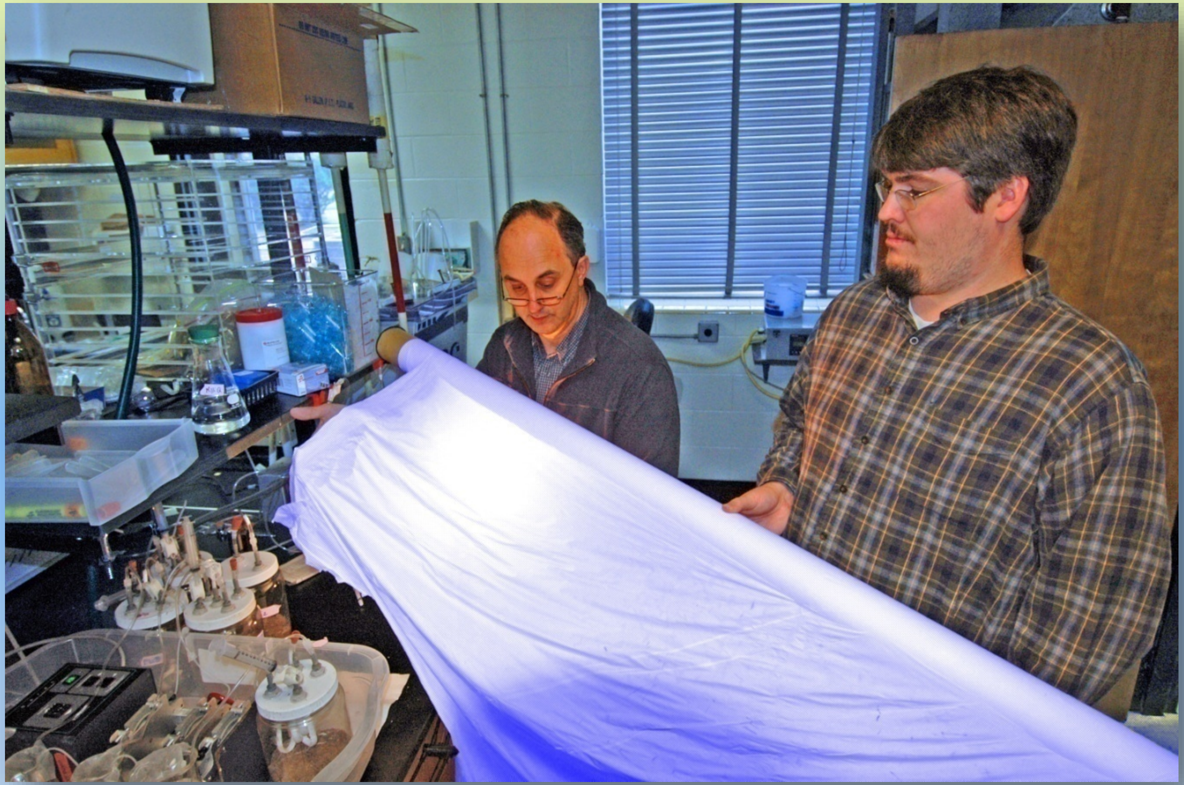
New technology: Recovery of Ammonia from Manure

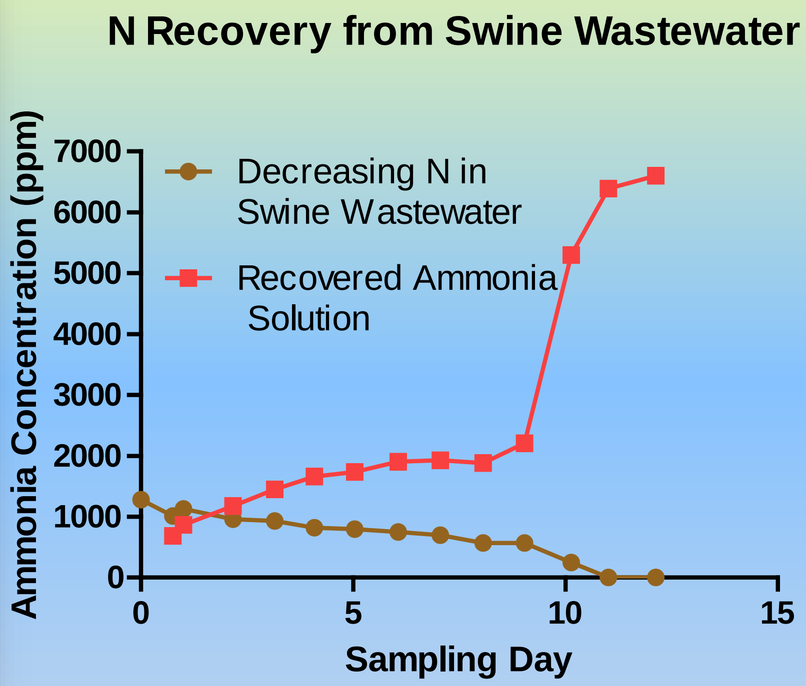




- ❑ Ammonia is separated using gas-permeable membranes
- ❑ Applications include liquid manures and air in livestock houses
- ❑ Product is liquid fertilizer with 50,000 to 100,000 ppm N

Recovery and Concentration of Ammonia





- **Ammonia permeation through microporous, hydrophobic membranes**
- **Reduced ammonia emissions from livestock operations**
- **Product is ammonia solution with > 50,000 ppm N**

Gas-permeable membranes

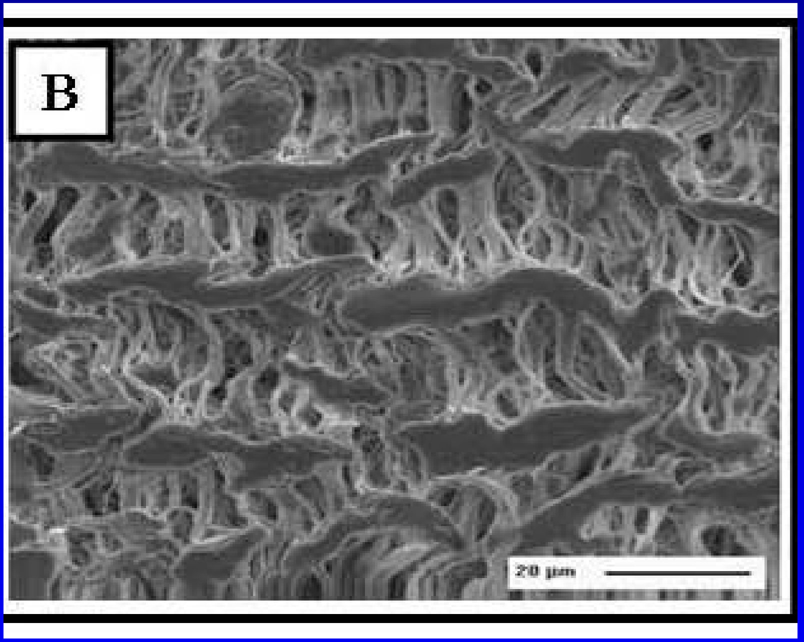
- **Medical uses:** Used in membrane oxygenators to imitate the function of the lungs in cardiopulmonary bypass, to add oxygen to, and to remove carbon dioxide from the blood (Gaylor, 1988).

- **Clothing & shoe industries:** Used to provide waterproof and <u>breathable</u> fabrics in sportswear and footware (i.e. *GORE-TEX® Products, 1968)*

For this research we used gas-permeable membranes made of expanded polytetrafluoroethylene (ePTFE)

PTFE is stretched to form a strong, porous material

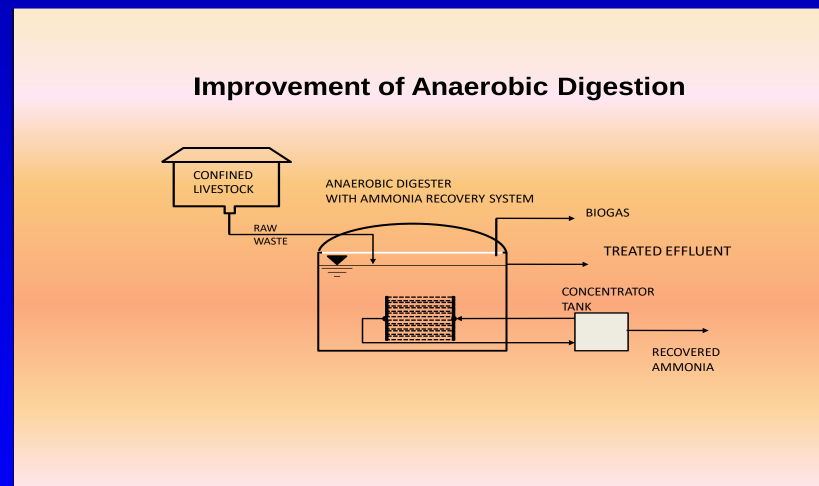
Manufacture of Gas Permeable Membrane

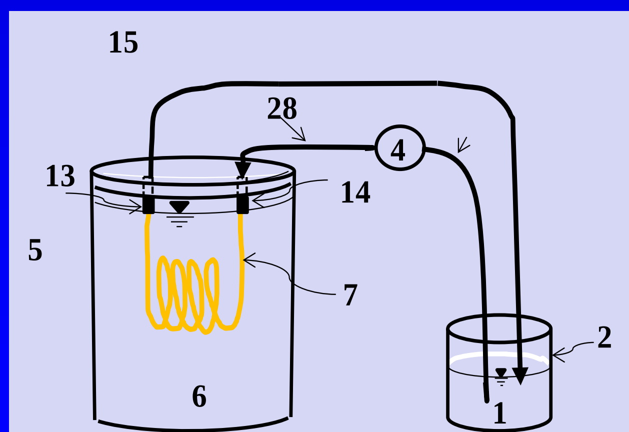


Gas Permeable Membrane
Microscopic structure (SEM)

Recovery of Ammonia from Liquid Manure with Gas-permeable Membranes

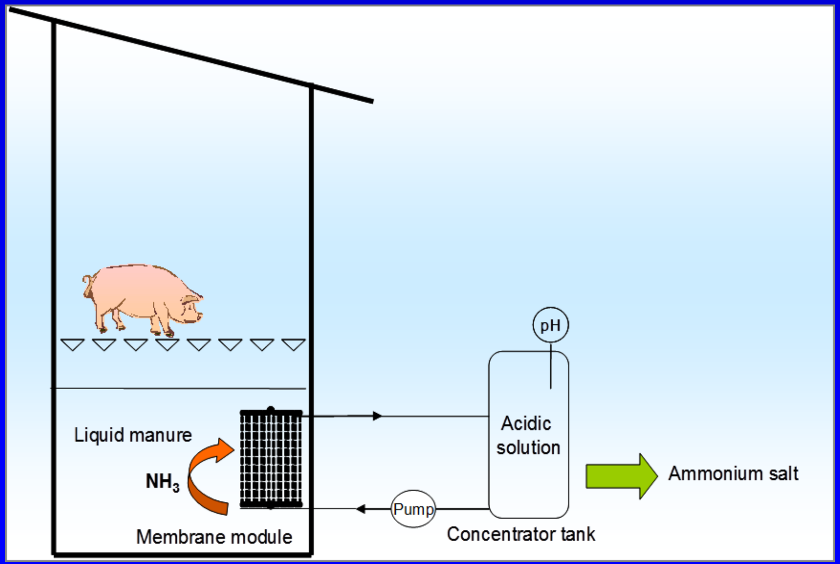
- Technology captures ammonia emissions
- Produces liquid fertilizer with > 50,000 ppm nitrogen



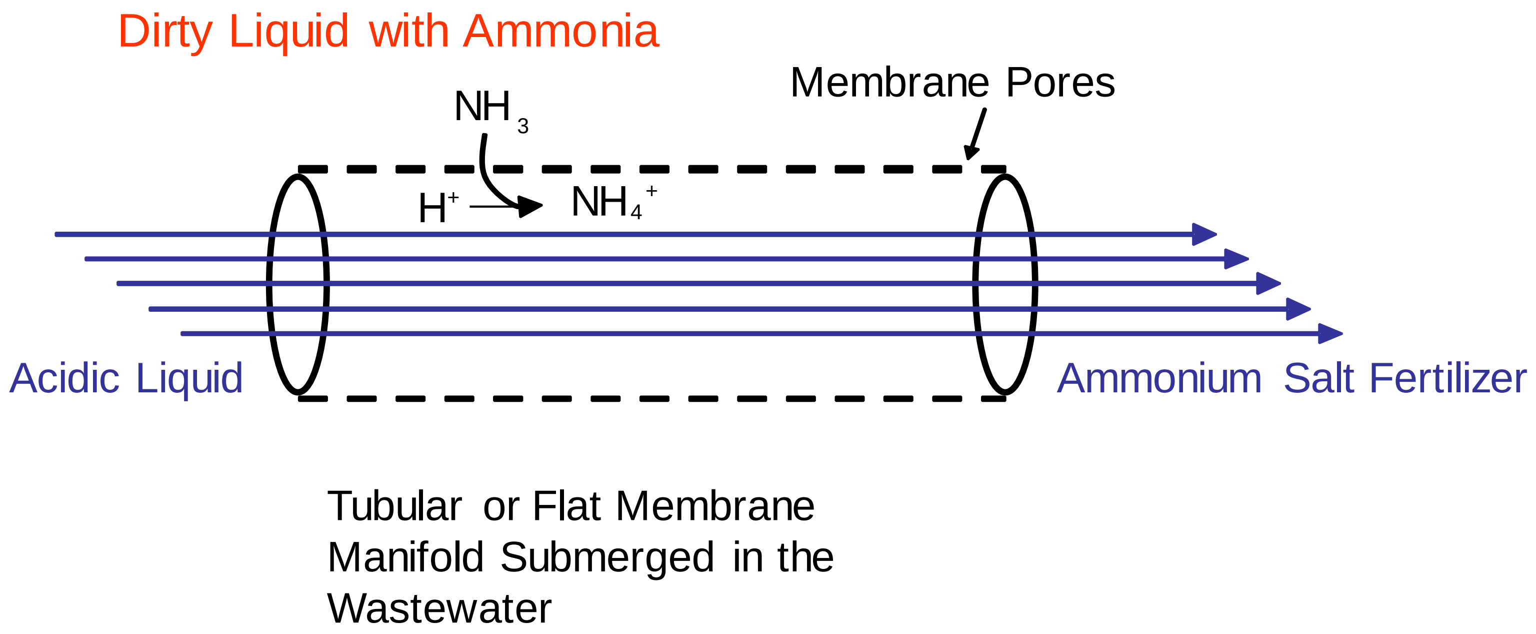


WHAT IS INTENDED TO DO?

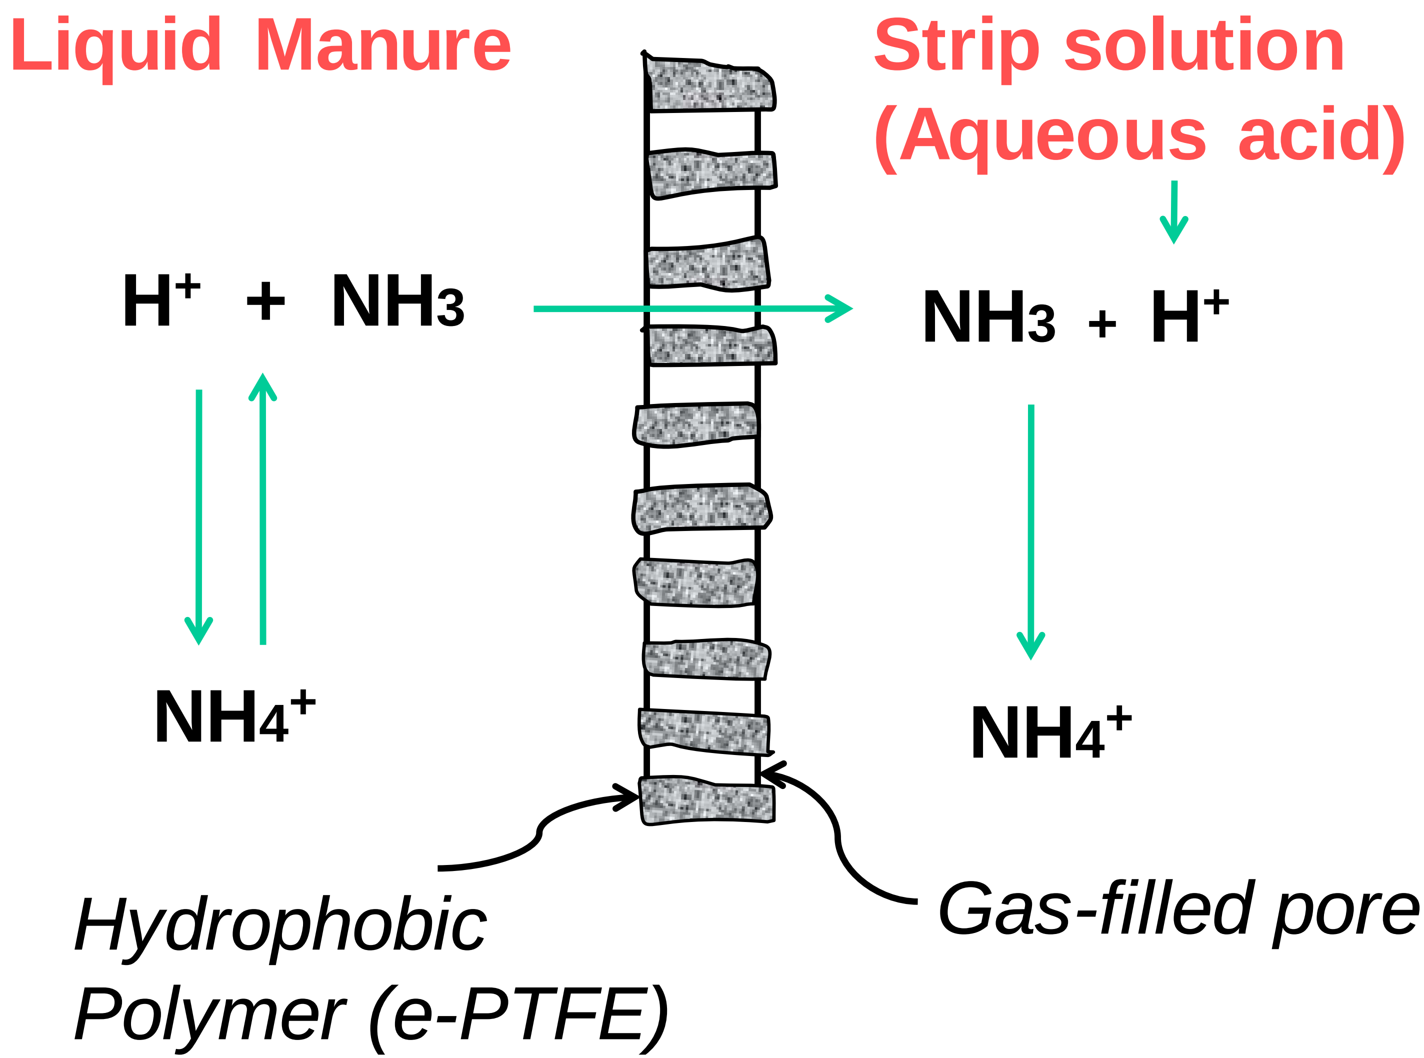
- Removal of ammonia gas from the liquid manures before it escapes into the air.
- Nitrogen is recovered from liquid manures in a concentrated, purified form



Concept of Ammonia Capture from Wastewater using Gas Permeable Membrane

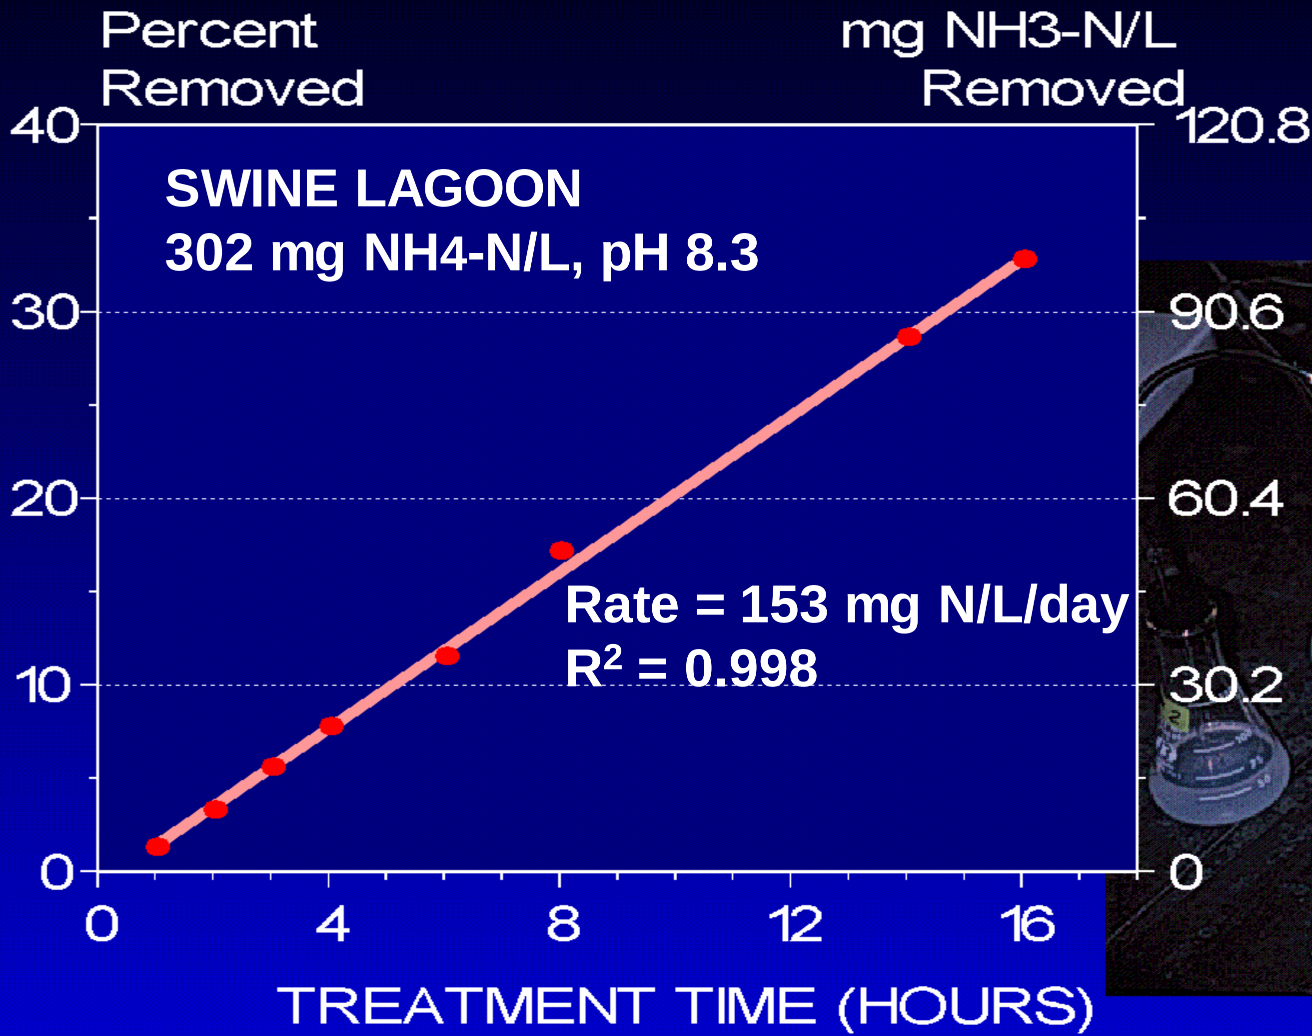


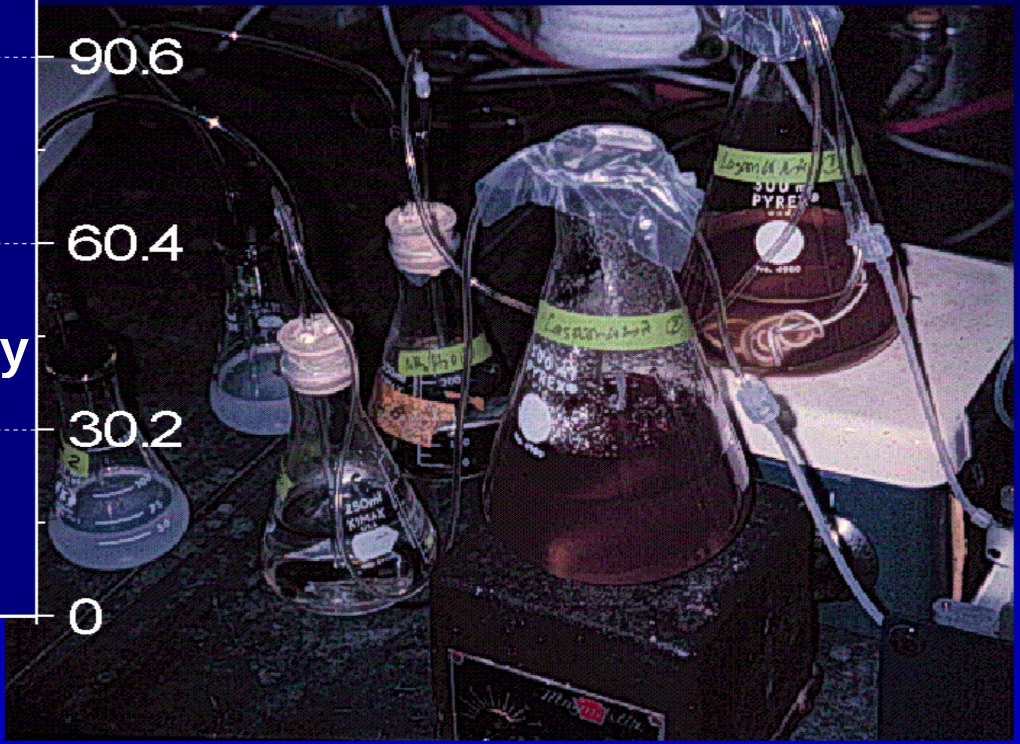
Gas-permeable membrane system:
The ammonia gas (NH3) passes through



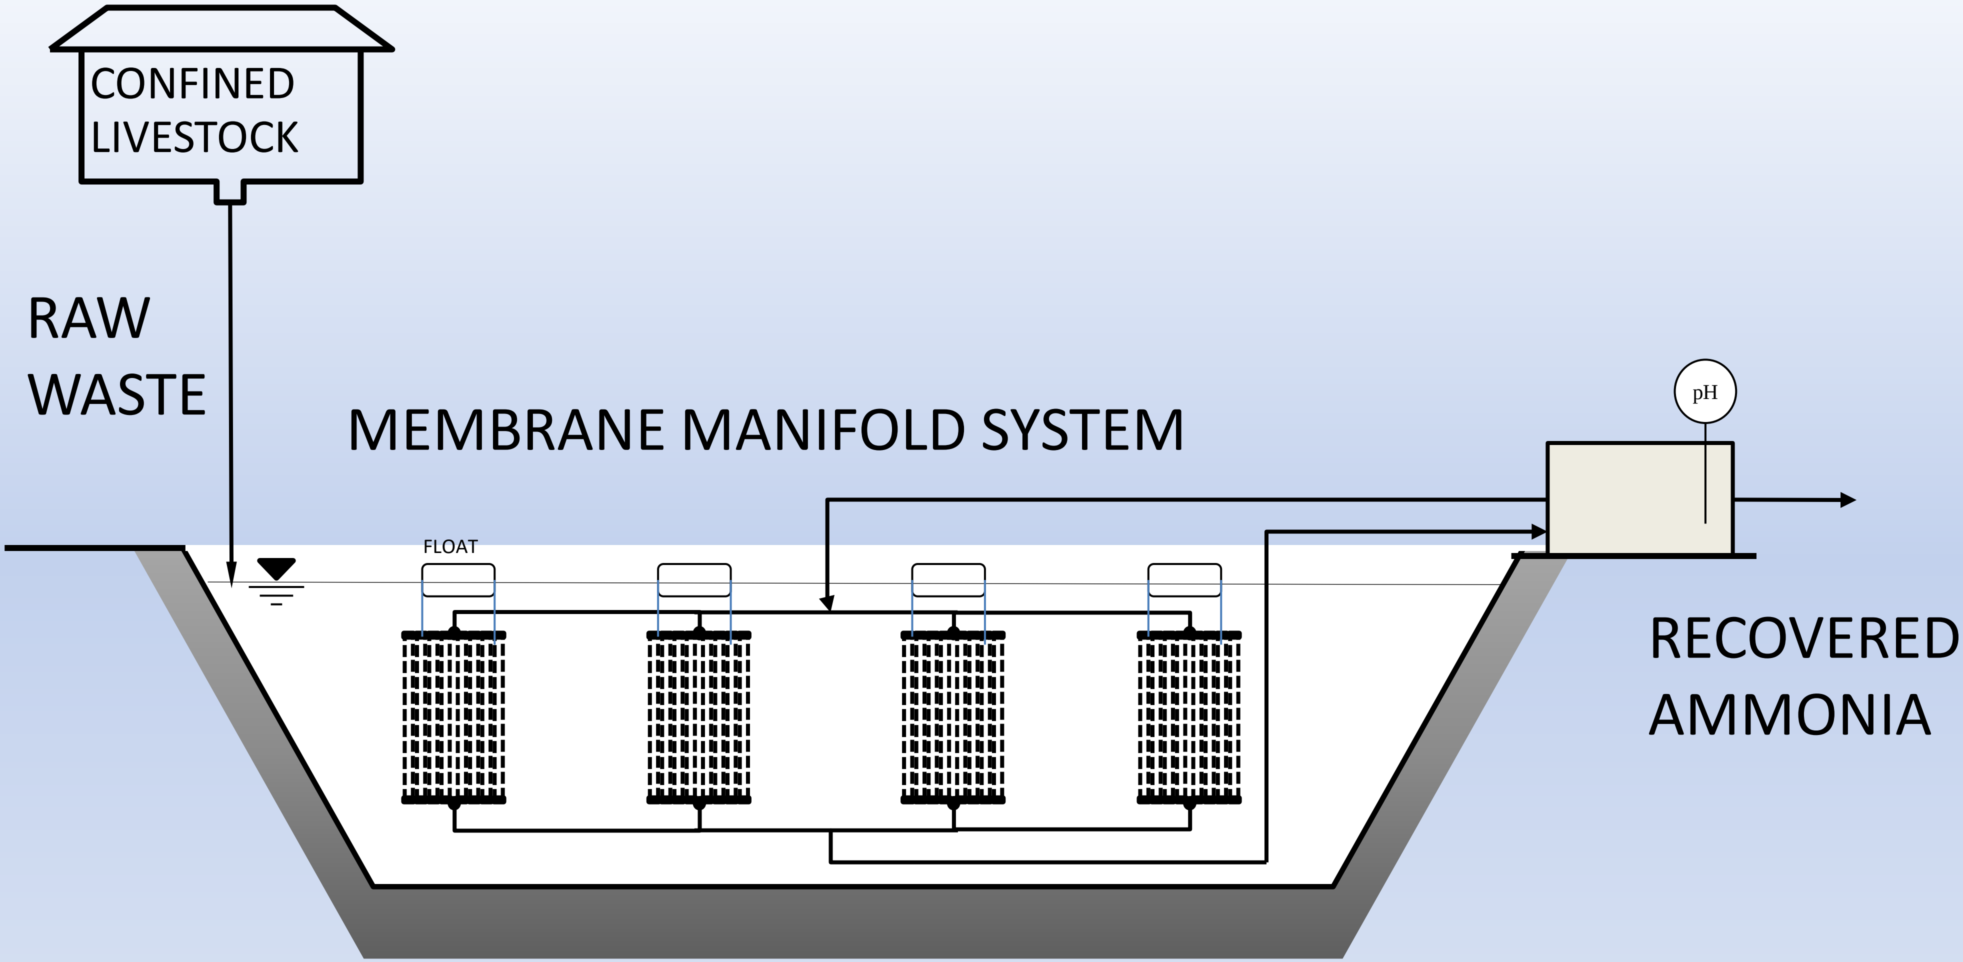
Does it work?

Ammonia removal from animal waste using gas permeable membranes





Retrofit of manure storage units to harvest the ammonia



Anaerobic Livestock Wastewater Lagoon with

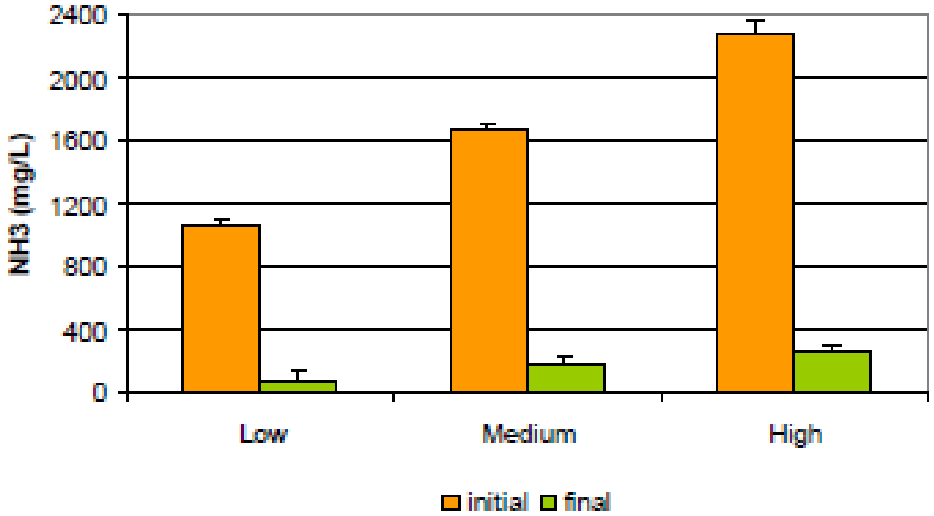
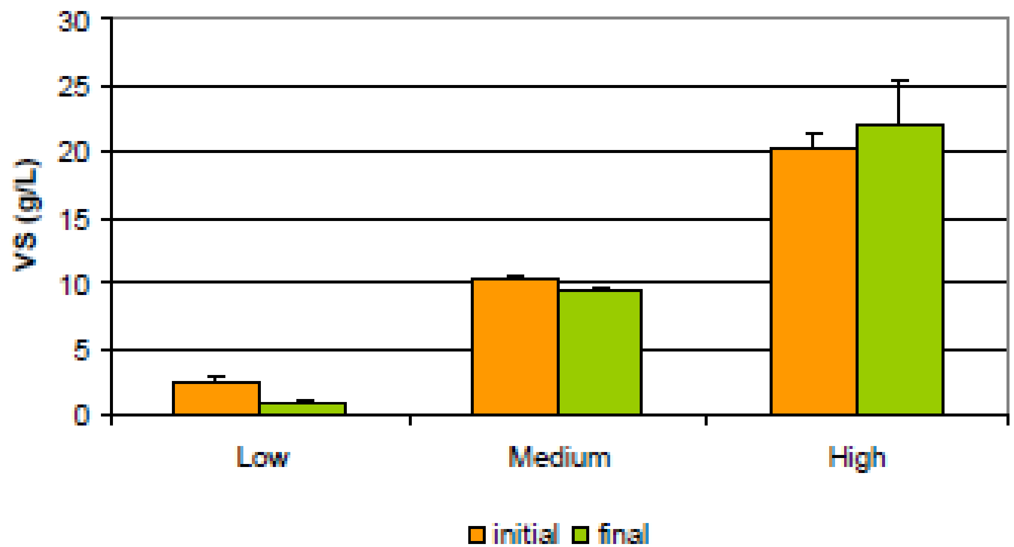
medium	2184	90	90	92
high	2971	88	90	194

M.C. Garcia and M.B. Vanotti, Waste Management 2014 (in press)

Ammonia was removed

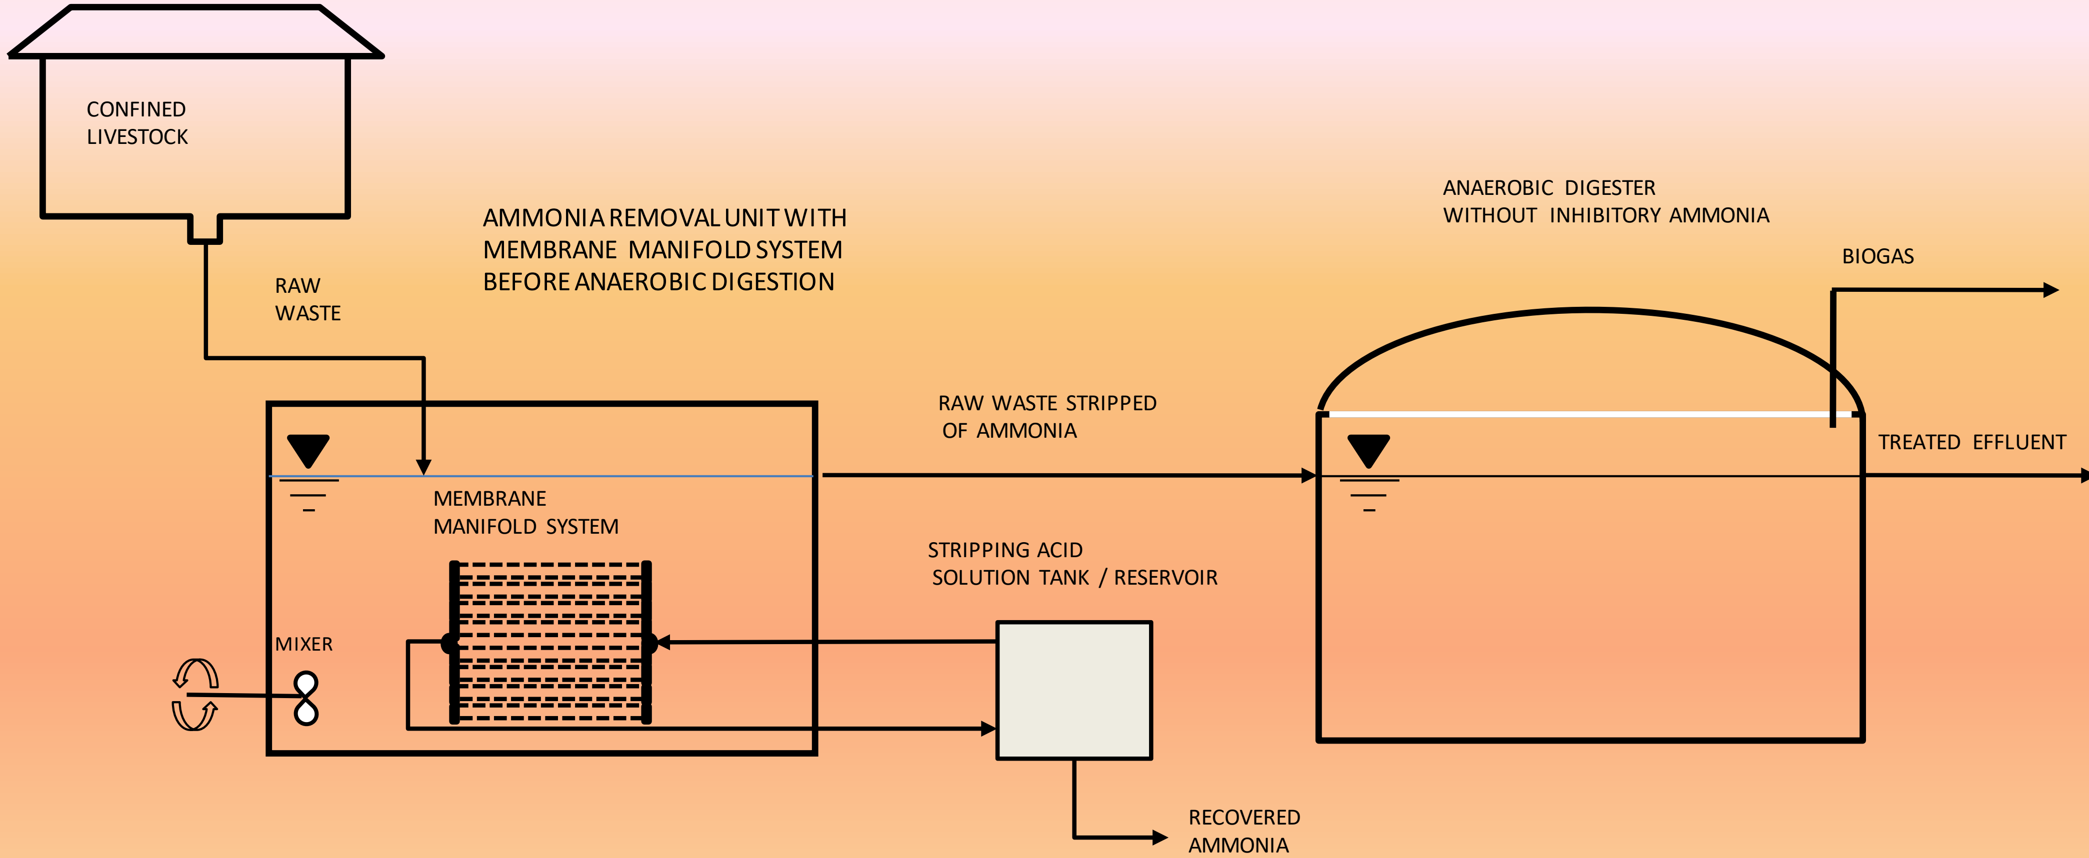


but carbon (volatile solids) was not removed



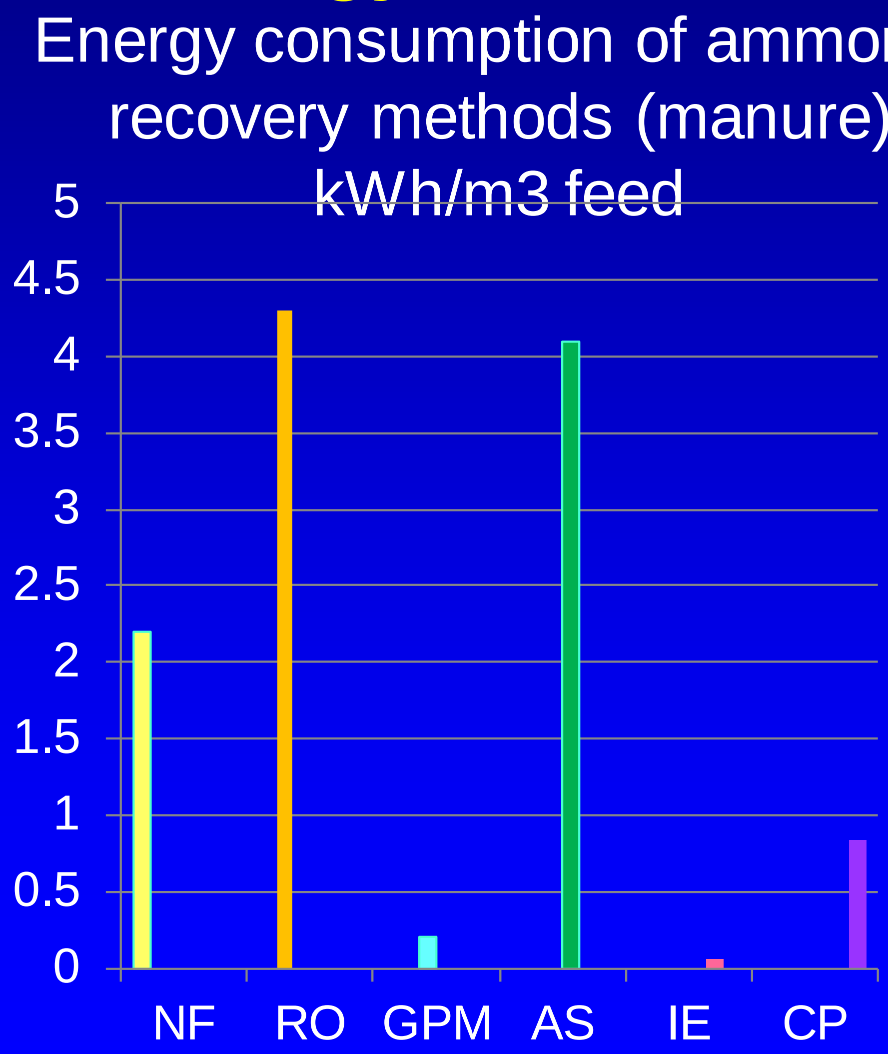
Technology can be combined with <u>anaerobic digestion</u> to recover both the ammonia and the energy from manure.

Ammonia Recovery System with Anaerobic Digestion



Zarebska et al. (2015) Ammonium fertilizers production from manure: A critical review.

The gas-permeable membrane method had very low energy demand



NF= nanofiltration

RO = reverse osmosis

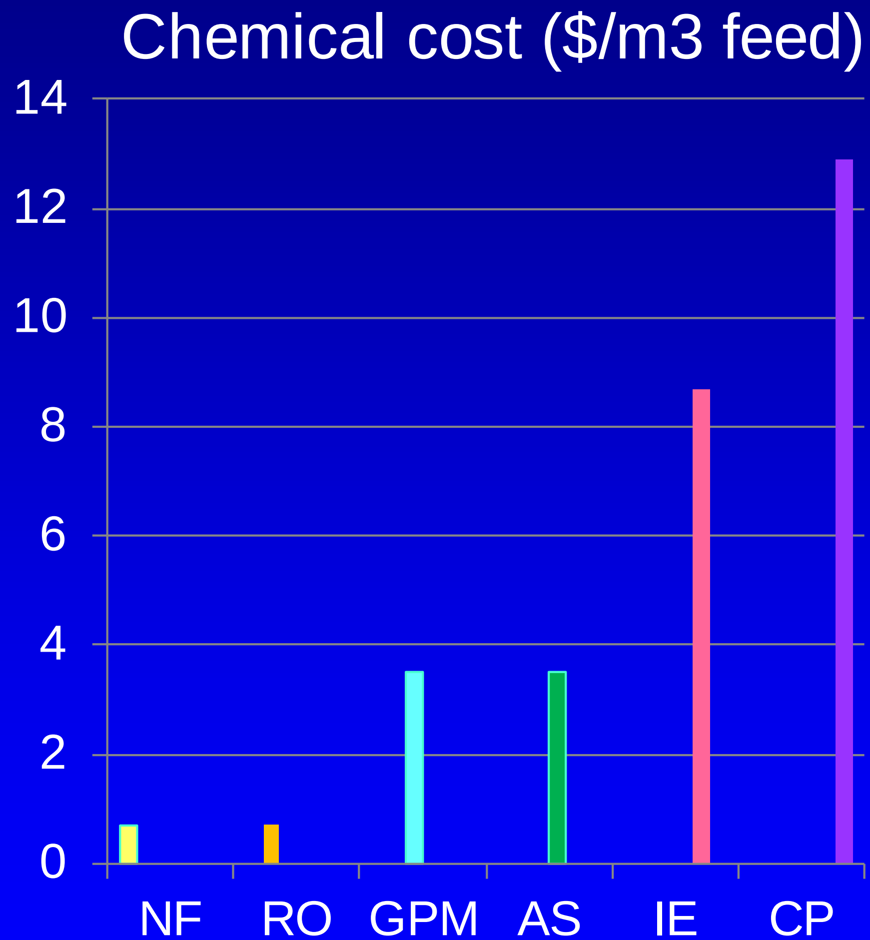
GPM = gas permeable memb.

AS = air stripping

IE = ion exchange/ zeolites

CP = Chemical precipitation

The gas-permeable membrane method (MD) had high chemical demand (NaOH to increase pH)



NF= nanofiltration

RO = reverse osmosis

GPM = gas permeable memb.

AS = air stripping

IE = ion exchange/ zeolites

CP = Chemical precipitation

Zarebska et al. (2015) Ammonium fertilizers production from manure: A critical review.

Design Parameter: Effect of aeration

Two ways can be used to increase manure pH and N recovery efficiency by the gas-permeable membrane system:

1. **Add alkali chemicals (OH^-)**

2. **Low-rate aeration**

$$HCO_3^- + \text{air} \rightarrow OH^- + CO_2$$

$$NH_4^+ + OH^- \rightarrow NH_3 + H_2O$$

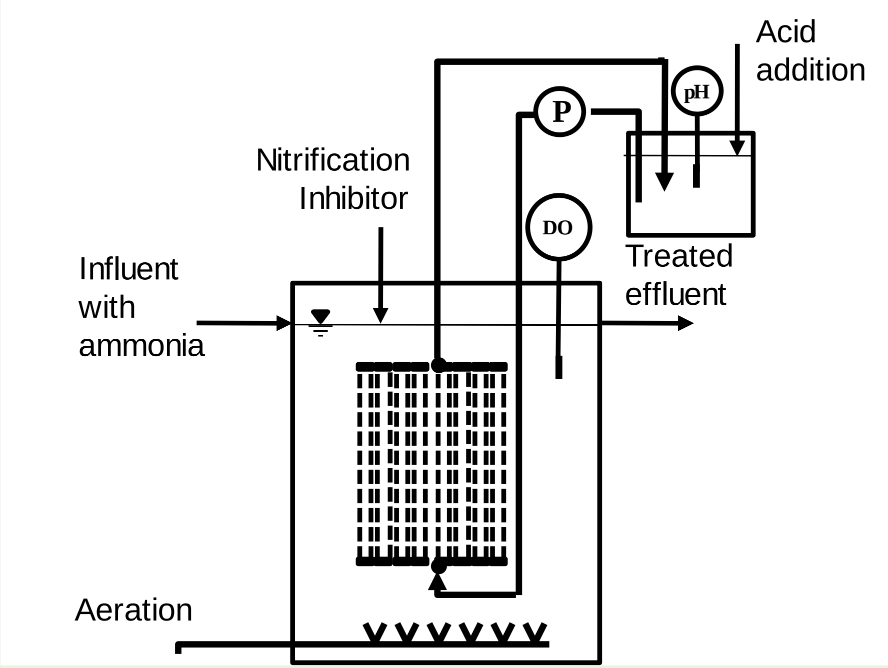
Design Parameter: Effect of aeration

Two ways can be used to increase manure pH and N recovery efficiency by the gas-permeable membrane system:

1. Add alkali chemicals (OH^-)

2. **Low-rate aeration**

$$HCO_3^- + air \rightarrow OH^- + CO_2$$
$$NH_4^+ + OH^- \rightarrow NH_3 + H_2O$$



- **Aeration increases manure pH about 1 unit**
- **The aeration rate must be low to inhibit nitrification**
- **Nitrification inhibitor can be used (< 10 ppm)**

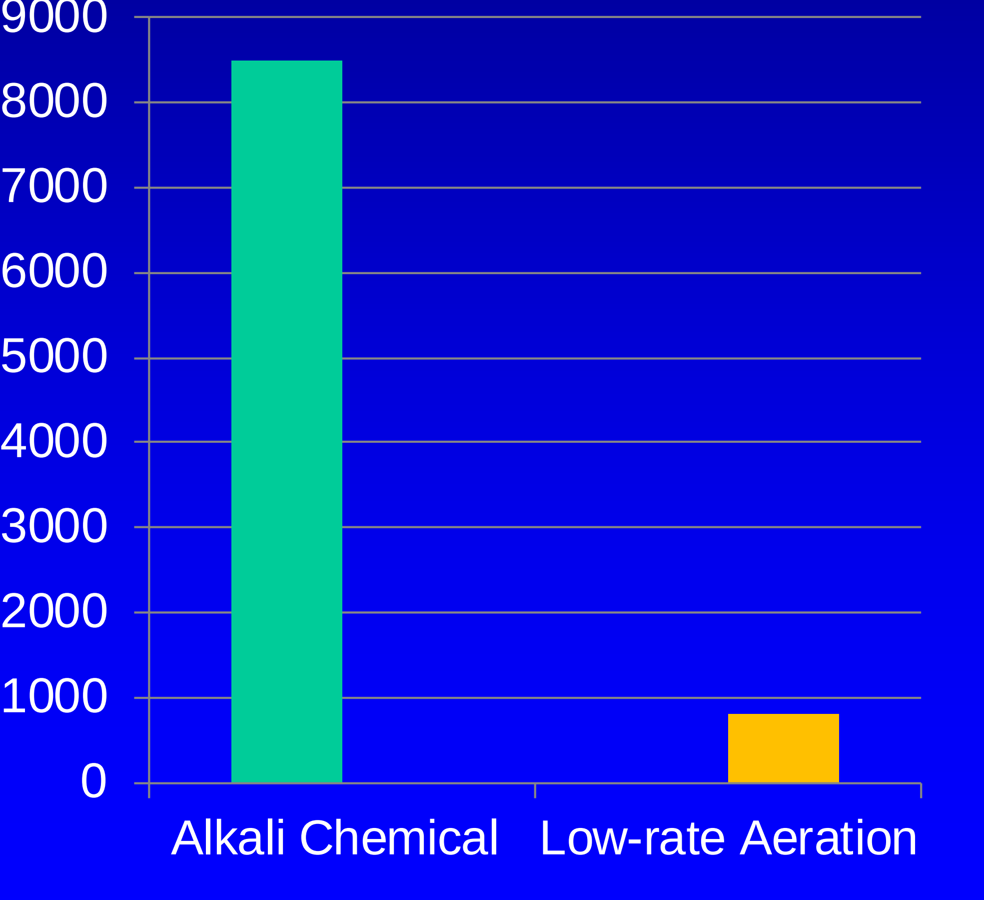
ARTICLE INFO ABSTRACT

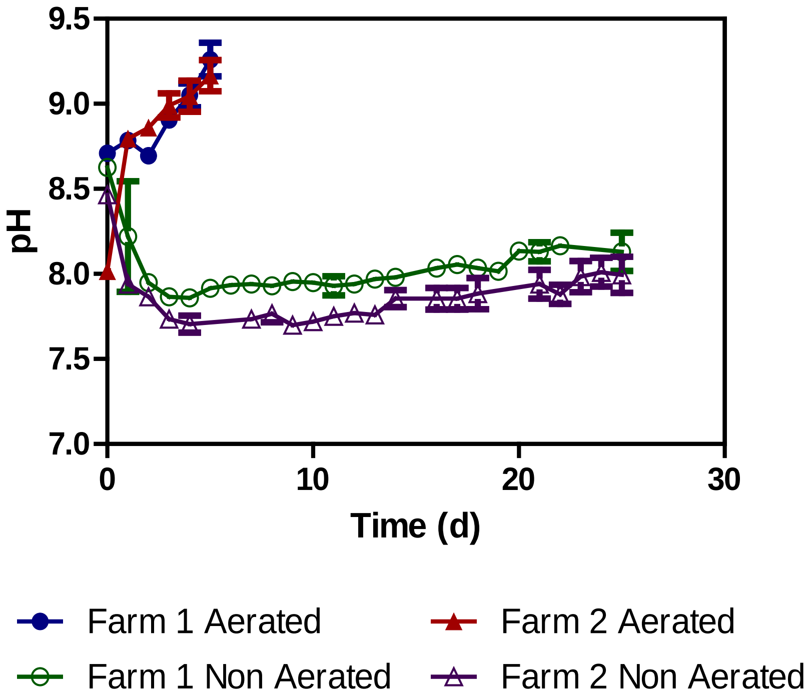
Significant cost reductions can be achieved with new concepts and research

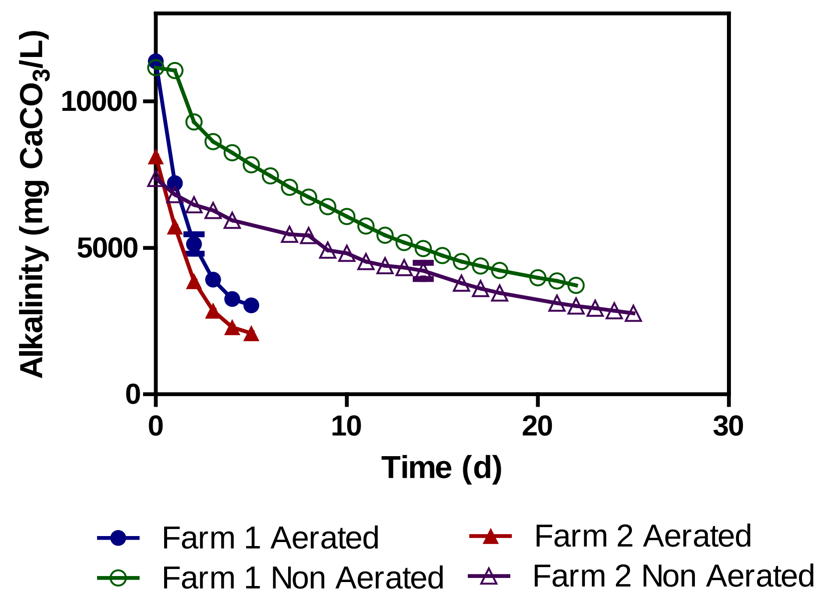
Operational cost of NH_3 recovery using gas-permeable membranes ($/4000 pigs/year)



Changes in pH and alkalinity of manure during N recovery process

Covered anaerobic lagoon effluent, NC





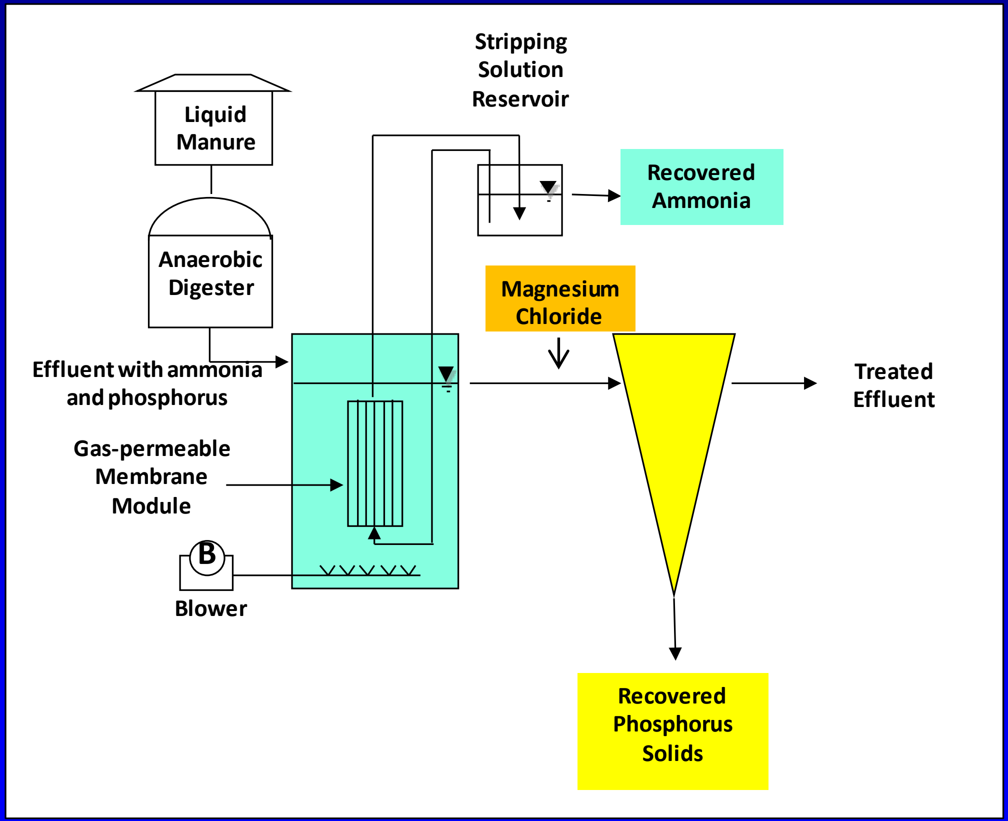
Key finding

- The process removes ammonia and alkalinity and increases pH.

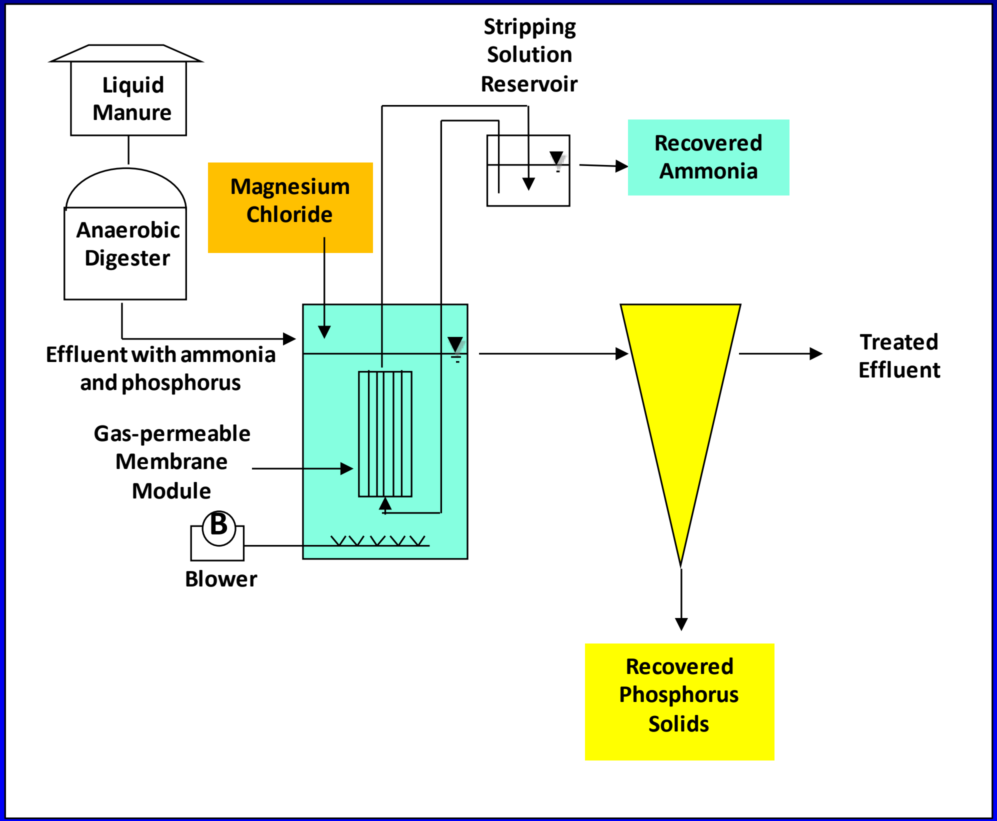
- These are ideal conditions for phosphorus precipitation and recovery

Recovery of ammonia and phosphorus from animal manure

Configuration 1



Configuration 2



Influent P concentration: 150-200 mg/L

Influent N concentration: 1500-2000 mg/L

US Pat. Appl. 62/169,387 (USDA 6/1/2015)

For Mg phosphates, two potential forms that can precipitate in liquid systems that contain Mg^{2+}–NH_4^+–PO_4^{3-} and a high Mg/Ca ratio are struvite and newberyite

(Boistelle et al., 1983; Abbona et al., 1988; Muster et al., 2013).

Struvite

$Mg^{2+} + H_2PO_4^- + NH_3 \rightarrow \mathbf{MgNH_4PO_4} + H^+$

Newberyite

$Mg^{2+} + H_2PO_4^- \rightarrow \mathbf{MgHPO_4} + H^+$

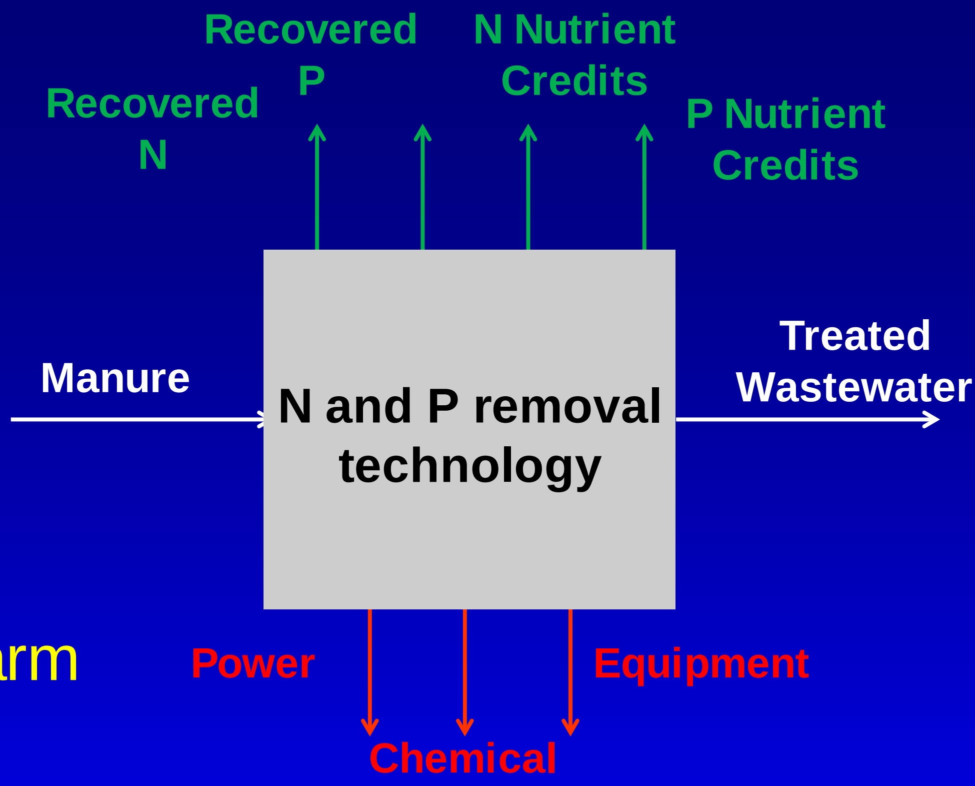
Ecosystem Cost Map



5200-head swine farm (finishing)

Capital and Operational Costs	
Equipment, Chemical, Power	$57,168.47 / year
Potential Revenue	
Sale of fertilizer products (N & P)	$58,538.63 / year
Additional Revenue: Sale of Non-point Nutrient Credits (2:1 trading ratio)	$ 61,449.93 / year

Conclusions

- Phosphorus recovery was combined with ammonia recovery using gas-permeable membranes
- Aeration destroyed carbonates, increased pH, and enhanced N capture
- The process provided approximately 100% phosphorus recovery efficiencies
- With substantial ammonia capture, the recovered P contained very-high phosphate grade (biomineral newberyite)

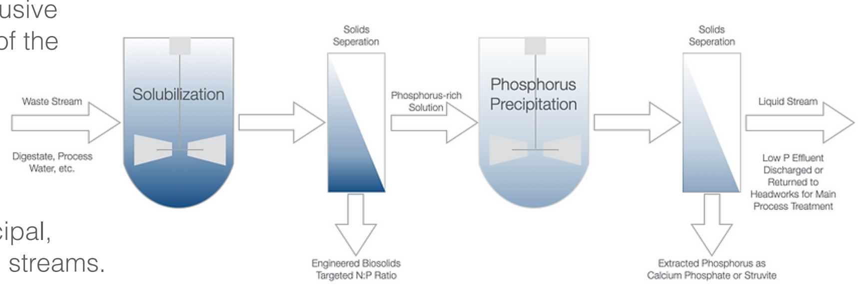
QUICK WASH®

Phosphorus Extraction & Recovery

Renewable Nutrients is rethinking phosphorus with Quick Wash®, a proprietary system that draws on exclusive technology to extract and recover 95% or more of the phosphorus found in biosolids.



Quick Wash is equally effective at treating municipal, industrial, and agricultural waste solids and side streams.

- Extracts and recovers more than 95% of phosphorus

Quick Wash® is effective at extracting and recovering 95% or more of the phosphorus from a treatment facility's solid stream or side stream.

- Alternative treatment locations

Quick Wash® is flexible in solving phosphorus issues. It is the only system that can treat your solids pre digestion, post digestion, or post dewatering.

- Reduces or eliminates phosphorus recycle load

When deployed on the side stream of thickening or dewatering operations, Quick Wash® can reduce or eliminate the recycle flow of phosphorus.

- Reduces polymer and metal salts

Quick Wash® can reduce or even eliminate a facility's reliance on costly metal salts for phosphorus removal. The system also helps to increase dewatering efficiencies and reduce polymer consumption.

- Reduces disposal costs

Quick Wash® lowers the phosphorus content of liquid and dewatered biosolids — making the dewatering process more efficient, which lowers the volume of solids for disposal. Quick Wash® can reduce or eliminate biosolids landfilling fees by making the solids more viable

- Eliminates struvite scaling

Eliminates the costly maintenance fees associated with struvite scaling in digesters and treatment pipes.

- Increases revenue

Facilities can sell the recovered phosphorus, participate in nutrient credit trading opportunities, and potentially create locally blended custom fertilizers.

- Meet EPA nutrient TMDL requirements

Quick Wash® can help facilities meet increasingly stringent nutrient loading regulations.

- Represents a new, sustainable source of phosphorus

Quick Wash® represents a new and sustainable source of phosphorus to meet accelerating demand, while providing a solution that helps curtail phosphate pollution in groundwater and waterways.

National Hog Farmer Article

National Hog Farmer

Renewable Nutrients announces pilot of Quick Wash process in the animal ag sector

Aug 12, 2015

Renewable Nutrients LLC, a firm focused on nutrient extraction, recovery, and reuse, today announced that it will be piloting its Quick Wash phosphorus extraction and recovery process later this month at Walk Stock Farm, a large swine production farm near Neoga, Ill.

“This will mark our first in-field operation in the animal agriculture sector, outside of small, bench scale tests in the laboratory,” says Jeff Dawson, President and chief executive officer of Renewable Nutrients. “We couldn’t be more pleased in the interest that Walk Stock Farm has expressed in finding a scalable, economical solution to recovering phosphorus from their swine waste. The Renewable Nutrients team is eager to test and prove Quick Wash’s effectiveness and practicality for on-farm operations,” Dawson adds.

Quick Wash has been successfully piloted at waste water treatment facilities throughout the mid-Atlantic, including Ephrata, Pa., Westminster, Md., and Greenville, Chapel Hill and Raleigh, N.C. The upcoming pilot at Walk Stock Farm represents the first time Quick Wash will be tested and utilized to extract and recover phosphorus from animal manure in a real-world, on-farm scenario. “We have been following Renewable Nutrients’ rollout of their Quick Wash technology within the waste water treatment industry, and we feel that it's a very promising solution for reducing and recovering the phosphorus loads in our hog manure," says Roger Walk, president of Walk Stock Farms. "If Quick Wash can extract an acceptable level of phosphorus from our manure, we feel we will have a very sustainable — perhaps future-proof — solution for managing our manure and transporting and spreading it on our crop fields. We are excited to host this first animal agriculture-specific pilot of the Quick Wash system, and we look forward to seeing it in operation and reviewing its performance," Walk adds.

Animal and plant growing operations throughout the country (specifically in areas close to or leading to fragile watersheds) are under increasing pressure to employ best farming practices that eliminate or lessen nutrient runoff from crop fields where manure has been applied. Given a tool — like Quick Wash — to extract and recover phosphorus from animal manure, farmers can spread the resultant low or no-phosphorus manure without fear of phosphorus runoff or soil saturation. Quick Wash also provides farmers with a means of selling the extracted phosphorus on the open market or engaging in the trading of nutrient credits.

"Quick Wash has surfaced as a proven and practical methodology for reducing phosphorus loads in waste water treatment plant sludge and effluent," says Mike Schmid, chief marketing officer at Renewable Nutrients. "It only makes sense to extend this new technology to the animal agriculture sector, where it can basically eliminate the occurrence of non-point source runoff of phosphorus, and provide farmers with an efficient, scalable means of extracting and recovering such a valuable nutrient from their animal waste."

RENEWABLE
NUTRIENTS

Innovative Nutrient Recovery Technologies

- Renewable Nutrients is a privately owned US company currently commercializing exclusive, proprietary & patented nutrient recovery technologies in the municipal, industrial, and agricultural markets.

- Renewable Nutrients is a full service technology company with the capacity to license, sell, design, and build nutrient recovery technologies for full scale implementation

- Renewable Nutrients owns exclusive licenses for multiple USDA patents for **Phosphorus & Nitrogen** recovery technologies commercially known as Quick Wash®

RENEWABLE NUTRIENTS

- Renewable Nutrients has redefined nutrient recovery with Quick Wash, a proprietary patented system that draws on exclusive patented technology to extract and recover **Phosphorus & Nitrogen** from municipal, agricultural, and industrial markets

- Renewable Nutrients has completed numerous Quick Wash pilots and trials in municipal, agricultural, and industrial applications and has effectively proven the performance of Quick Wash

- Quick Wash technologies are cost effective and completely customizable based on the costumers needs for nutrient extraction and recovery with the ability to focus on **Phosphorus & Nitrogen individually or as a combined recovery technology.**

- Quick Wash is poised to be the solution for treatment, recovery & recycling of high strength **Phosphorus & Nitrogen** waste streams in any food waste digestate, municipal sludge or centrate, agricultural applications, and other high strength waste streams

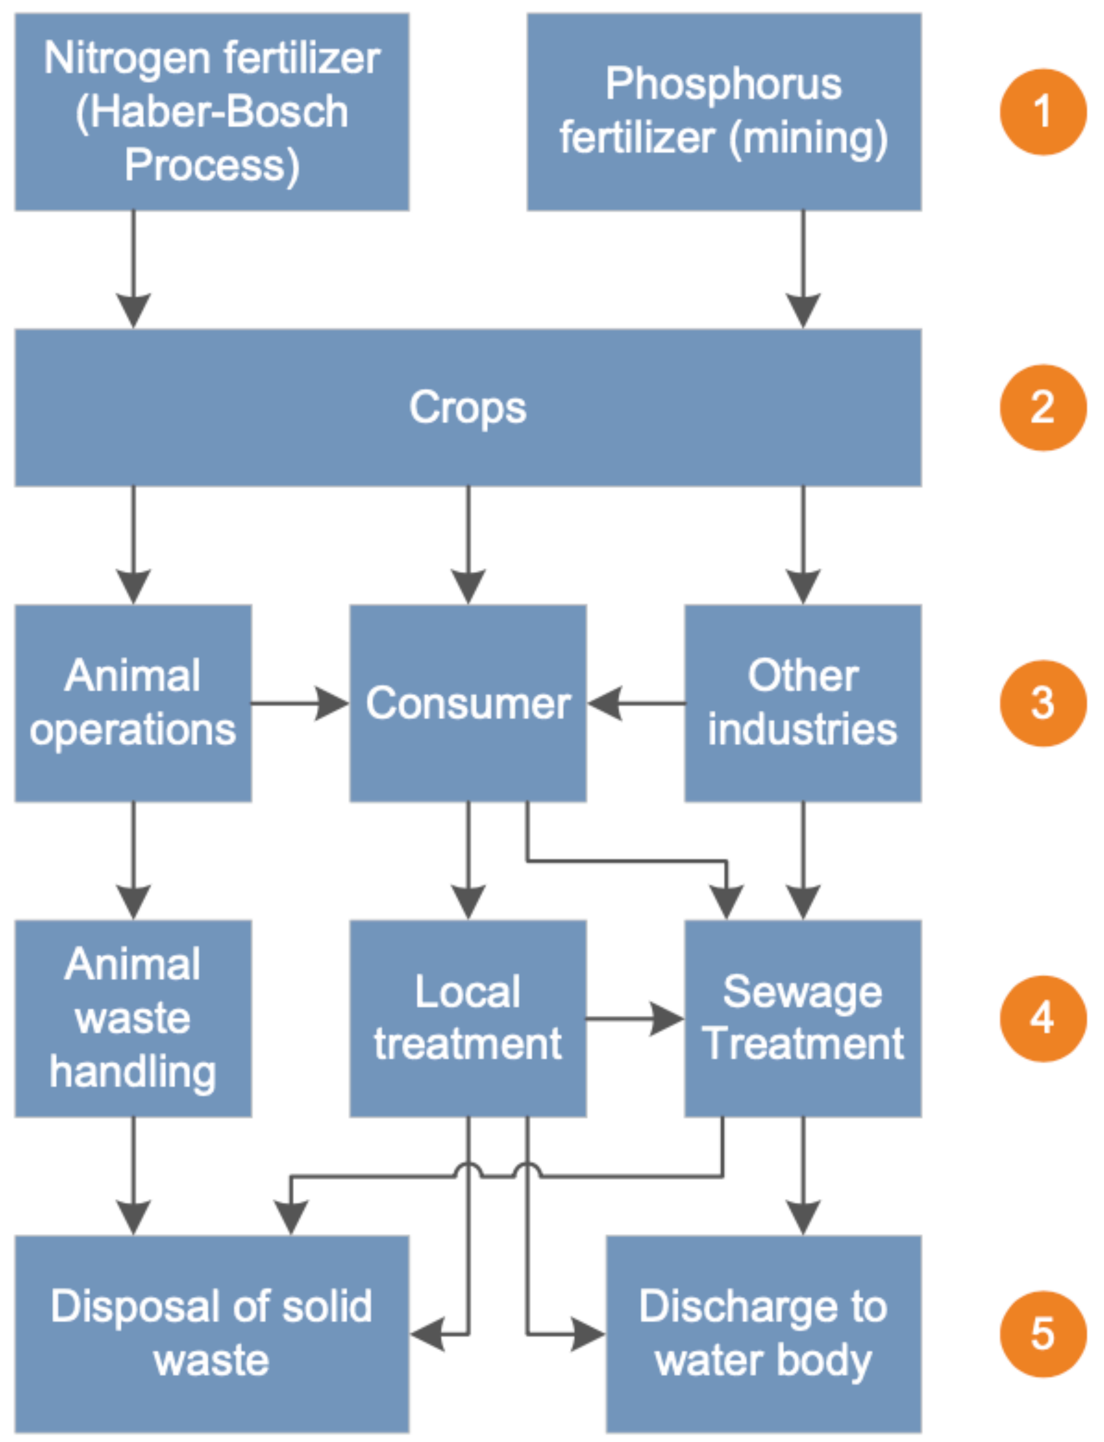
QUICKWASH®

IP Portfolio Summary

Patent	Description	Transformative Invention	Market Applicability
Phosphorus	Phosphorus extraction & recovery	**Yes** - moves facilities from simply sequestering P to biosolids to P extraction & recovery. Yields a recovered commodity (calcium phosphate)	Municipal Industrial Agriculture
Ammonia Liquid	Passive ammonia recovery from liquid waste streams	**Yes** – drives efficiency and reduces cost of nitrification/ de-nitrification operations. Yields a recovered commodity (ammonium sulfate)	Municipal Industrial Agriculture
Ammonia Gaseous	Passive ambient ammonia recovery from a gaseous ammonia-rich environment	**Yes** – potential to competley transform current costly ventilation practices in confined animal agriculature	Agriculture
Combined **Phosphorus & Ammonia**	Protects the IP when combining both phosphorus and ammonia recovery	**Yes** – aids in the operational efficiency of phosphorus recovery and yields two commodities (calcium phosphate & ammonium sulfate)	Municipal Industrial Agriculture

QUICK WASH®

- More than 16,000 municipal waste treatment plants in US
- Animal production is a major component of the US economy
- Existing solutions to water treatment and disposal of animal waste are costly and ineffective
- Concern for public health risks and treatment costs of contaminated water supplies
- Increasing demand for fertilizer and nutrients and limited world phosphorus reserves
- Major environmental risks around important bodies of water like the Chesapeake Bay, Susquehanna River, Lake Michigan and the Gulf of Mexico etc.
- Current "old" technology does not produce usable and marketable co-products



General scheme of nutrient pathways

QUICK WASH®

Competitive Technology Comparison

Nutrient Removal/Recovery Technologies

	Chemical	EBPR	Algea	Struvite	Renewable Nutrients
Characteristics	Alum, Ferric Chloride, Cerium Chloride	A2/), 4-5 Stage Bardenpho, Biological/ Chemical, SBR	Clearas, ABNR. Algae Wheel, Lagoon Settling Systems	Ostara, Multi-Form Harvest, CNP-Airprex, Phospaq, Crystalactor, NuReSys	QUICK WASH®
Side Stream vs Main Stream	Both	Side Stream	Mainstream	Side Stream	Both
Solids Stream Application	No	No	No	No	Yes
Phosphorus Removal	Yes	Yes	Yes	Yes	Yes
Phosphorus Recovery	No	No	Yes	Yes	Yes

Ammonia Recovery	No	No	No	No	Yes
Sludge Bulkin	Yes	Yes	No	No	No
Byproduct Recovered	N/A	N/A	Algae Biomass	Struvite Fertilizer	Calcium Phosphate - Hydroxylapatite / Ammonia Sulphate
% Efficiency of Recovery	N/A	N/A	>95%	45-90%	>95%
Scalability	Small to Large Facilities	Typically Larger Facilities >10MGD	Scales from small to large facilities	Large facilities - only economical when sidestream contributes large % of total P	Scales from small to large

"The EPA will actively promote those Municipal Biosolids management practices that provide for the beneficial use of Biosolids while maintaining or improving environmental quality and protecting public health" -- Federal Register Vol. 49, p 24358

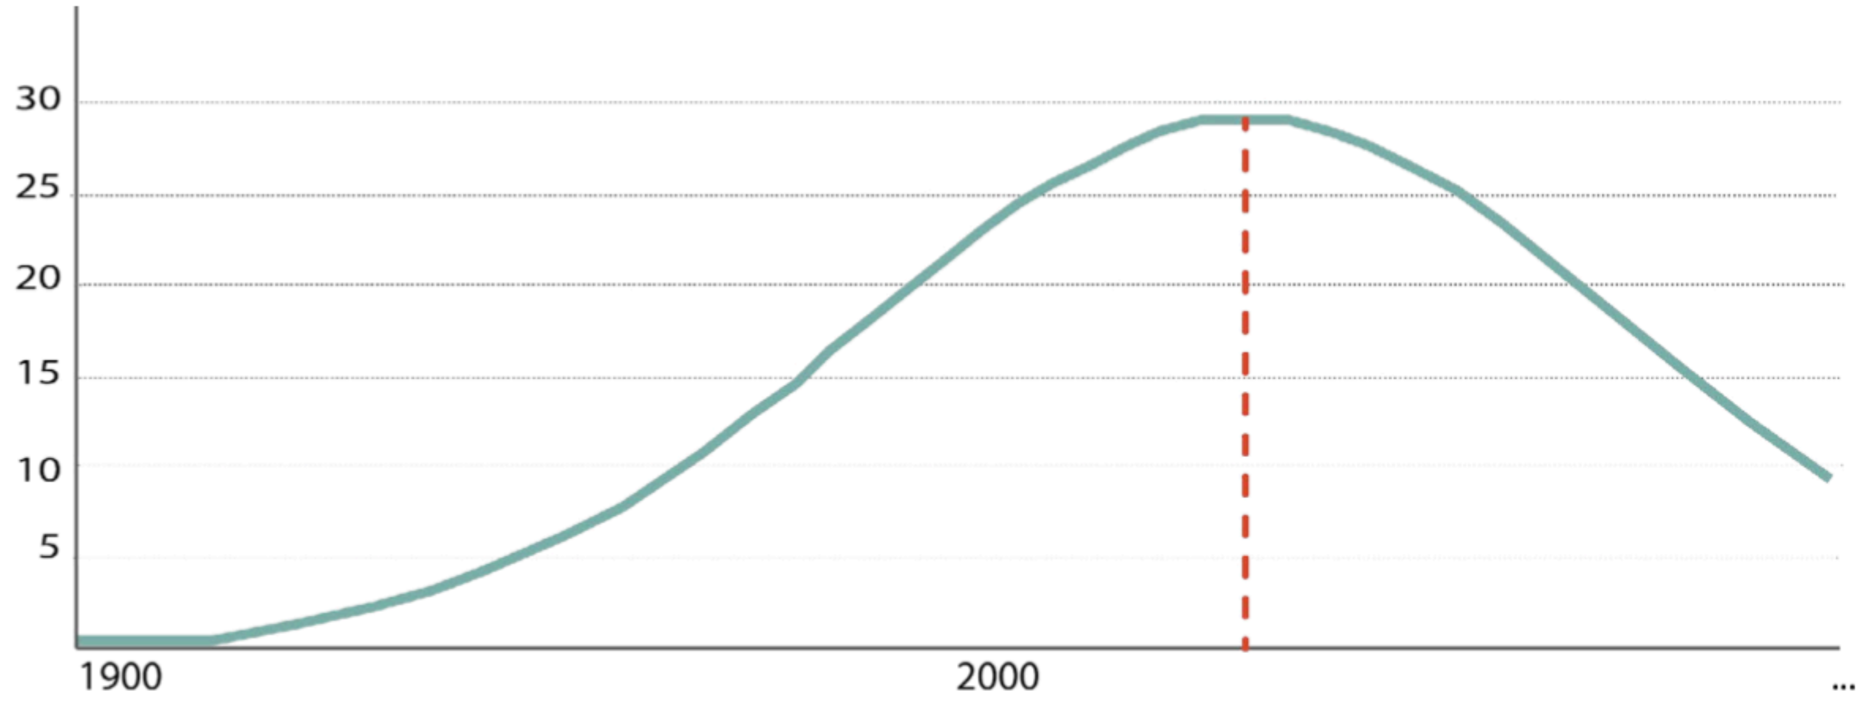
Environmental Issue	Scope
Hazards of Disposing of Nutrient rich Waste Biosolids from Wastewater Treatment Plants	• (WWTPs) in U.S. generate approximately 7 million dry tons of sludge each year • Causes more pollution per acre than other "fertilizer" and 4x more phosphorous
Contamination from animal waste	• Over 10.2 million tons of poultry litter alone are generated in the US
Public Health Risks and Treatment Costs from Contaminated Drinking Water Supplies	• Current disposal methods result in contamination of surface waters • Problems compounded by population growth through increased storm water runoff, municipal wastewater discharges, and air carried pollutants
Limited World Phosphorus Reserves	• World will reach peak Phosphorus mining production in 50 to 100 years • Necessity to sustain life • No synthetically reproducible alternative for phosphorus; technology to extract and reuse phosphorus is appealing

The Environmental Crisis

Demand for phosphorus has greatly expanded since 1960 and appears to be continuing on this trend

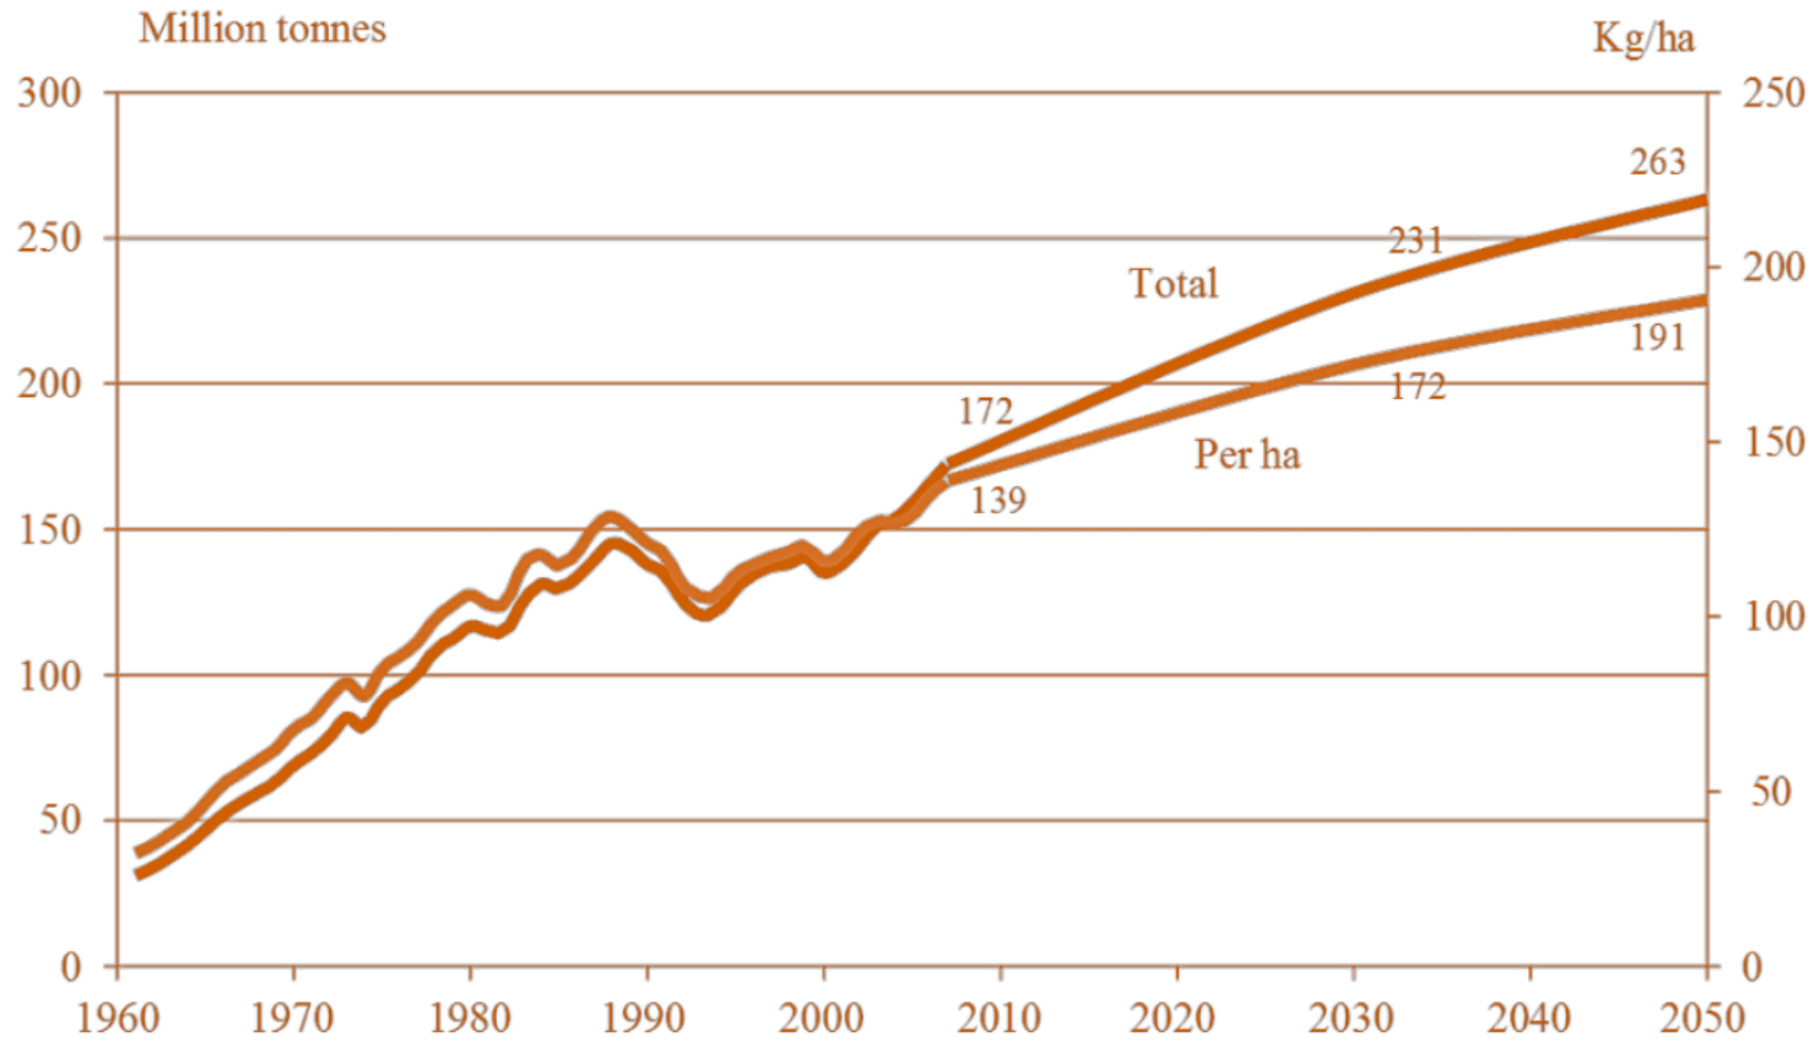
WORLD PHOSPHATE ROCK PRODUCTION (TONS)

*Source: USGS



Peak Phosphorus refers to a time when production reaches a maxcimum, and high quality, highly accesible reserves have been depleted

WORLD PHOSPHATE ROCK PRODUCTION (TONS)



World fertilizer use: past and projected (nitrogen, phosphorus and potassium aggregated). Source: FAO, World

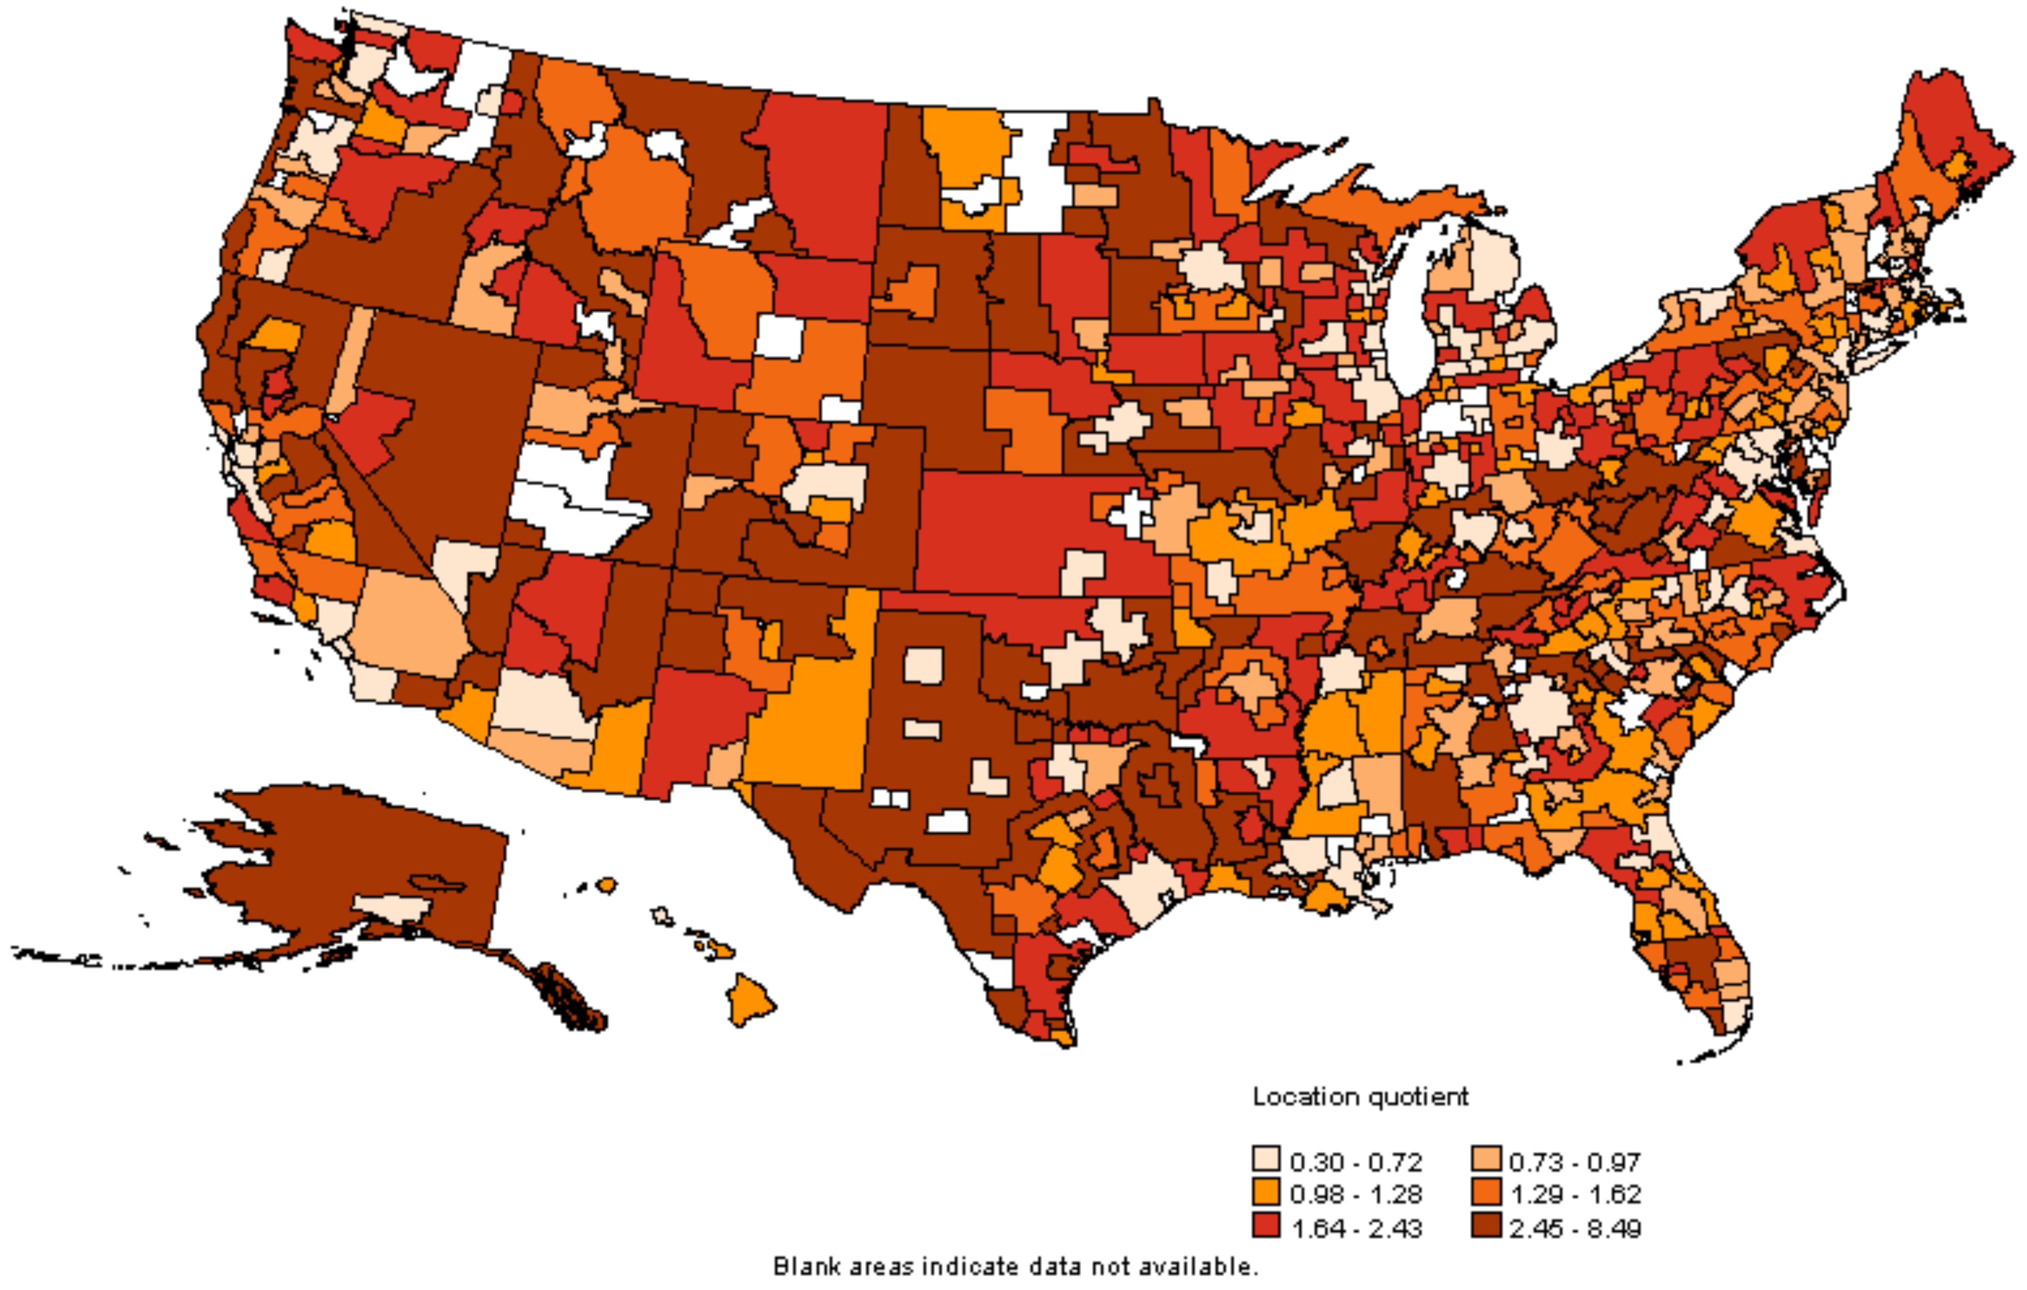
QUICK WASH®

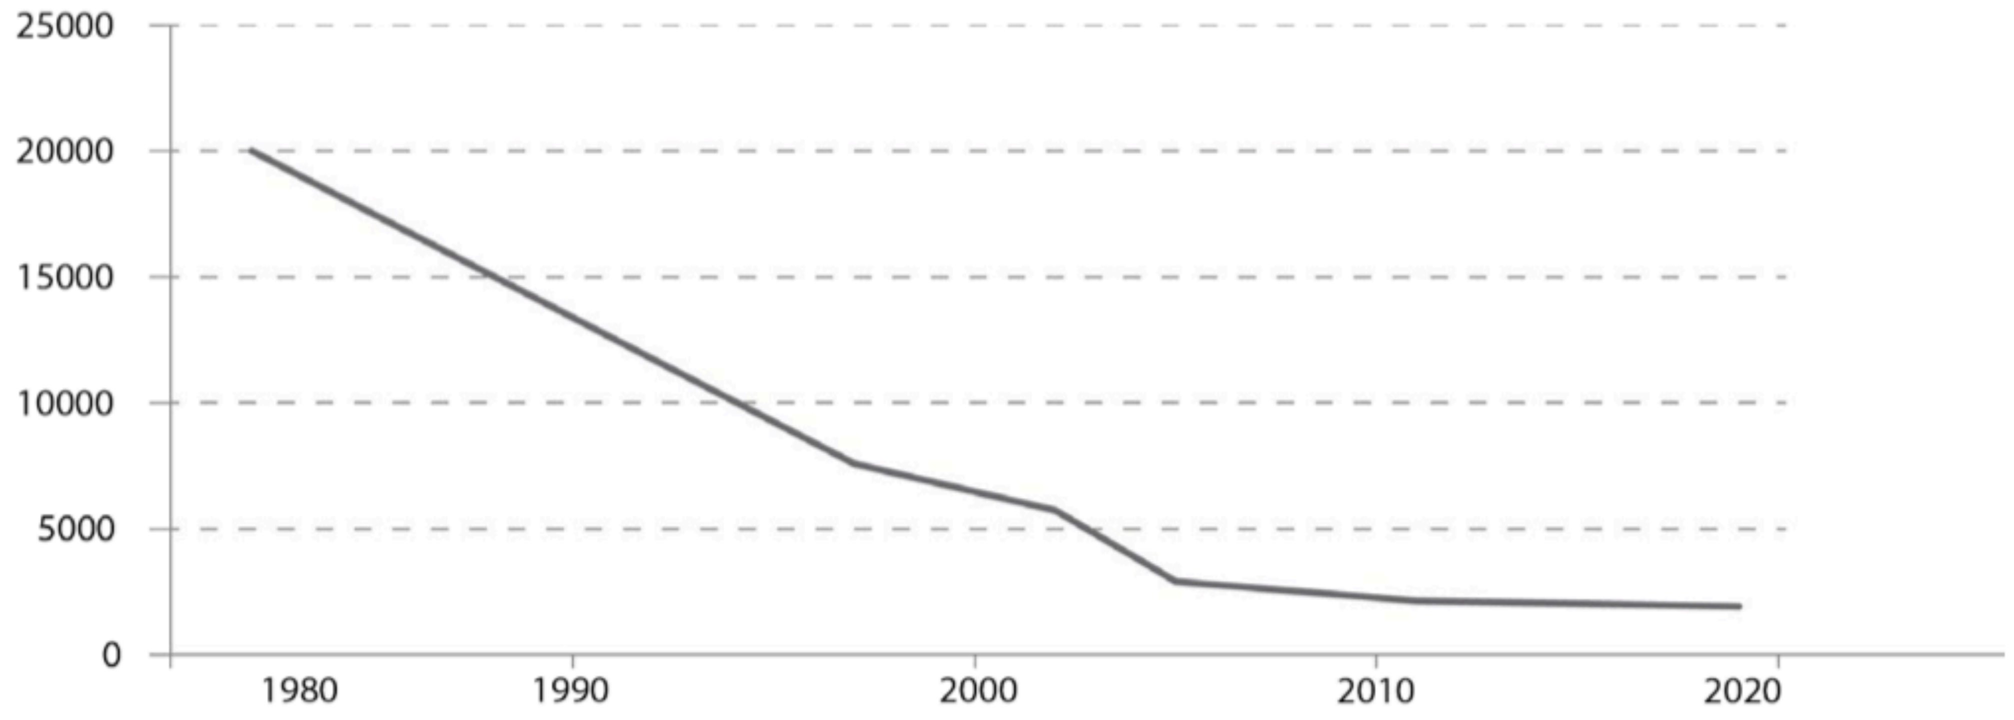
Key Drivers for Adoption of Nutrient Recovery

Environmental	Regulatory	Operational
•Eutrophication of waterways •Drinking water concerns •Growth of toxic algae •Depletion of phosphorus reserves •Impact to fisheries, aquatic species, and food supply	•Facility operational permitting based on nutrient effluent management •Reduction of phosphorus effluent limits to < 1ppm and some will be required to reach "ultra-low" levels for discharge under 0.04 mg/l •Facilities operating near impaired waterways to see phosphorus effluent limits < 0.5ppm •Reduction in permitted "free ammonia" ($NH3$) effluent levels •Farmers forced to store or dispose of animal manure vs land application	•Reducing the level of phosphorus in biosolids allows facilities and farmers to land apply vs dispose biosolids •Drives greater efficiency of biological nutrient removal by reducing overall phosphorus and nitrogen load in the facility •Eliminates costly struvite scaling •Reduced biosolids production •Incremental revenue gain through sale of recovered coproducts

Key Drivers for Adoption of Nutrient Recovery

Municipal System Operators (16,000 +) are located across the entire United States, creating a market and customer base for Renewable Nutrients with regards to waste treatment.

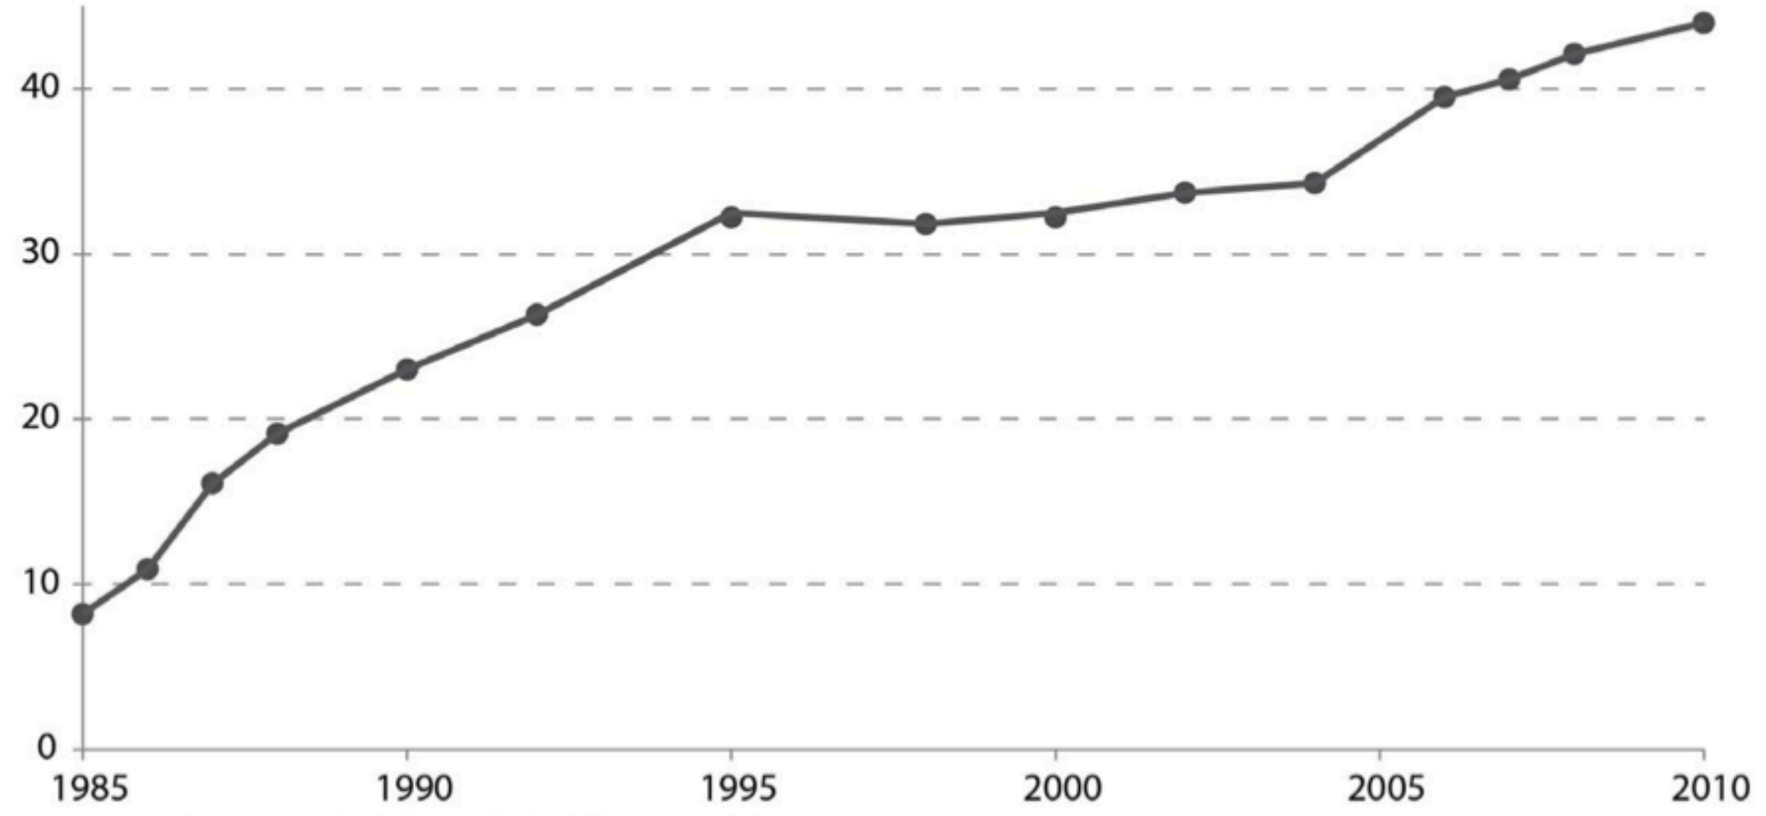




US LANDFILL DECLINE

*Source: Waste & Recycling News

The number of US landfill has been declining since the late 1970s,



US AVERAGE TIPPING FEE

*Source: Waste & Recycling News

The decreasing number of landfills has led to increases in tipping fees at an average of $1.24 per ton across the US each year. In the future, landfill may not be the least expensive biosolid management alternative

RENEWABLE NUTRIENTS

Technology Summary

QuickWash®

Nutrient Extraction & Recovery

LIFT©

isle

USDA

- A combined application of both **Phosphorus & Nitrogen** extraction and recovery technologies to solve the total nutrient issue for high strength streams without additional treatment steps
- The use of existing tankage, piping, and pumping is highly possible and recommended
- We anticipate that regulatory agencies will enforce more stringent discharge requirements for both **Phosphorus & Nitrogen**
- Economy of scale can be achieved by implementing both exclusive **Phosphorus & Nitrogen** technologies
- Renewable Nutrients is the only company with a combined IP protected **Phosphorus & Nitrogen** recovery offering in addition to individual **Phosphorus & Nitrogen** recovery solutions
- Utilizing Quick Wash technologies will enable the extraction, recovery, and reuse of valuable nutrients in an efficient and cost effective offering.

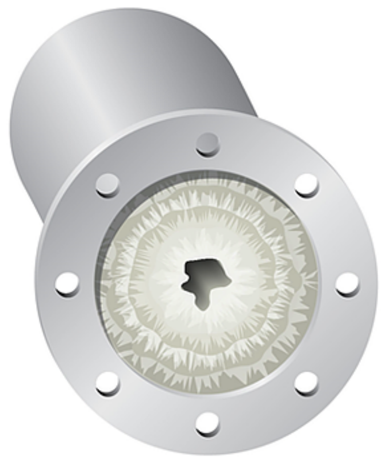
Configurations/Applications

- Side Stream from dewatering (aerobic or anaerobic)
- Solids Prior to dewatering
- Prior to thickening & anaerobic digestion
- Pre-treat a high **Phosphorus & Nitrogen** industrial discharge
- Animal agriculture applications
- Other custom configurations
- Renewable Nutrients has designed multiple process flow diagrams for different applications of the Quick Wash process

QuickWash®

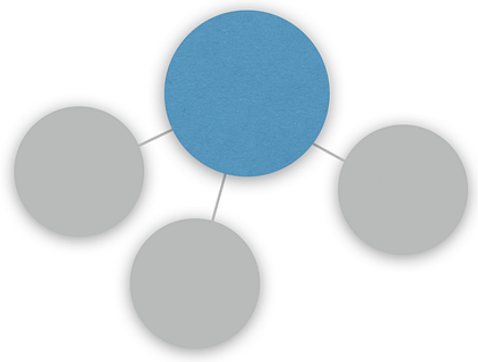
Phosphorus Extraction Benefits

- Removes and recovers more than 95% of **Phosphorus**
- Reduce phosphorus concentration in high strength recycle streams such as digester supernatant liquid waste
- Reduce polymer & metal salts
- Reduce disposal costs
- Eliminate struvite scaling
- Increase revenue from sales of phosphorus by-product
- Meet EPA nutrient TMDL requirements



QUICK WASH®

Nitrogen / Ammonia Extraction Benefits



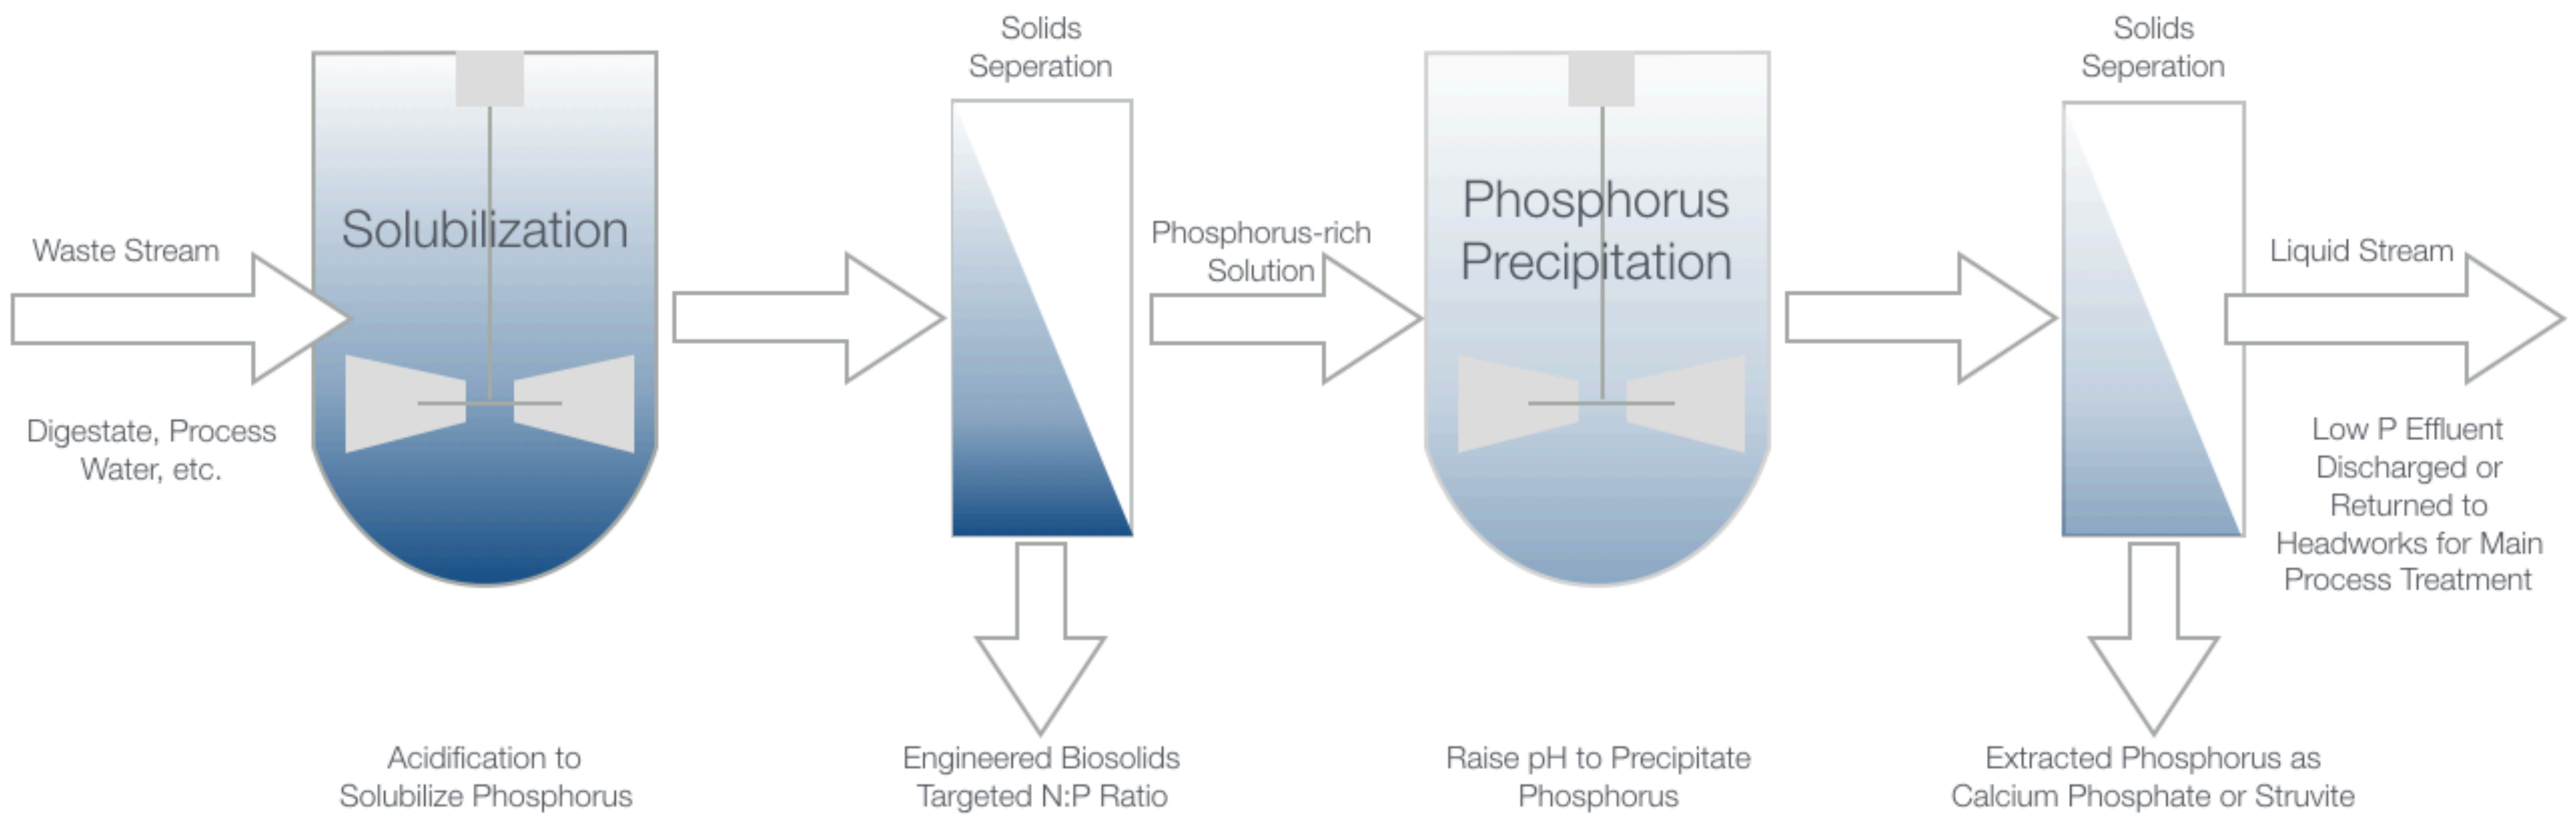
- Removes and recovers more than 95% of **Nitrogen**
- Reduce inputs of energy, carbon, alkalinity
- Recover rather than destroy a valuable resource
- Produce a high quality, marketable ammonium compound product ie ammonium sulfate or ammonium citrate
- Improve the quality of the effluent by enhancing exiting nutrient removal processes
- Allow the reduction of ammonia alkalinity
- Potentially free existing capacity and allow the re-rating of treatment plants in lieu of additional capital investment
- Provide a solution for additional capacity in plants with limited footprint for expansion

QuickWash®

A Multitude of Intangible Benefits

Description	Discussion	Value
Ability to treat high-strength side stream digestate, centrate, filtrate without complex or expensive equipment	Depends on application. Compared to other technologies, the RN technology can serve as an enabling technology, solving the problems that are generated from anaerobic digestion	Possibly worth millions depending on specific project application and compared to alternative technologies
Production of beneficial use byproducts	Our standard design produces calcium phosphate and ammonium sulfate. Both are valuable and popular in the agronomics/agriculture sector for fertilizer and other uses.	We recognize the byproducts do not generate significant revenue. But they generate revenue rather than a byproduct that requires further cost for disposal. Value in tens of thousands to hundreds of thousands annually depending on system size
Elimination of struvite formation	Many agencies are struggling with the effects of scaling and struvite formation in piping, pumps, and equipment. By recovering the P, and not allowing it back into the plant to form struvite scaling.	Many agencies are spending hundreds of thousands, even millions, annually to mitigate struvite issues. The value of elimination of struvite is significant.
Small footprint	Unlike some technologies, the RN technologies do not require a great deal of space	Many other technologies are disqualified due to space requirements. Having a technology with a small footprint requirement may save significant project dollars.
Low cost of operations	The input chemicals are relatively inexpensive and the power costs are low. Depending on the hydraulic grade considerations for a specific site, much of the process can flow via gravity	Sulfuric acid is a low cost chemical in comparison to many, as is lime or caustic. Because this is a chemical solution, there are chemical costs, but they are simple, affordable chemicals.
Fast process	Compared to other technologies, the RN technologies are fast acting, therefore not requiring large tankage for long HRT's. This reduces CapEX and OpEx.	Compared to many, the RN technologies are fast. Speed is related to cost. The value in treatment costs is significant.
Major opportunity to reuse existing facilities	Existing tankage, pumps, and other facilities can be reused with ease to reduce costs	The equipment required for the technology is simple and is not proprietary. Therefore, existing tanks, mixers, pumps, piping and other facilities can be repurposed reducing project costs and saving money.
Flexibility in targets for performance	Adjustments in stoichiometric can allow for flexibility in performance and results and costs	Facilities can be sized and operated to achieve specific targets. The flexibility is valuable and allows for a system to follow changing conditions. The value of this flexibility is significant.
Technology is more robust than biological process - chemistry vs biology	With biology, a rogue contaminant, or rapid changes in conditions, can upset the active organism causing treatment failure. Chemistry is more predictable and reliable.	Other technologies that rely on bacteria, algae, microorganisms, or other biological presence have struggled to treat nutrient rich water (particularly) high strength due to the sensitive nature of the organisms. Having a reliable process that is more robust is priceless.
Processes will be more familiar to operations staff	Most operations staff are familiar with the use of pH modifications to manipulate treatment processes. Not much new to learn with RN tech.	Reduction in training and an acceleration in process acceptance has significant value.
Site specific Benefits	Depending on conditions and finanical opportunities ie. Insurance & nutrients trading	Potential to be game changing for a privately owned facility

Quick Wash Phosphorus Extraction and Recovery extracts phosphorus from municipal, agricultural, or industrial waste streams in solids or liquids (effluent) and recovers the phosphorus in the form of Calcium Phosphate or Struvite.



- Ammonia **LIQUID** technology relates to a system and methods for the removal, recovery and use of ammonia from ammonia-containing liquid effluents such as animal and municipal wastewater.
- Ammonia **GASEOUS** technology relates to a system and method for the removal of gaseous nitrogen to reduce emissions from systems that produce gaseous nitrogen.

Abstract: Anaerobic lagoons are a critical component of confined swine feeding operations. These structures can be modified, using a synthetic cover, to enhance their ability to capture the emission of ammonia and other malodorous compounds. Very little has been done to assess the potential of these covers to alter lagoon biological properties. Alterations in the physicochemical makeup can impact the biological properties, most notably, the pathogenic populations. To this aim, we performed a seasonal study of two commercial swine operations, one with a conventional open lagoon, the other which employed a permeable, synthetic cover. Results indicated that lagoon fecal coliforms, and *Escherichia coli* were significantly influenced by sampling location (lagoon vs house) and lagoon type (open vs. covered), while *Enterococcus* sp. were influenced by sampling location only. Comparisons against environmental variables revealed that fecal coliforms (r^2 = 0.40), *E. coli* (r^2 = 0.58), and *Enterococcus* sp. (r^2 = 0.25) significantly responded to changes in pH. Deep 16S sequencing of lagoon and house bacterial and archaeal communities demonstrated grouping by both sampling location and lagoon type, with several environmental variables correlating to microbial community differences. Overall, these results demonstrate that permeable synthetic covers play a role in changing the lagoon microclimate, impacting lagoon physicochemical and biological properties.

Keywords: anaerobic lagoons; permeable cover; microbial communities; pathogens; *Enterococcus*; *Escherichia coli*

1. Introduction

Anaerobic lagoons remain the preferred option of manure treatment for confined swine production systems in the Southeastern United States. These earthen structures, utilized for both passive treatment and storage, are aimed at reducing the organic load of fresh manure and consequently, concentrating the nutrients contained within these waste materials. These nutrients, combined with anaerobic conditions, provide a suitable growth environment for a variety of microorganisms, including a number of pathogenic bacteria [1]. In the Southeastern U.S., liquid manure is collected under the barns using slotted floors and a shallow pit filled daily or weekly with the supernatant lagoon effluent. Any excess lagoon liquid not used for filling the shallow pit is land applied on spray fields during the crop season. Therefore, pathogens can be reintroduced into the barns with recycled lagoon liquid or deposited into the surrounding environment during land application of the lagoon wastewater, where they may eventually infect livestock or truck crops, thereby potentially entering the food chain [2].

While the construction of anaerobic lagoons tend to follow general engineering design criteria [2], swine operators have the discretion to add additional safeguards and management measures as long as such modifications continue to meet federal, state, and local regulations [3]. For instance, swine operations adjacent to communities may opt to employ synthetic lagoon covers for the control of ammonia and other malodorous compounds [4,5]. These covers can be permeable (e.g., geotextile, foam, straw) or impermeable (e.g., plastic, wood, concrete), and despite differences in cover composition, they all serve a similar purpose—to reduce emissions. One benefit to permeable covers is their ability to allow oxygen penetration, resulting in microclimate formation at the cover/lagoon interface [6,7], and such microclimates have been documented to result in the formation of biofilms [7], enhance protozoa fauna populations [6], and alter nutrient cycling patterns [4].

Given the reliance on anaerobic lagoons by the swine industry as a waste treatment measure, significant research has been conducted into understanding pathogen fate [8], nutrient cycling [9], and emissions [10] in these systems. Many of these studies have focused on open (i.e., uncovered) lagoons, primarily because they dominate the treatment landscape. Despite research demonstrating that lagoon covers utilized in swine production reduce ammonia and malodor emissions, there remains a paucity of information regarding the microbial community composition of covered lagoons, and the potential for synthetic covers to impact pathogenic populations.

Given the lack of information on the microbial communities that populate covered lagoons, and whether these lagoons can control pathogenic populations, this study was conducted with two major objectives: (i) determine potential differences in pathogen kill rates and (ii) assess microbial community differences between a covered and uncovered lagoon. A third objective, if differences are identified in the first two objectives, is to determine the relationship between environmental factors and the noted differences between the two types of lagoon systems.

2. Materials and Methods

2.1. Site Description and Sample Collection

Two commercial swine finishing operations were chosen for this study. The first operation, supporting between 2100 and 2200 animals per cycle, had an uncovered 0.55 ha lagoon, while the second operation, supporting between 1200 and 1500 animals per cycle, functioned with a synthetic, permeable membrane covering the 0.4 ha lagoon, details of which have been previously described [6]. The covered lagoon operation employed a flush tank recirculation system, while the open lagoon operation employed a shallow pit with a pull-plug flushing system for moving waste out of the house. Samples were collected seasonally, starting with a spring sampling in April of 2017, and ending with a winter sampling in February of 2018. Samples from both lagoons and houses were performed in triplicate. For the uncovered house, samples were collected from the recirculation pump, while samples collected from the covered house were collected inside, during the flushing event. Lagoon samples were collected from the top of the water column at three separate locations.

2.2. Sample Analysis

Dissolved oxygen and temperature were recorded on site using a YSI ProODO optical dissolved oxygen meter (YSI Incorporated, Yellow Springs, OH, USA) prior to transport and storage of lagoon liquid samples on ice. Additional wastewater analyses, which included total suspended solids (TSS), volatile suspended solids (VSS), pH, ammonium (NH_4-N), and total Kjeldahl-N (TKN) were performed according to Standard Methods for the Examination of Water and Wastewater [11]. Anions (Cl, SO_4-S, NO_3-N, NO_2-N) were measured by chemically suppressed ion chromatography using a Dionex 2000 Ion Chromatograph according to ASTM Standard Method D4327-11 [12], while cations (Ca, K, Mg, and Na) were measured according to ASTM Standard Method D6919-09 [13].

2.3. Pathogen Detection

Escherichia coli, fecal coliforms, and *Enterococcus* sp. were enumerated on CHROMAgar E. coli (CHROMagar, Paris, France), mFC (Sigma, St. Louis, MO, USA), and mE (Becton Dickinson, Franklin Lakes, NJ) agar, respectively. To determine colony-forming units (CFU), wastewater samples were serially diluted in sterile phosphate-buffered saline (PBS) and spiral plated in triplicate on the corresponding plates. All incubations were done aerobically, at temperatures and times as follows: *E. coli* at 37 °C for 24 h; fecal coliforms at 44.5 °C for 24 h; and *Enterococcus* sp. at 37 °C for 48 h. Due to the variability in suspended solids from sample to sample, all CFU were adjusted per gram of volatile suspended solids (CFU/gVSS) prior to log10 normalization for statistical analysis purposes.

2.4. DNA Extraction

A total of 2 mL of each wastewater sample was set aside for DNA extraction using a Qiagen Allprep PowerViral DNA/RNA Kit (Qiagen Sciences Inc, Germantown, MD). A total of 200 µL of each sample was used per extraction using protocol modifications designed to extract DNA only (no RNA) from wastewater and manure samples (i.e., no β-mercaptoethanol added to buffer solutions, and DNase steps skipped). The remaining wastewater samples were archived at −80 °C. DNA purity was determined by absorbance at 260 and 280 nm using a spectrophotometer, and quantity was determined fluorometrically using a Qubit dsDNA assay kit (ThermoFisher Scientific, Waltham, MA, USA).

2.5. Deep 16S sequencing and Analysis

Deep 16S sequencing of the V3–V4 region was performed on an Ion Torrent PGM sequencer, using a 316v2 chip and Hi-Q View sequencing reagents. Barcoded bacterial 341F (5′-CCTAYGGGRBGCASCAG-3′) and 806R (5′-GGACTACNVGGGTWTCTAAT-3′), and archaeal ARC787F (5′-ATTAGATACCCSBGTAGTCC-3′) and ARC1059R (5′-GCCATGCACCWCCTCT-3′) primers were designed according to the Ion Amplicon Library Preparation Fusion Methodology (Life Technologies, Carlsbad, CA, USA), and included 12 base pair error-correcting Golay barcodes [14]. Primers were synthesized by Integrated DNA Technologies (IDT, Coralville, IA, USA). Individual amplicon libraries for bacterial and archaeal community analysis were generated by PCR using the following protocol: activation of enzyme at 94 °C for 3 min, followed by 40 cycles of denaturation at 94 °C for 30 s, annealing at 58 °C for 30 s, and elongation at 68 °C for 45 s. Amplicons were quantified using a Qubit Fluorometer (Invitrogen, Carlsbad, CA, USA), quality controlled on an Agilent 2100 BioAnalyzer (Agilent, Santa Clara, CA, USA), and amplicons from each sample were mixed in equimolar amounts prior to sequencing.

Full-length forward- and reverse-direction sequencing libraries for each sample were verified for read quality, assembled, and analyzed using the Ion Reporter v5.10 platform and metagenomics workflow (ThermoFisher Scientific, Waltham, MA, USA). Operational taxonomic units (OTUs) were assigned at a cutoff of 97% for genus identification using the curated MicroSEQ 16S v2013.1 and Greengenes v13.5 [15] reference libraries. For determination of substrate utilization for methanogenesis, archaeal families were sorted into three groups: acetoclastic, hydrogenotrophic, and methylotrophic. *Methanosaetaceae*, *Methanosarcinaceae*, and *Methermicoccaceae* were classed as acetoclastic. The *Methanomassiliicoccaceae* was classed as methylotrophic. The remaining were classed as hydrogenotrophic.

2.6. Statistical Analysis

All statistical analyses were performed using Minitab 17 (Minitab Incorporated, State College, PA). Analysis variance (ANOVA) was conducted using the general linear model, with pairwise comparisons using Fisher's Least Square Difference Method (LSD); difference between any two means was considered significant with $p < 0.05$. Regressions of bacterial CFUs (log10 CFU/gVSS) with environmental variables were performed using a linear model. Non-metric multidimensional scaling (NMS) of microbial community population data was performed in PC-Ord v.6 (MJM Software Design, Gleneden Beach, OR, USA).

3. Results and Discussion

3.1. Wastewater Characteristics

Wastewater physicochemical characteristics are summarized in Table 1. Results are consistent with the wastewater properties of other swine-studied anaerobic lagoons [8,9]. Seasonal effects were documented for temperature, with summer samples showing significantly higher ($p < 0.05$) temperatures than other samples, and dissolved oxygen, with spring samples (0.74 ± 0.07 SE mg L^{-1}) demonstrating significantly higher dissolved oxygen (DO) levels ($p < 0.05$) than fall samples (0.37 ± 0.01 SE mg L^{-1}). Sampling location (i.e., lagoon vs house) was significant ($p < 0.05$) for pH, temperature, TSS/VSS, and TKN. Lastly, when examining the lagoons, the type of system (i.e., open versus covered) demonstrated significant differences ($p < 0.05$) for pH and TKN. Covered lagoons (1009 ± 24 SE mg L^{-1}) have more than double the TKN of open lagoons (473 ± 44 SE mg L^{-1}), this may be explained by the TKN levels originating in the animal houses that feed into those lagoons. TKN in the house feeding into the covered lagoon had mean TKN levels of 3632 ± 339 SE mg L^{-1}, while the house feeding into the open lagoon had mean TKN levels of 1306 ± 211 SE mg L^{-1}. These results differ from those of VanderZaag et al. [4], which showed no significant difference between TKN levels of a covered lagoon system when compared to an open control lagoon system filled from the same wastewater source.

Table 1. Fisher pairwise comparisons of lagoon and house physicochemical characteristics.

Season	System	Site	pH	DO	Temp	Total Suspended Soils	Volatile Suspended Solids	Total Kjeldahl Nitrogen
				mg L^{-1}	°C		mg L^{-1}	
Spring	Open	Lagoon	8.11 [a1]	0.60 [bcde]	20.5 [i]	189 [e]	166 [d]	630 [gh]

[1] Means followed by the same letter are not significantly different at $p = 0.05$.

Analysis of cation and anion concentrations of swine wastewater are found in Table 2. While NO_2-N and NO_3-N were assayed, they were below detectable limits throughout the course of the study. No significant seasonal effects were noticed amongst samples, although sampling location was significant for all cations and anions detected, with significantly increased concentrations ($p = 0.05$) in swine houses. When examining the lagoon system used, SO_4-S was significantly higher ($p < 0.05$) in the open lagoons (30.8 ± 4.9 SE mg L^{-1}) as compared to covered lagoons (4.5 ± 0.6 SE mg L^{-1}); conversely, NH_4-N was significantly increased ($p < 0.05$) in covered lagoons (858 ± 11 SE mg L^{-1}) as compared to open lagoons (379 ± 38 SE mg L^{-1}). As already noted for TKN, the higher NH_4-N concentrations in the covered lagoon most likely were a consequence of higher N loading in the more concentrated wastewater derived from the house feeding into it.

Table 2. Fisher pairwise comparisons of lagoon and house anions and cations (mg L^{-1})[1].

[1] F, NO_2-N, and NO_3-N were below detectable limits (<2 mg/L); [2] Means followed by the same letter are not significantly different at $p = 0.05$; [3] BDL, below detectable limits (<2 mg/L).

3.2. Pathogen Reduction

Fecal coliforms, *E. coli*, and *Enterococcus* sp. were identified and enumerated in all samples (Supplementary Table S1). The highest rates of enumeration were found in animal houses, and at no point were CFU rates higher in a lagoon when compared to its respective house.

3.2.1. House vs. Lagoon

Comparisons between animal houses and their respective lagoon can be found in Figure 1. Differences in bacterial levels (Figure 1; Supplementary Table S1) between the houses and wastewater lagoons demonstrate that transfer of wastewater from the houses to the lagoons results in significant reductions to all three bacterial indicators measured. Given that all CFUs were adjusted based on volatile suspended solid levels, these reductions are independent of the solids concentration of the wastewater. Significant relationships ($p < 0.05$) were observed between fecal coliforms, *E. coli*, and *Enterococcus* sp. with pH, N (TKN; NH_4), chloride, K, and Na. These chemical properties demonstrated significantly higher concentrations in the houses as compared to the lagoons (Tables 1 and 2). These results are supported by Viancelli et al. [16] that similarly documented reductions in total coliforms and *E. coli* after movement of swine manure to anaerobic lagoons, a result that may be due to reductions in organic material leading to increased competition for resources.

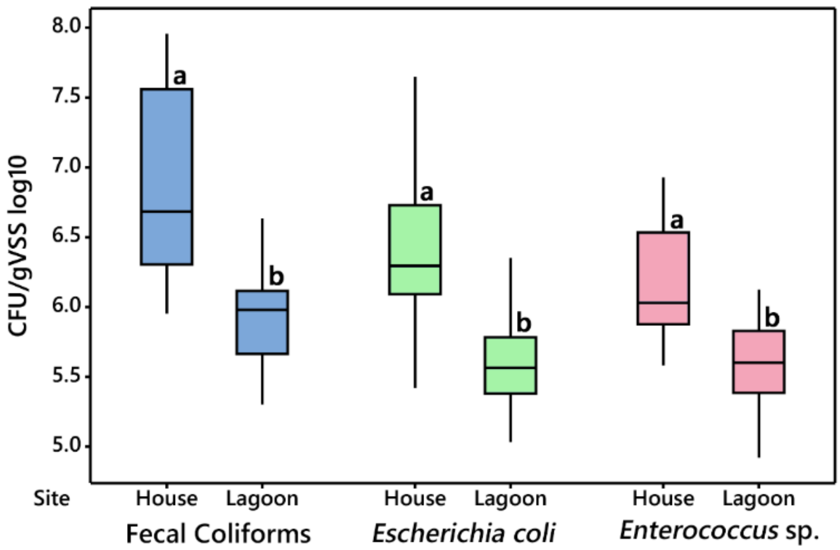

Figure 1. Comparison of colony-forming units (CFU)/gVSS $\log_{10}$ values between animal houses and lagoons, for fecal coliforms (blue), Escherichia coli (green), and Enterococcus sp. (red). Means followed by the same letter are not significantly different at $p = 0.05$.

3.2.2. Open vs. Covered Lagoon

Comparisons between open and covered lagoons can be found in Figure 2. Fecal coliform densities in the open lagoon ranged from 5.41 to 6.35 CFU/gVSS $\log_{10}$ to 5.73 to 7.04 CFU/gVSS $\log_{10}$ in the covered lagoon. *E. coli* ranged from 5.13 to 5.83 CFU/gVSS $\log_{10}$ in the open lagoon, to 5.34 to 6.47 CFU/gVSS $\log_{10}$ in the covered lagoon. *Enterococcus* sp. counts ranged from 4.88 to 5.94 CFU/gVSS $\log_{10}$ in the open lagoon, to 5.44 to 5.86 CFU/gVSS $\log_{10}$ in the covered lagoon. The CFU counts are listed in Supplementary Table S1.

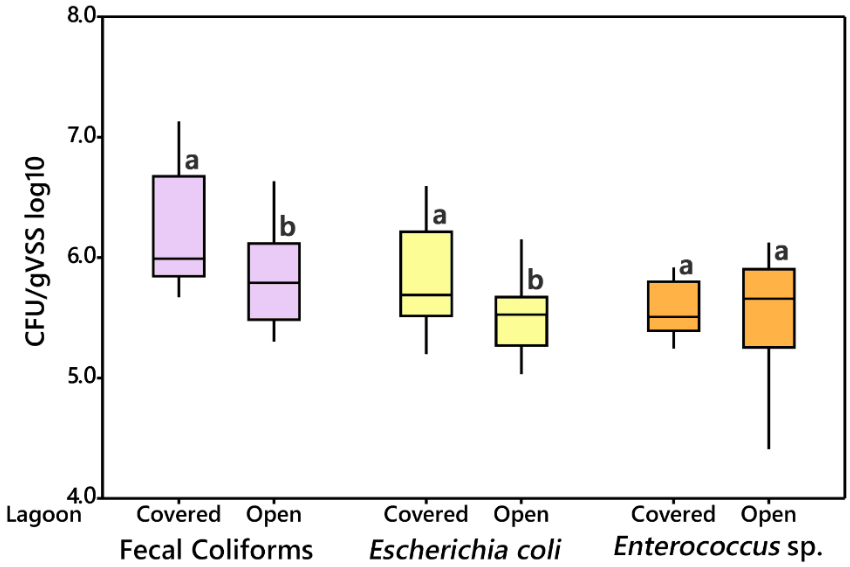

Figure 2. Comparison of CFU/gVSS $\log_{10}$ values between the covered and open lagoon, for fecal coliforms (blue), Escherichia coli (green), and Enterococcus sp. (red). Means followed by the same letter are not significantly different at $p = 0.05$.

Analysis of variance examining seasonal, site specific, and sampling location effects demonstrated that all three variables play significant roles in pathogen reduction. While seasonal patterns emerged in CFU counts for all three measured bacterial populations, with highest densities tending to be in the summer samplings, and the lowest densities observed during the winter, only fecal coliform counts demonstrated a significant relationship with temperature (r^2 = 0.485, p = 0.003). Examination between pathogen counts and physicochemical characteristics revealed significant relationships between pH and fecal coliforms (r^2 = 0.404, p = 0.008), *E. coli* (r^2 = 0.577, p = 0.001), and *Enterococcus* sp. (r^2 = 0.248, p = 0.05). For *E. coli*, significant relationships between TKN (r^2 = 0.261, p = 0.04), chloride (r^2 = 0.471, p = 0.003), potassium (r^2 = 0.272, p = 0.04), and sodium (r^2 = 0.394, p = 0.009) were also identified. No further influences on bacterial counts by physicochemical parameters were noted.

Additionally, for the lagoons, it appears that the addition of a cover had a significant impact on fecal coliform and *E. coli* levels, resulting in increased CFUs. It is possible that these higher bacterial densities in the covered lagoon may be due to solar radiation. Reductions in solar radiation have been demonstrated to result in increased bacterial counts [8], and may be a contributing factor in the increased bacterial counts in the studied covered lagoon. For the open lagoon, pH was significantly higher as compared to its covered counterpart (Table 1), and Curtis et al. identified that pH levels over 7.5, combined with sunlight, reduced fecal coliform levels [17]. *E. coli* thrive in a relatively neutral pH range, up to around pH 7.75, after which they begin to become stressed [18]. It should be noted that the open lagoon had pH ranges at or above this 7.75 pH value and could be contributing to the lower CFU counts observed. While increased pH may contribute to reductions in bacterial pathogens, it also results in increased ammonia volatilization. To counter this phenomenon, acidification is employed to reduce ammonia emissions from swine wastewater [19], and if modest reductions in pH (by two to three units) can also achieve significant pathogen reduction levels, it may provide producers with an additional means to reduce environmental impacts. This was demonstrated by Odey et al. who utilized lactic acid fermentation to inactivate fecal coliforms in human fecal sludge by reducing the pH to 3.9 [20]. Additionally, *E. coli* is considered a major reservoir of antibiotic resistance genes [21], so any employable means to reduce *E. coli* CFUs could prove to be a treatment capable of disrupting the cycle of antimicrobial resistance of animal origin.

3.3. Microbial Community Composition

Microbial community analysis using non-metric multidimensional scaling (Figures 3 and 4) revealed significant differences in the bacterial and archaeal population structures of the open and covered systems. While the samples taken from the lagoon and house of the open system showed a high degree of similarity, as evidenced by their overlapping groupings (Figures 3 and 4), the lagoon and house from the covered system neither overlapped with the open system, or each other. This pattern was similar in both the bacterial and archaeal NMS plots, and indicate larger differences in the population structure of the covered system. A number of environmental relationships correlate with these differences for bacterial populations (Figure 3), and are as follows: along the first axis, pH (r^2 = 0.354), TSS/VSS (r^2 = 0.467), TKN (r^2 = 0.513), K (r^2 = 0.532), and Na (r^2 = 0.338); and along the second axis, chloride (r^2 = 0.316), pH (r^2 = 0.266), and Na (r^2 = 0.258). Both TKN and suspended solids have been previously demonstrated to correlate with bacterial community structure [22]. Archaeal populations (Figure 4) correlated with several environmental variables along the first axis, Ca (r^2 = 0.468), K (r^2 = 0.468), and TKN (r^2 = 0.422). Calcium has been demonstrated to impact anaerobic digestion at concentrations as low as 100 mg L^{-1} [23], while potassium has been reported as toxic to acetate-utilizing methanogens [24].

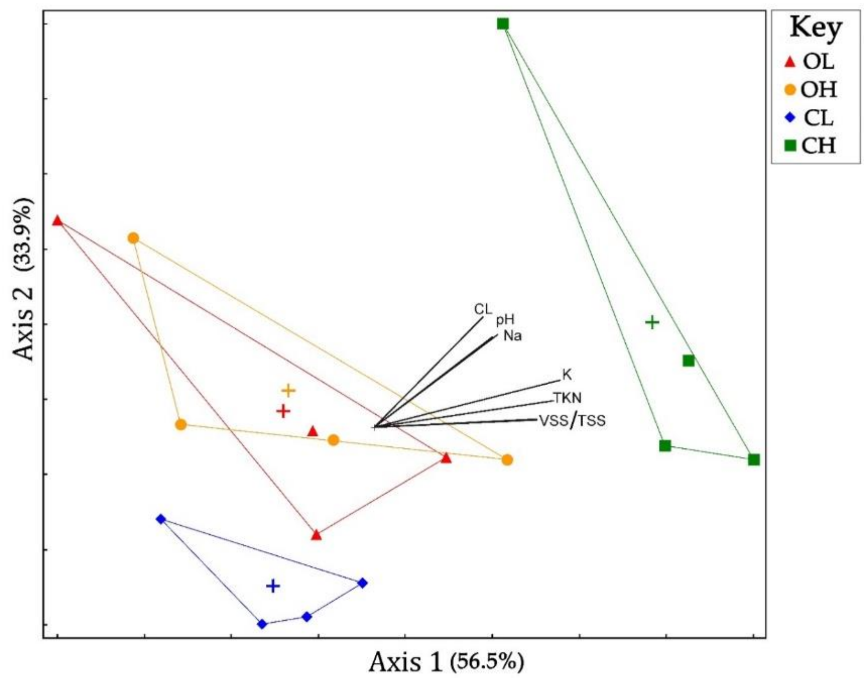

Figure 3. Non-metric multidimensional scaling (NMS) plot of microbial communities (based on relative abundances of bacterial families identified). Only explanatory environmental variables with a combined $r^2 > 0.45$ for both axes are included as vectors. Centroid for each group is marked by (+). O = open; C = cover; L = lagoon; H = house.

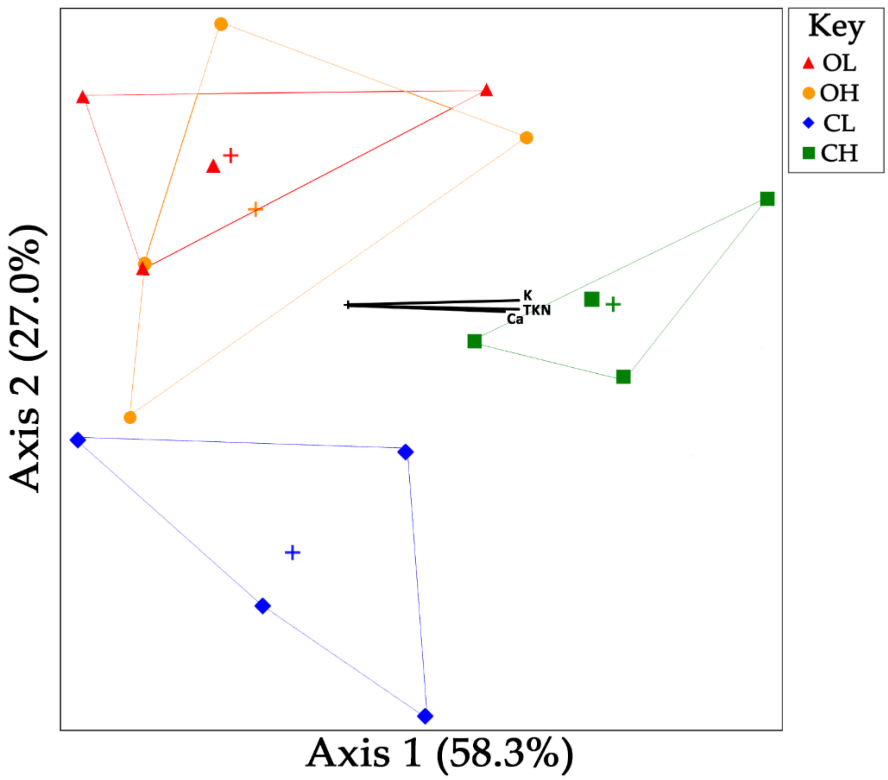

Figure 4. Non-metric multidimensional scaling (NMS) plot of archaeal communities (based on relative abundances of archaeal families identified). Only explanatory environmental variables with a combined $r^2 > 0.45$ for both axes are included as vectors. Centroid for each group is marked by (+). O = open; C = cover; L = lagoon; H = house.

The bacterial populations of both the covered and open lagoons demonstrate similarity to lagoons previously reported [22,25]. Of the 231 families identified in the 16 waste samples collected over the course of the study, using the universal bacterial primer set, only 22 bacterial families (9.5%) were represented in all 16 samplings. However, these bacterial families account for an average of 62.2% (± 4.2% SE; range 33.1% to 86.3%) of the OTU sequences classified in each sample (Figure 5; Supplementary Material Table S2). A total of 34 (14.7%) bacterial families were represented in all 8 lagoon samplings (see Supplementary Material Table S2). Of these 34 families, several were previously reported as being ubiquitous in analyzed anaerobic swine lagoons [22], such as *Ruminococcaceae*, *Chlostridiaceae*, *Lachnospiraceae*, *Peptostreptococcaceae*, and *Synergistaceae*. One noticeable difference is that while previous studies demonstrated high levels of *Chromatiaceae*, in this particularly study, this family went unidentified in the covered lagoon samples. The *Chromatiaceae*, also referred to as purple sulfur bacteria, rely primarily on phototrophic growth [26], and their growth in open lagoons is often quite evident, particularly when the lagoons adopt a purplish to red hue [27]. This family accounted for approximately half the OTU sequences for the open lagoon in the spring (56.3%) and summer (55.0%) samplings (see Figure 5). The greenish tint of the covered lagoon samples compared to the purplish tint of the open lagoon samples during sampling lent support to these findings. These findings potentially correlate with the significantly higher levels of SO_4-S in the open lagoons as compared to the covered lagoons, due to sulfate oxidation by purple sulfur bacteria [28]. These results are similarly reflected in the identification of *Desulfomicrobiaceae*, a family of sulfate reducers [29], only in samples taken from the open lagoon system. Additional sulfate reducers belonging to the families *Desulfobacteraceae* (8 of 8), *Desulfobulbaceae* (8 of 8), and *Desulfovirbrionaceae* (7 of 8) were found in a majority of all lagoon samples [30]. Additionally, while primers 341F and 806R were designed as bacterial-specific, they have been known to pick up archaeal sequences [31]. This led to the identification of the *Methanobacteriaceae*, an archaeal family of hydrogenotrophic (H_2/CO_2) methane (CH_4) producers, and the *Methanosaetaceae*, a family of archaeal acetoclastic methanogens, both of which were found in all 16 samples. The identification of these two archaeal families is of particular importance given the interest of the pork industry to use impermeable lagoon covers to trap methane for energy production in their "manure-to-energy" program initiative [32].

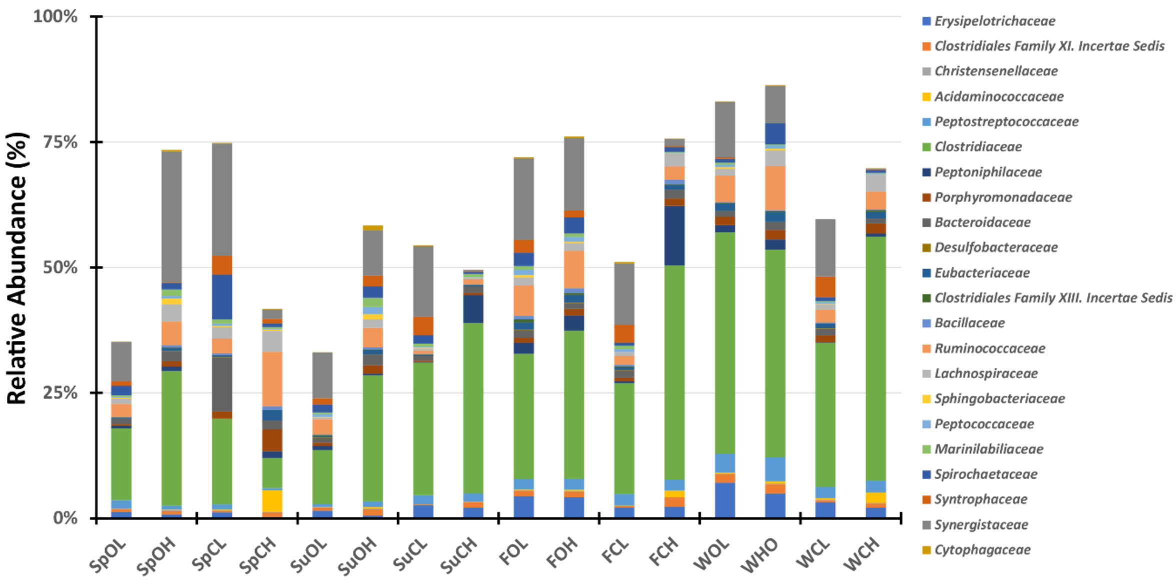

Figure 5. Bacterial community structure, shown as relative abundance. The legend listing selected bacterial families is displayed to the right of the chart. Samples are distinguished by columns. Sp = spring; Su = summer; F = fall; W = winter; O = open; C = cover; L = lagoon; H = house.

A closer look at the archaeal community composition (Figure 6; Supplementary Table S3), using archaeal-specific primers confirmed the presence of OTUs classified to *Methanobacteriaceae* and *Methanosaetaceae,* as well OTUs classified to five other methanogenic archaeal families, identified in all 16 samples: *Methanospirillaceae*, *Methanomicrobiaceae*, *Methanosarcinaceae*, *Methanocorpusculacea*, and the methylotropic *Methanomassiliicoccaceae.* The family *Thermofilaceae* was also identified in all 16 samples, bringing the number of families found in all 16 samples up to eight. When looking at just the eight lagoon samples, a total of 11 families were identified, and include the above-mentioned eight, as well as *Methanpyraceae*, *Methanocalculaceae*, and *Thermococcaceae*. The remaining classified OTUs were assigned to families not found in all samples, and typically found in low percentages (often less than 1%). Examination of archaeal families in relation to sampling source reveals a number of associations (Supplementary Figure S4). For example, both the *Methanosaetaceae* and *Methanoregulaceae* associate closely with the closed lagoon samples, while the *Methanospirillaceae*, *Methanocorpusculaceae*, and *Methanopyraceae* closely associate with the open lagoons and houses. The *Methanobacteriaceae,* on average the most identified archaeal family across all samples (Mean: 34.5%; SE: ± 6.0%), associate most closely with the closed house samples.

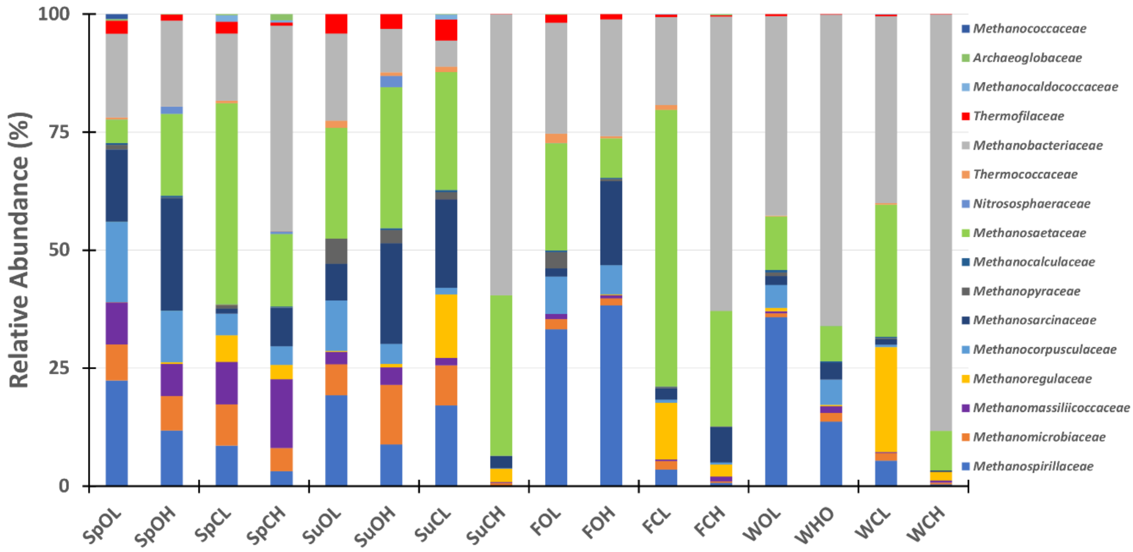

Figure 6. Archaeal community structure, shown as relative abundance. The legend listing specific families is displayed to the right of the chart. Samples are distinguished by columns. Sp = spring; Su = summer; F = fall; W = winter; O = open; C = cover; L = lagoon; H = house.

Of all the archaeal families identified, a majority of the OTUs corresponded to three, *Methanospirillaceae*, *Methanobacteriaceae*, and *Methanosaetaceae*, with the first two classified as being hydrogenotrophic methanogens, and the third classified as acetoclastic methanogens. Overall, our results demonstrate that while hydrogenotrophic methanogens make up the largest segment of methanogens in the two systems studied, acetoclastic methanogens also make up a sizeable portion of the overall methanogenic community. Seasonally, methylotrophic methanogenic OTUs were highest in the spring, acetoclastic methanogenic OTUs were highest in the summer and fall, and hydrogenotrophic methanogenic OTUs peaked in the winter (Figure 7). These OTUs point to both the open and covered lagoons as having significant potential for methane production—a process likely supported by the anaerobic conditions of the lagoons and houses, as indicated by low DO measurements (Table 1).

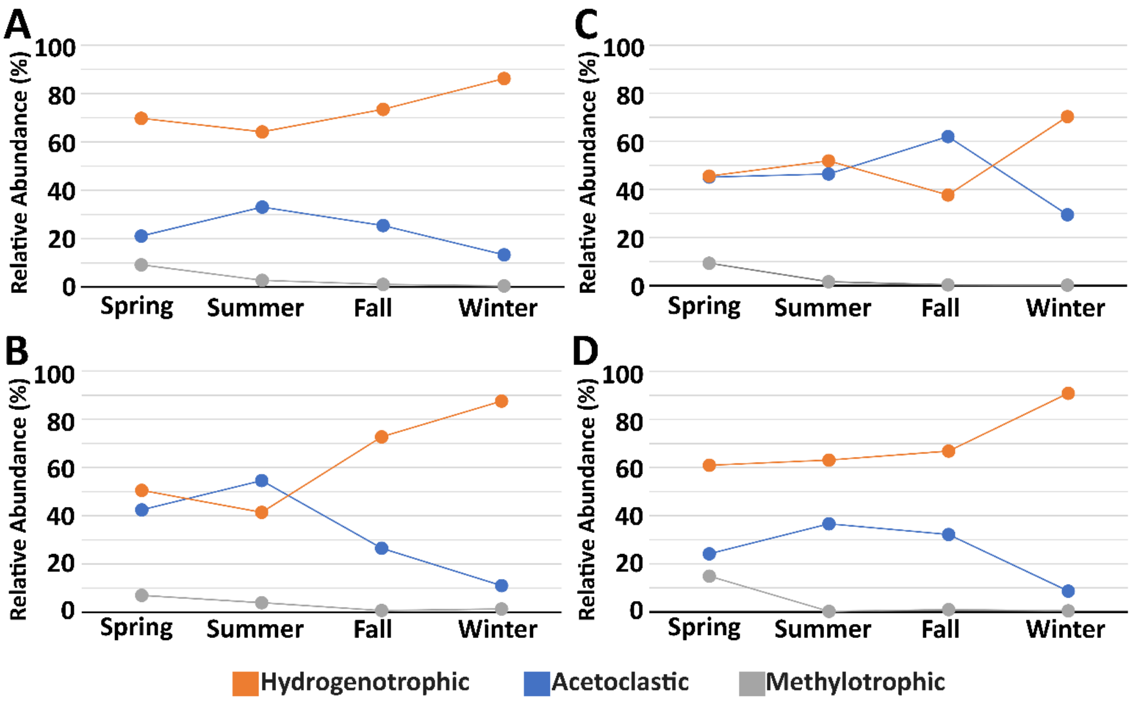

Figure 7. Relative abundance of classified operational taxonomic units (OTUs) potentially involved in methanogenic pathways. (**A**) Open Lagoon; (**B**) Open House; (**C**) Covered Lagoon; (**D**) Covered House.

4. Conclusions

While synthetic covers provide an option for swine producers to reduce odor emissions from anaerobic lagoons, there have been few studies focused on analyzing the biological responses to the microclimates generated at the cover/lagoon interface. Several wastewater physicochemical characteristics demonstrated seasonal variation, while additional differences were seen in comparisons by sampling site (lagoon vs. house) and by the type of lagoon system employed (open vs. covered). Fecal coliforms, *E. coli*, and *Enterococcus* sp., all demonstrated significant relationships with pH. When looking at fecal coliforms and *E. coli*, significant differences in CFU were identified seasonally, by sampling site, and type of lagoon system. Enterococcus sp. were unaffected by the lagoon system employed.

Microbial community analysis identified over 200 bacterial families, with 10.4% represented in all 16 samples, and an additional 19 archaeal families were identified, with eight represented by OTUs in all 16 samples. Evidence for the potential for sulfate-reduction, acetoclastic, hydrogenotrophic, and methylotrophic methanogenesis in the lagoons was demonstrated by the identification of microbial populations responsible for those processes across all lagoon samples. The in-depth sequence analysis of methanogenic communities indicates the potential for—or presence of—methane production from these anaerobic lagoons, although inhibitory concentrations of several nutrients such as Ca and K, need to be accounted for if lagoons are converted for biogas capture with impermeable covers.

Supplementary Materials: The following are available online at http://www.mdpi.com/2076-3298/6/8/91/s1, Figure S4: NMS ordination plot, as seen in Figure 4, demonstrating lagoon and house community structure in relation to individual archaeal family relative abundances, Table S1: Fisher pairwise comparisons of lagoon and house pathogen levels (CFU/gVSS log10), Table S2: Relative abundances of OTUs identified using universal bacterial primer set, presented as relative abundances (%) Only bacterial families are counted in Figure 5 and discussion involving bacterial family identification, Table S3: Relative abundances of OTUs identified using archael primer set, presented as relative abundances (%).

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY
WASHINGTON, D.C. 20460

EXTERNAL CIVIL RIGHT COMPLIANCE OFFICE
OFFICE OF GENERAL COUNSEL

January 18, 2017

Dear Colleague:

All applicants for and recipients of EPA financial assistance[i] have an affirmative obligation to comply with federal civil rights obligations.[ii] EPA's External Civil Rights Compliance Office (formerly Office of Civil Rights (OCR), within the Office of General Counsel, (ECRCO),[iii] also has a duty to ensure that applicants for and recipients of federal financial assistance ("EPA recipients") comply with federal civil rights laws in their programs or activities that apply for and receive federal financial assistance (including subrecipients of EPA financial assistance). All persons, regardless of race, color, national origin, age, disability or sex, are entitled to receive the benefits of and participation in the programs and activities of EPA recipients without discrimination.[iv] EPA ensures compliance with federal civil rights laws in several ways – through complaint investigations, compliance reviews, technical assistance, community engagement, and policy formulation.[v]

Strong civil rights compliance and enforcement are essential. Furthermore, enforcement of civil rights laws and environmental laws are complementary and can be achieved in a manner consistent with sustainable economic development and that ensures the protection of human health and the environment.

The purpose of this letter is to introduce the **U.S. EPA's External Civil Rights Compliance Office Compliance Toolkit ("Toolkit")**, which is a clarification of existing law and policy intended to provide guidance to promote and support EPA recipients' compliance with federal civil rights laws. With this letter, we are issuing **Chapter 1 of the Toolkit**, which highlights the application of the federal civil rights laws and the legal standards used in investigating and resolving civil rights complaints at EPA. In addition, we are including a companion **Frequently Asked Questions (FAQs)** document to assist in responding to potential questions addressed in Chapter 1.

What is the purpose of the Toolkit?

The overall purpose of the Toolkit is to support and advance our external civil rights compliance and enforcement efforts. We have now finalized the External Civil Rights Compliance Office Strategic Plan for FY 2015-2020 ("Strategic Plan") to promote mission-critical program accountability through measurable goals.[vi] The Strategic Plan is one part of a multi-prong approach to prompt, effective and efficient docket management that includes a Case Resolution Manual together with a Strategic Case Assessment Management Plan,[vii] and deployment of EXCATS,[viii] which is ECRCO's internal docket management system. The Toolkit is previewed in the Strategic Plan to support EPA's goals of enhancing its strategic docket management and developing a proactive compliance program.[ix]

We designed the Toolkit to help you comply with your federal civil rights obligations. The information, guidance, and examples or hypotheticals are intended to assist you in conducting your programs and activities in a nondiscriminatory manner. We created the Toolkit with an understanding that you build a civil rights program around a legal analytical framework that depends upon the legal standards pursued and the nature of facts gathered, such as, direct or indirect/circumstantial evidence. In other words, we recognize that a "one-size-fits-all" approach to civil rights compliance may not adequately address all of your needs. You may have different civil rights concerns in communities within your jurisdiction, different amounts of resources, and different organizational structures.

The Toolkit does not address every scenario that may arise under federal civil rights laws; nor does the Toolkit come with a guarantee that you will not receive a civil rights complaint if you abide by and implement the guidance contained within it. The Toolkit may not apply in a particular situation based upon the circumstances, and EPA retains discretion to adopt approaches on a case-by-case basis that differ from those discussed in the Toolkit where appropriate. Importantly, the Toolkit does not change in any way, your obligation to comply with applicable environmental laws or create any new legal rights or responsibilities.

The Toolkit is a "living document." EPA may revise it from time to time to make improvements, reflect emerging case law or reflect policy changes in EPA's approach to implementing federal civil rights laws.

In introducing the Toolkit, EPA affirms its commitment to work with EPA recipients to achieve their compliance with federal civil rights laws; that is, for recipients to operate and administer their programs and activities in a manner free from discrimination. We look forward to issuing additional Toolkit Chapters that address other civil rights compliance areas. Please do not hesitate to contact me if you have questions relating to the content of this letter and the Toolkit, or if we can otherwise assist you in your federal civil rights compliance efforts.

Sincerely,

Lilian S. Dorka
Director
EPA External Civil Rights Compliance Office
Office of General Counsel

[i] "Applicant means any entity that files an application or unsolicited proposal or otherwise requests EPA assistance." 40 C.F.R. § 7.25. Generally, a recipient means an entity that receives financial assistance from EPA. EPA regulations define recipient as follows:

> Recipient means, for the purposes of this regulation, any State or its political subdivision, any instrumentality of a State or its political subdivision, any public or private agency, institution, organization, or other entity, or any person to which ***Federal financial assistance is extended directly or through another recipient***, including any successor, assignee, or transferee of a recipient, but excluding the ultimate beneficiary of the assistance. 40 C.F.R. § 7.25 (emphasis added).

[ii] *See, e.g.*, http://apply07.grants.gov/apply/forms/sample/SF424B-V1.1.pdf.

[iii] This document generally references EPA throughout. Within EPA, ECRCO is the primary office that enforces federal civil rights laws.

[iv] EPA enforces and ensures compliance with federal civil rights laws that together prohibit discrimination on the bases of race, color, national origin (including limited-English proficiency), disability, sex and age. The five federal civil rights laws that we enforce are as follows: Title VI of the Civil Rights Act of 1964 (42 U.S.C. §§ 2000d *et seq.*); Title IX of the Education Amendments of 1972, as amended (20 U.S.C. §§ 1681 *et seq.*); Section 504 of the Rehabilitation Act of 1973, as amended (29 U.S.C. § 794); Age Discrimination Act of 1975 (42 U.S.C. §§ 6101 *et seq.*); and the Federal Water Pollution Control Act Amendments of 1972, Pub. L. 92-500 § 13, 86 Stat. 903 (codified as amended at 33 U.S.C. §§ 1251 *et seq.* (1972)). *See also* 40 C.F.R. Parts 5 and 7 (EPA's nondiscrimination regulations).

[v] EPA is required to seek the cooperation of applicants and recipients in securing compliance EPA's nondiscrimination regulations and is available to provide help in that regard. 40 C.F.R. § 7.105. Members of the public who believe that he or she or a specific group of persons have been discriminated against may file a complaint alleging discrimination in violation of federal civil rights laws. 40 C.F.R. § 7.120. In such cases, EPA is authorized to investigate and resolve these complaints, as a part of its responsibility to develop and administer a means of ensuring compliance with federal civil rights laws. *See Alexander v. Sandoval*, 532 U.S. 275, 293 (2001) (holding that there is no private right of action to enforce disparate impact regulations promulgated under Title VI). EPA is also authorized to initiate compliance reviews to determine compliance with the civil rights laws enforced by EPA. *See* 40 C.F.R. §§ 7.110, 7.115. This regulatory provision is incorporated by reference in the regulations implementing other statutes enforced by ECRCO. *See* 40 C.F.R. § 5.605. *See also* External Civil Rights Compliance Office Strategic Plan (2015-2020), at 12 (https://www.epa.gov/sites/production/files/2017-01/documents/final_strategic_plan_ecrco_january_10_2017.pdf).

[vi] *See* Strategic Plan at 5.

[vii] See ECRCO Case Resolution Manual (https://www.epa.gov/sites/production/files/2017-01/documents/final_epa_ogc_ecrco_crm_january_11_2017.pdf).

U.S. EPA's EXTERNAL CIVIL RIGHTS COMPLIANCE OFFICE COMPLIANCE TOOLKIT

CHAPTER 1: Application of the federal civil rights laws and the civil rights legal standards used in investigating and resolving civil rights complaints at EPA

I. Who is Covered by Federal Civil Rights Laws?

Federal civil rights laws apply to the programs and activities of applicants for and recipients of federal financial assistance.[1] EPA's nondiscrimination regulation[2] defines a "recipient" to include both public[3] and private entities, such as a State, public or private agency, institution, organization, or other entity or person to which Federal financial assistance is extended.[4]

Applicants for EPA financial assistance must submit an assurance with their applications stating that they will comply with federal civil rights laws.[5] In turn, the acceptance of EPA financial assistance is an acceptance of federal civil rights obligations.[6] Some programs and activities involve more than one recipient of EPA financial assistance. The "primary recipient" is the entity that directly receives the federal financial assistance. The primary recipient then may distribute the funds to a separate entity, known as a "subrecipient,"[7] to carry out a program or activity. Whether you are a primary recipient or subrecipient, you are covered by and must conform your

State Department of Environmental Quality (SDEQ) is the recipient of an EPA Brownfields revolving loan fund grant. SDEQ makes a subgrant to one of its counties, Green County, to carry out cleanup activities at a brownfield site within the county. Therefore, Green County is a subrecipient of EPA financial assistance.

conduct to federal civil rights laws.[8] Generally, a recipient can also include one that is a successor (*e.g.* one who legally acquires the rights and obligations of another through merger, buy-out, or other means), transferee (*i.e.*, one to whom a transfer of property has been made), or assignee (*i.e.*, one to whom an assignment – a transfer of rights – is made) of EPA financial assistance.[9]

As a recipient, you also may not release yourself of your federal civil rights obligations by hiring a contractor or agent to perform or deliver assistance to beneficiaries. EPA's regulations clearly state that prohibitions against discriminatory conduct, whether intentional or through facially neutral means that have a disparate impact, apply to a recipient, whether committed directly or through contractual or other arrangements.[10]

II. What is Covered by Federal Civil Rights Laws?

Civil rights laws prohibit discrimination in "any program or activity" of recipients of federal financial assistance. With regard to certain recipients, such as public institutions, the "program or activity" that Title VI covers encompasses the entire institution and not just the part of the institution that receives the federal financial assistance.[11] For example, many state environmental agencies receive federal funding for their regulatory and environmental protection functions. Those agencies should be aware that all actions, not just permitting decisions, taken by state agencies funded by EPA are subject to federal civil rights laws.

Note: If in a given circumstance you are complying with applicable environmental laws, that fact alone does not necessarily mean that you are complying with federal civil rights laws.

It is also important to note that civil rights laws and environmental laws function separately. Thus if, in a given circumstance, you are complying with applicable environmental laws that fact alone does not necessarily mean that you are complying with federal civil rights laws.

III. Analyzing Discrimination Complaints at EPA

Federal civil rights laws prohibit recipients from intentionally discriminating[12] based on race, color, national origin, disability, sex and age. In addition, federal law authorizes federal agencies to enact "rules, regulations, or orders of general applicability" to achieve the law's objectives.[13] The Supreme Court has held that such regulations may validly prohibit practices that have a *disparate impact* on protected groups. This includes policies, criteria or methods of administering programs that are neutral on their face but have the effect of discriminating.[14] Therefore, both intentionally discriminatory actions (as discussed in section A below) and actions that have the effect of subjecting individuals to discrimination (as discussed in section B below) are prohibited.[15]

In 1973, EPA issued such nondiscrimination regulations and revised them in 1984.[16] Under these regulations, recipients of EPA financial assistance are prohibited from taking actions in their programs or activities that are intentionally discriminatory and/or have a discriminatory effect. EPA regulations also prohibit retaliation and intimidation.[17] No applicant, recipient nor other person may intimidate, threaten, coerce, or engage in other discriminatory conduct against anyone because he or she has either taken action or participated in an action to secure rights protected by the non-discrimination statutes that the EPA External Civil Rights Compliance Office (ECRCO) enforces.[18]

A complainant does not have the burden to cite to specific evidence supporting the claim of discrimination, but may wish to provide supporting information for its complaint. A complainant reports what he or she believes is an act violating federal civil rights laws by an EPA recipient of financial assistance. EPA is not in an adjudicatory role, evaluating evidence produced by opposing sides. Rather, if the jurisdictional criteria in 40 C.F.R. § 7.120 have been established (*see also* ECRCO's Case Resolution Manual, at § 2.4),[19] EPA will investigate the allegations about its recipient to determine if a federal civil rights violation has occurred, even absent specific supporting evidence from a complainant.

A. What constitutes intentional discrimination (disparate treatment)?

Federal civil rights laws prohibit recipients from intentionally discriminating in their programs and activities based on race, color, or national origin, disability, age, or sex. This is also referred to as *disparate treatment*. A claim of intentional discrimination alleges that a recipient intentionally treated individuals differently or otherwise knowingly cause them harm because of their race, color, or national origin, disability, age or sex. Intentional discrimination requires a showing that a "challenged action was motivated by an intent to discriminate."[20] Evidence of "bad faith, ill will or any evil motive of the part of the [recipient] is not necessary.[21] Evidence in a disparate treatment case will generally show that the recipient was not only aware of the complainant's protected status, but that the recipient acted, at least in part, because of the complainant's protected status.[22]

Various methods of proof are available to organize evidence to show whether intentional discrimination has occurred. These methods are described briefly below and one or more of these methods may apply to the facts in an investigation. EPA will evaluate the "totality of the relevant facts" including direct, circumstantial, and statistical evidence to determine whether intentional discrimination has occurred.[23]

The clearest case of intentional discrimination involves direct evidence, such as with a policy or decision that is discriminatory on its face. For example, a policy or decision that includes explicit language requiring individuals or groups of one race to be treated differently from individuals or groups of another race – such as explicitly conditioning the receipt of benefits or services on the race, color, or national origin of the beneficiary – evidences an express classification and thus, direct evidence of intentional discrimination. Comments or conduct by decision-makers that express a discriminatory motive, such as racist or similar discriminatory statements or actions, are also direct evidence that can establish intentional discrimination.

Intentional discrimination also occurs when a policy or decision that is facially neutral (for instance, if the language used does not explicitly differentiate between groups on

SDEQ has a policy on its website stating that it provides fair and equal access to its programs and activities and does not discriminate based on race, color, national origin, disability, sex, age or any other protected category under law. SDEQ is aware that individuals in the community with physical mobility disabilities wish to participate in a public meeting regarding a proposed environmental action; however, SDEQ decides to hold the meeting at a facility that is inaccessible to those individuals because the facility is more centrally located for SDEQ staff. This action, though based on an apparently neutral rationale, may constitute a viable intentional disability discrimination.

the basis of race) is administered by the recipient in a discriminatory manner that is motived, at least in part, by the race, color, national origin, disability, age or sex of the alleged victims of discriminatory treatment.

SDEQ determines to hold a public hearing on the permitting of a controversial landfill in Green County Township. SDEQ decides it will hold public hearings in different sections of the Township to cover the two main areas of town. SDEQ holds two hearings in the East Section, a predominantly white part of the Township and one hearing several miles away in the West Section, a predominately African-American part of the Township.

The East Section hearings are held during the daytime, as well as in the evening after work hours, and both hearings provide three-hour time slots for community comments. The hearing that is held in the West Section is held during the day hours only and limits comments from the community to one hour. Armed security officers also attend the West Section hearing.

SDEQ's decision to hold three public hearings appears to reflect an effort to provide access to all areas of the Township. However, the fact that the hearing in the West Section provides significantly less time for community comment and is scheduled and staffed differently than the two hearings in the East Section raises different treatment concerns. Given these facts, SDEQ's actions may result in a viable claim of disparate treatment based on race.

Direct proof of discriminatory motive is often unavailable. However, EPA will consider both direct and circumstantial evidence of discriminatory intent. For example, evidence to be considered may include:

- statements by decision makers,
- the historical background of the events in issue,
- the sequence of events leading to the decision in issue,
- a departure from standard procedure (*e.g.*, failure to consider factors normally considered),
- legislative or administrative history (*e.g.*, minutes of meetings),
- the foreseeability of the consequences of the action,
- a history of discriminatory or segregated conduct.[24]

Finally, disparate treatment can be shown based on evidence of a substantial disparate impact on a protected group, together with other evidence of motive, such as that listed in the bulleted list above, showing that the recipient acted with discriminatory intent.[25]

SDEQ granted a permit to operate a cement grinding facility. Plaintiffs timely filed an intentional discrimination complaint against SDEQ under Title VI. Plaintiffs alleged: 1) the operation of a cement grinding facility would have a disparate impact upon the predominantly minority community of Waterfront South; 2) SDEQ was well-aware of the potential disproportionate and discriminatory burden placed upon that community and failed to take measures to avoid, minimize, or mitigate that burden; and 3) SDEQ had historically engaged in a statewide pattern and practice of granting permits to polluting facilities to operate in communities where most of the residents are African-American and/or Hispanic to a greater extent than in predominately white communities. These facts may establish circumstantial evidence of intentional discrimination.

An offshore oil spill has caused contamination affecting a Vietnamese community in Green County Township. The spill has contaminated the local beachfront and killed fish and waterfowl. SDEQ does not provide initial response to the incident until four days after receiving notification of the spill, exposing the community to health effects, including stinging eyes, rashes, nausea, dizziness, headaches, coughs and other *respiratory symptoms. The response time has resulted in additional adverse impacts, such as economic impact to the local fishing industry and food supply from the fish kill. During the past few years, SDEQ has provided initial response to six other environmental events, including two oil spills within 12 to 24 hours of being notified. Each of those events occurred in areas outside of the Vietnamese community, in areas with a majority white population. These facts may establish a viable discrimination complaint from the Vietnamese community based on disparate treatment.*

Additionally, in situations where direct proof of discriminatory motive is unavailable, EPA may analyze claims of intentional discrimination using the Title VII[26] burden shifting analytic framework established by the Supreme Court in *McDonnell Douglas Corp. v. Green*.[27] This framework is usually most applicable where a complaint is about one or a few individuals, and involves easily identifiable, similarly-situated individuals not in the protected class. To establish a prima facie case of disparate treatment under the *McDonnel Douglas* framework, EPA must determine that:

(1) the complainant is a member of a protected class;

(2) the complainant was eligible for the recipient's program, activity or service;

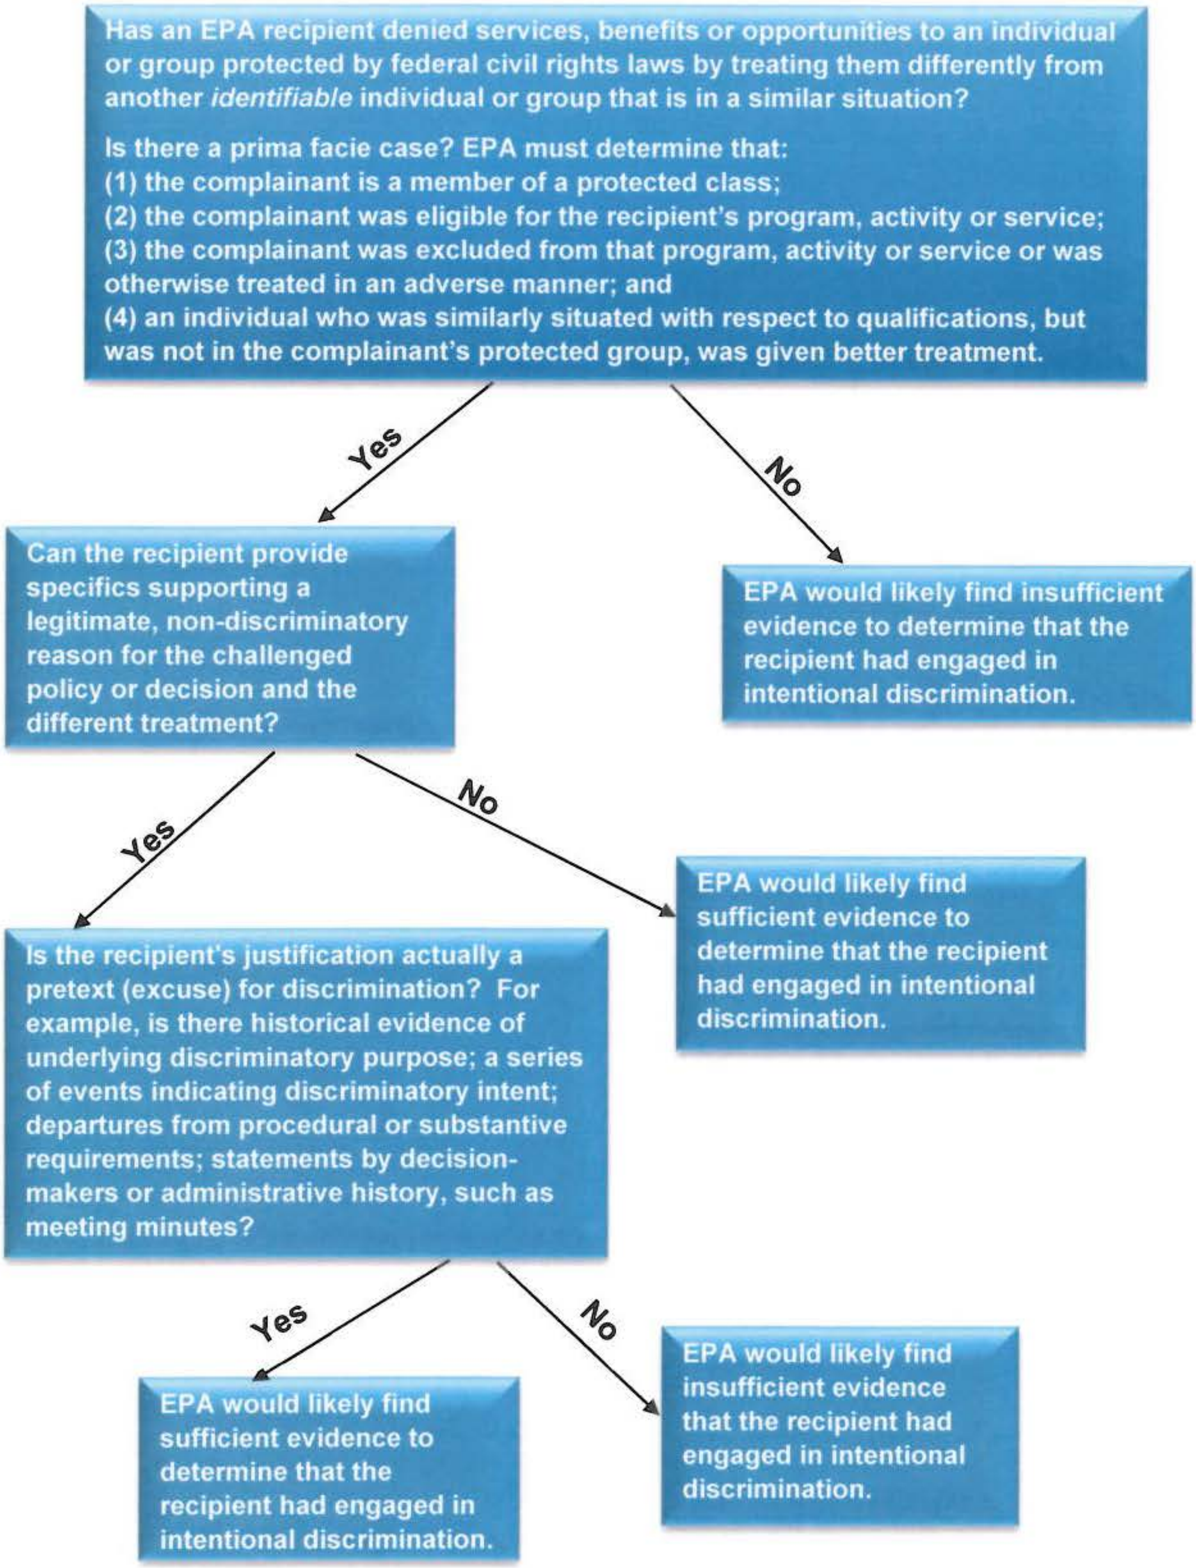
(3) the complainant was excluded from that program, activity or service or was otherwise treated in an adverse manner; **and**

(4) an individual who was similarly situated with respect to qualifications, but was not in the complainant's protected group, was given better treatment.

If a prima facie case of disparate treatment is established, the recipient then has the burden of producing a legitimate, non-discriminatory reason for the challenged policy or decision and the different treatment.[28] If the recipient articulates such a reason, EPA must then determine if there is evidence that the proffered reason is false, *i.e.*, that the nondiscriminatory reason or reasons or the defendant gives for its actions are not the true reasons and are actually a pretext for discriminatory intent.[29]

The chart below illustrates this burden-shifting framework as applied in an administrative complaint.

Intentional Discrimination – McDonnell-Douglas Framework



Similar principles may be used to analyze claims that a recipient has engaged in a *pattern or practice* – or systemic violations – of unlawful discrimination.[30] A showing of more than the mere occurrence of isolated, accidental or sporadic discriminatory acts may prove such claims.[31] In such cases, EPA would look to determine if the recipient regularly engaged in less favorable treatment of a protected group in some aspect of its program as part of its standard policy or operating procedure.[32] A standard policy or operating procedure may be established by a strong statistical disparity that affects a large number of individuals.[33] Statistical evidence can sometimes serve by itself to establish a prima facie case of a pattern or practice of unlawful discrimination[34] but in many cases, statistics are coupled with anecdotal evidence of an intent to treat the protected class unequally.[35] Once the existence of such a discriminatory pattern has been shown, it may be presumed that every disadvantaged member of the protected class was a victim of the discriminatory policy, unless the recipient can rebut the inference that its standard operating policy or operating procedure is discriminatory.[36]

Finally, it is important to understand that establishing that a recipient acted because of race, color, or national origin does not mean that the recipient's actions automatically violate Title VI. Race may be used when a governmental entity has a compelling interest supporting its use, and that use is narrowly tailored to support the stated compelling interest.[37] EPA regulations recognize circumstances under which recipients' consideration of race may be permissible, including providing remedies to those injured by past discrimination.[38]

B. What constitutes disparate impact discrimination?

The second primary method for proving a federal civil rights violation is based on federal nondiscrimination regulations and is known as the *disparate impact* or *discriminatory effects* standard.[39] As noted previously, EPA and other federal agencies are authorized to enact regulations to achieve the law's objectives in prohibiting discrimination. For example, EPA regulations state:

> A recipient shall not use criteria or methods of administering its program or activity which have the effect of subjecting individuals to discrimination. ...[40]

In a disparate impact case, EPA must determine whether the recipient uses a facially neutral policy or practice that has a sufficiently adverse (harmful) and disproportionate effect based on race, color, or national origin. This is referred to as the prima facie case. To establish an adverse disparate impact, EPA must:

(1) identify the specific policy or practice at issue;
(2) establish adversity/harm;[41]
(3) establish disparity;[42] **and**
(4) establish causation.[43]

The focus here is on the consequences of the recipient's policies or decisions, rather than the recipient's intent.[44] The neutral policy or decision at issue need not be limited

SDEQ issued a Clean Air Act permit for the construction and operation of a power station to be located in Green County Township. Although the site for the power station is zoned for industry, the majority of residents in the immediate vicinity of the power station are African-American. If those residents have reason to believe that SDEQ's permitting of the power station will cause them to suffer adverse health impacts at comparatively higher rates than other communities without a significant African-American population, then this may potentially raise a viable disparate impact claim and provide a reason to file a federal civil rights complaint.

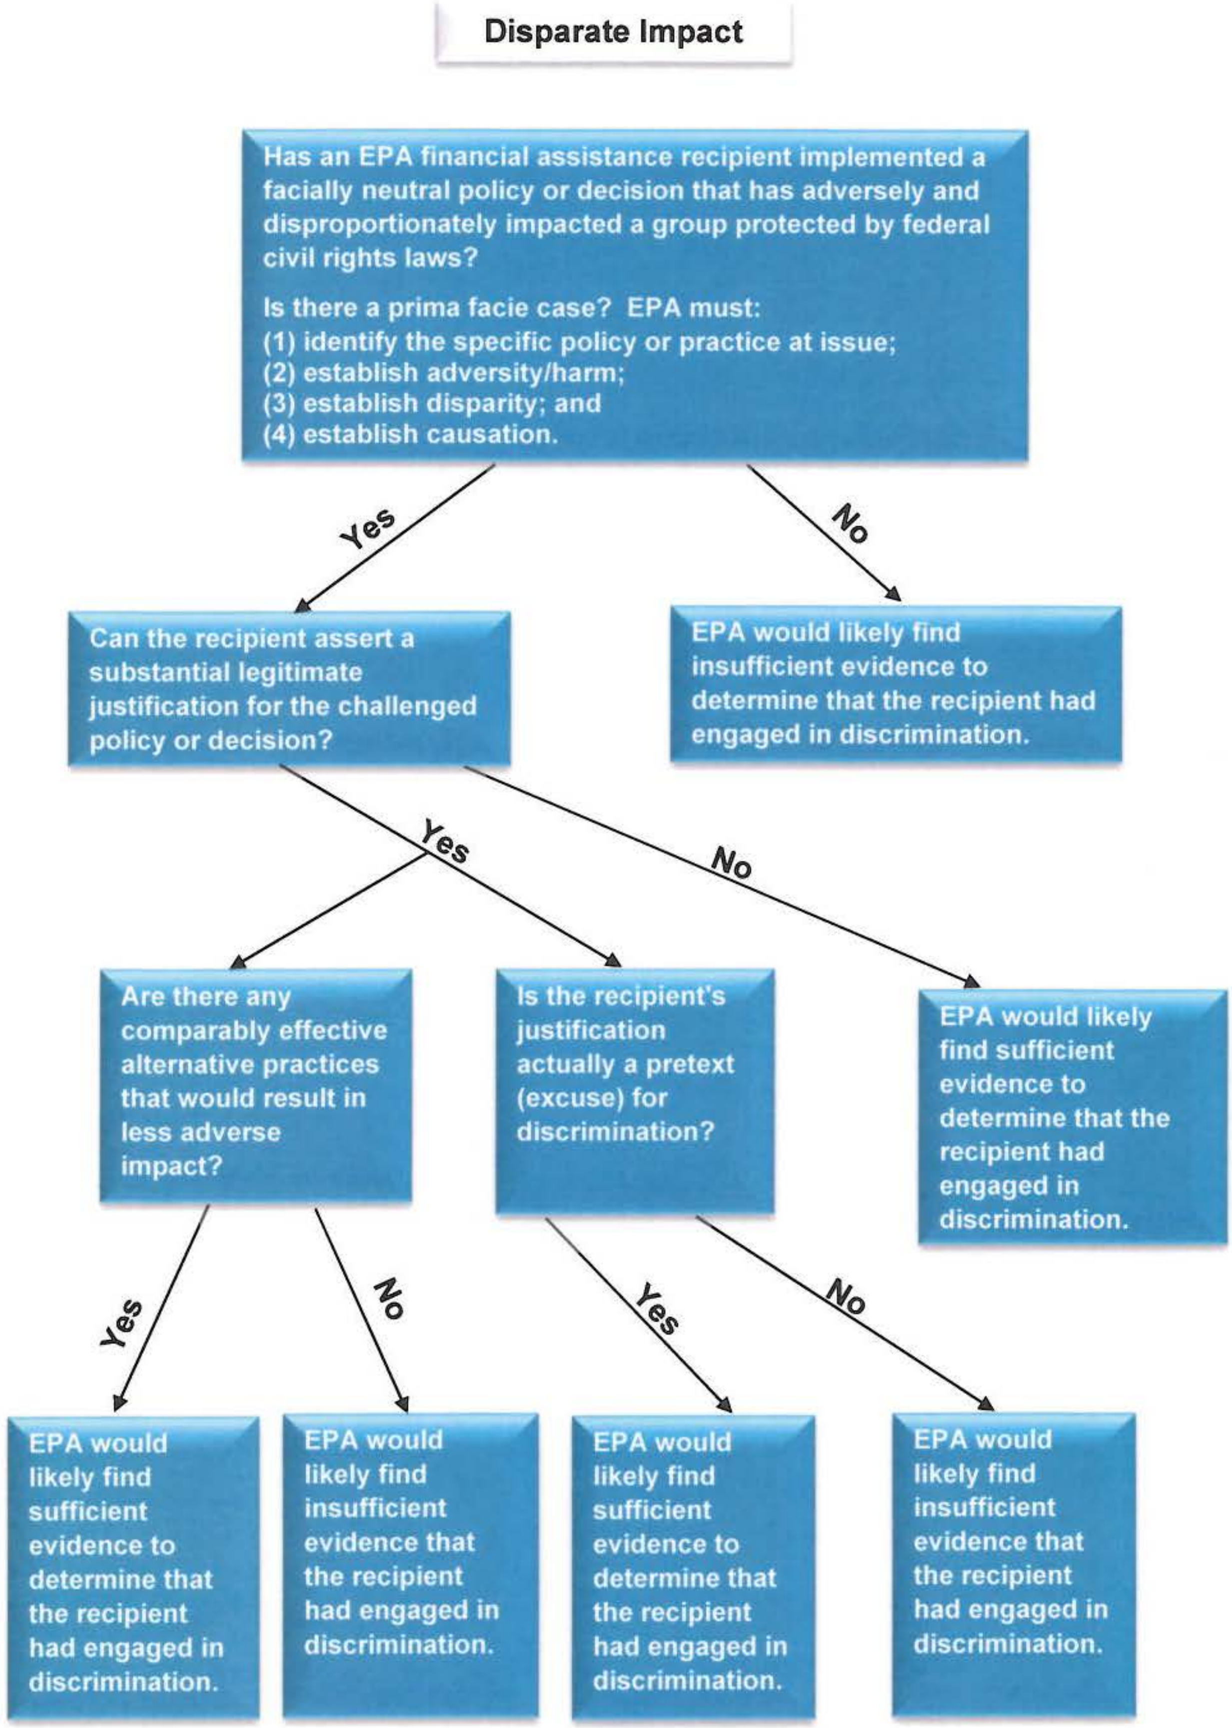
to one that a recipient formalizes in writing, but also could be one that is understood as "standard operating procedure" by recipient's employees.[45] Similarly, the neutral practice need not be affirmatively undertaken, but in some instances could be the failure to take action, or to adopt an important policy.[46]

If the evidence establishes a prima facie case of adverse disparate impact, as discussed above, EPA must then determine whether the recipient has articulated a "substantial legitimate justification" for the challenged policy or practice.[47] "Substantial legitimate justification" in a disparate impact case, is similar to the Title VII employment concept of "business necessity," which in that context requires a showing that the policy or practice in question is demonstrably related to a significant, legitimate employment goal.[48] The analysis requires balancing recipients' interests in implementing their policies with the substantial public interest in preventing discrimination.

Although determining a substantial legitimate justification is a fact-specific inquiry, EPA will generally consider whether the recipient can show that the challenged policy was "*necessary* to meeting a goal that was *legitimate, important, and integral to the [recipient's] institutional mission*" in order to establish a "substantial legitimate justification."[49] EPA will evaluate whether the policy was "necessary" by requiring that the justification bear a "manifest demonstrable relationship" to the challenged policy.[50] As part of its assessment, EPA will generally consider not only the recipient's perspective, but the views of the affected community in its assessment of whether a permitted facility, for example, will provide direct, economic benefits to that community.

If a recipient shows a "substantial legitimate justification" for its policy or decision, EPA must also determine whether there are any comparably effective alternative practices that would result in less adverse impact. In other words, are there "less discriminatory alternatives?"[51] Thus, even if a recipient demonstrates a "substantial legitimate justification," the challenged policy or decision will nevertheless violate federal civil rights laws if the evidence shows that "less discriminatory alternatives" exist.

The chart below illustrates the analysis that EPA utilizes in the investigation of a case involving disparate impact.



Disparate Impact
Has an EPA financial assistance recipient implemented a facially neutral policy or decision that has adversely and disproportionately impacted a group protected by federal civil rights laws?
Is there a prima facie case? EPA must:
(1) identify the specific policy or practice at issue;
(2) establish adversity/harm;
(3) establish disparity; and
(4) establish causation.
Yes
No
Can the recipient assert a substantial legitimate justification for the challenged policy or decision?
EPA would likely find insufficient evidence to determine that the recipient had engaged in discrimination.
Yes
No
Are there any comparably effective alternative practices that would result in less adverse impact?
Is the recipient's justification actually a pretext (excuse) for discrimination?
EPA would likely find sufficient evidence to determine that the recipient had engaged in discrimination.
Yes
No
Yes
No
EPA would likely find sufficient evidence to determine that the recipient had engaged in discrimination.
EPA would likely find insufficient evidence that the recipient had engaged in discrimination.
EPA would likely find sufficient evidence to determine that the recipient had engaged in discrimination.
EPA would likely find insufficient evidence that the recipient had engaged in discrimination.

1. *Disparate Impact: Adversity prong of prima facie case-NAAQS Example*

Referring back to the power station example cited above, this section will focus on the adversity portion of the *prima facie* case analysis, as this issue has been the topic of previous EPA draft guidance papers.[52]

Under these facts, assume that EPA has jurisdiction over a complaint. The complaint alleges that SDEQ's issuance of a construction and operating permit for the power station under its Clean Air Act permitting program has resulted in discrimination. The complaint asserts that SDEQ's action has caused a disparate impact based on alleged adverse health effects that are occurring or will occur from the power station's emission of pollutants for which EPA has established National Ambient Air Quality Standards (NAAQS). In addition, for the purpose of this example, assume that the area in which the power station is located is designated as being in attainment for all of the NAAQS.

In analyzing the complaint, EPA will follow the disparate impact analysis framework in the discussion and chart above. EPA will consider the information provided in the complaint, including any information pertinent to whether the air quality in the area in question does not meet the NAAQS. EPA will examine whether site-specific information demonstrates the presence of adverse health effects from the NAAQS pollutants, even though the area is designated attainment for all such pollutants and the facility recently obtained a construction and operating permit that ostensibly meets applicable requirements.[53] For instance, EPA's assessment would seek to establish whether a localized adverse health impact, as indicated by the NAAQS, exists in the area at issue and has been (or will be) caused by the emissions from the power station even though the impact of the facility had previously been modeled to demonstrate that the source met the criteria for obtaining a construction permit. (Note that some NAAQS, especially those that are source-oriented in nature, are more likely to be associated with localized air quality impacts than those that are more regional.) The localized adverse health impact may result from the increased emissions from the power station, but was not identified at the time of the permit review.

EPA's assessment of such evidence will likely, but not always, be based on gathering pre-existing technical data, including data generated by air quality monitors, general air quality assessments, records from source-specific permitting actions, and information provided by a complainant, rather than EPA generating new data. Such an assessment would not seek to reexamine the characteristics of the NAAQS itself. Rather, EPA's purpose in seeking such evidence is to assess whether a policy or practice of a grant recipient is preventing the area in question from benefiting from the protection of the NAAQS.

Two critical points about the preceding discussion warrant clarification.

1. The fact that the area is designated as in attainment with the NAAQS and that the recent permitting record shows that emissions from the facility would not

cause a violation of the NAAQS would be insufficient by themselves to find that no adverse impacts are occurring for purposes of Title VI and other federal civil rights laws. EPA's investigation would seek to ascertain the existence of such adverse impacts (*e.g.*, violations of the NAAQS) in an area regardless of the area's designation and the prior permitting record. As stated previously, compliance with environmental laws does not necessarily constitute compliance with federal civil rights laws.[54]

2. Complainants do not bear the burden of proving adversity. EPA recognizes that it is responsible for conducting an investigation of the allegations to determine if there is adverse impact.[55]

That said, to the extent that a complainant is able to provide precise allegations and quantified information about the location and nature of the adverse impact from higher-than expected concentrations of the NAAQS pollutant, EPA may be in a better position to conduct a timely and responsive investigation of that complaint. Accordingly, EPA encourages complainants to provide as much information to EPA as they are able to and as early in the process as possible.[56]

For example, a complainant could – but is not required to – provided ECRCO with information that shows a localized adverse health impact based on air monitoring data or air quality modeling that has been prepared using publicly available simple screening tools. (See Air Quality Dispersion Modeling - Screening Models | Support Center for Regulatory Atmospheric Modeling (SCRAM) | US EPA). Complainants may also be able to provide ECRCO with information about relevant university research, or a public interest or industry investigation that has been reported.

EPA will determine if a health-based NAAQS is likely not being met at the location in question, and whether the likely localized violation of a NAAQS is due, at least in part, to the impact of the particular source of air pollution that has recently obtained permits to construct and operate. While the complainant does not bear the burden of proof, any relevant information that the complainant provides could assist the Agency in its analysis.[57]

2. *Disparate Impact – Municipal Solid Waste Landfill Permit example*

SDEQ, which has an approved State program to issue permits to municipal solid waste landfills, renewed a permit to operate a municipal solid waste landfill in State Center, a city in Green County. The facility site is located near neighborhoods that are predominately Latino. Representatives of the neighborhoods filed a civil rights complaint with EPA alleging race and national origin discrimination by SDEQ in reissuing the permit.

The complainants allege the following based on local, recent census data: Green County is 8% Latino and 92% white, African-American and other groups; within State Center, 20% are Latino; and close to the site of the facility, the population is 67% Latino.

Complainants state that during the public participation process leading up to the permitting of the facility, the community raised concerns about anticipated adverse health effects from the facility. Complainants assert that the facility was not appropriately managing waste, which resulted in water run-off polluting the drinking water. Complainants also assert that SDEQ ignored those community concerns. They allege that SDEQ's actions disparately impact Latinos because the Latino population near the facility site is disproportionately affected when compared with other groups in the greater State Center and Green County by adverse health effects stemming from the site. The alleged adverse health effects include headaches; dizziness; burning eyes, nose and throat; nausea; seizures and other chronic illnesses.

In addition, complainants allege that they suffer at a disproportionate level other adverse effects, including economic (e.g., depressed property values); nuisance odors; increased truck traffic and noise; vermin and other vectors.

Given these facts, again assume that EPA has jurisdiction over the complaint and it involves alleged adverse effects that are occurring at the State Center facility, which is regulated under Subtitle D of the Resource Conservation and Recovery Act (RCRA).

In analyzing the complaint, EPA will follow the disparate impact analysis framework in the discussion and chart above. Thus, to find a prima facie violation, EPA's investigation must establish by a preponderance of the evidence that SDEQ's permitting action resulted in adverse and disparate effects on the Latino community identified in the complaint.

EPA will analyze available data, including site-specific data, to determine whether it shows sufficient adverse health effects from site-related pollutants. As mentioned in the NAAQS example, EPA's assessment of health effects will likely, but not always, be based on gathering pre-existing technical data, including information provided by a complainant, rather than generating new data.[58] With respect to the non-health harms alleged (*e.g.*, economic, traffic, noise), Title VI allows agencies to consider whether these effects are occurring and, if so, whether they are sufficiently harmful to support a violation finding.[59]

EPA will consider whether SDEQ's methods of administering the programs at issue subjected the Latino community to disproportionate harm. In evaluating disproportionality, EPA must evaluate population or demographic information of the impacted community as compared to an appropriate comparison population that is similarly situated. The exact areas EPA will evaluate, including distance from the site and specific population centers, will necessarily vary based on the facts and circumstances of each case.

If EPA finds that SDEQ's actions in this case caused adverse and disproportionate impacts on Latinos, SDEQ has the opportunity to justify its permitting actions. To justify the action, the SDEQ must offer evidence that its policy or decision in question is demonstrably related to a significant, legitimate goal related to its mission. For example, have SDEQ's actions resulted in a benefit delivered directly to the affected community, such as public health or environmental benefits? Are there broader interests, such as economic development, as a result of the permitting action that would serve as an acceptable justification? Are the benefits delivered directly to the affected population and is the broader interest legitimate, important, and integral to SDEQ's mission? Will the Latino community, in fact, realize any of these benefits? In evaluating the justification, EPA would likely consider not only SDEQ's perspective, but also the views of the affected community, as appropriate.

Assuming SDEQ establishes such justification, EPA must further look to determine whether there are less discriminatory alternatives; that is, approaches that cause less disparate impact but are practicable and comparably effective in meeting the needs identified by recipient. For example, EPA may find evidence that SDEQ had the capacity to prevent any adverse and disproportionate effects by requiring that the facility be operated in a manner that would eliminate or mitigate its disproportionate impact; by modifying permit conditions or employing practicable mitigation measures to lessen or eliminate the demonstrated adverse disparate impacts; or by not renewing the permit. EPA will also examine whether the asserted justification is merely a pretext or excuse for discrimination.

[2] 40 C.F.R. Part 7 (https://www.gpo.gov/fdsys/pkg/CFR-2011-title40-vol1/pdf/CFR-2011-title40-vol1-part7.pdf).

[3] A federal agency is not a recipient under federal civil rights laws.

[4] *See* 40 C.F.R. § 7.25.

[5] 40 C.F.R. § 7.80(a)(1).

[6] *Id.*

[7] The term "subrecipient" generally refers to an entity that receives federal financial assistance from EPA through a primary recipient. *See* http://www.grants.gov/web/grants/learn-grants/grant-terminology.html#S (definition of subrecipient).

[8] A recipient is not the same as a beneficiary (*i.e.*, one who is entitled to receive a benefit). An ultimate beneficiary of any program or activity is not considered to be a recipient. *See* 40 C.F.R. § 7.25. *See also U.S. Dep't of Transp. v. Paralyzed Veterans*, 477 U.S. 597, 606-07 (1986). Federal civil rights obligations apply those who receive the aid, but do not apply to those who benefit from the federal financial assistance. *See id.* at 607. Beneficiaries do not enter into any formal contract or agreement with the federal government where compliance with federal civil rights laws is a condition of receiving the federal financial assistance. *See id.* at 605.

[9] *See* 40 C.F.R. § 7.25.

[10] 40 C.F.R. § 7.35(a), (b).

[11] *See* 40 C.F.R. § 7.25.

[12] *See Alexander v. Choate*, 469 U.S. 287, 293 (1985); *Guardians Ass'n. v. Civil Serv. Comm'n*, 463 U.S. 582 (1983). *Alexander* and *Guardians* are Title VI cases. However, Title VI is the model for several subsequent laws that prohibit discrimination on other grounds in federally assisted programs or activities, including Title IX (discrimination in education programs prohibited on the basis of sex) and Section 504 (discrimination prohibited on the basis of disability). *See Paralyzed Veterans*, 477 U.S. at 600 n.4; *Grove City Coll. v. Bell*, 465 U.S. 555, 566 (1984) (Title IX was patterned after Title VI); *Consol. Rail Corp. v. Darrone*, 465 U.S. 624 (1984) (Section 504 patterned after Titles VI and IX). Accordingly, courts have "relied on case law interpreting Title VI as generally applicable to later statutes," *Paralyzed Veterans*, 477 U.S. at 600 n.4.

[13] 42 U.S.C. § 2000d-1.

[14] *Guardians*, 463 U.S. 582; *Alexander*, 469 U.S. at 292-94; *see Elston v. Talladega Cty. Bd. of Educ.*, 997 F.2d 1394, 1406 (11th Cir. 1993). Under the disparate impact analysis, a recipient, in violation of agency regulations, uses a neutral procedure or practice that has a disparate impact on individuals of a particular race, color, or national origin, and such practice lacks a "substantial legitimate justification." *Larry P. v. Riles*, 793 F.2d 969, 983 (9th Cir. 1984); *New York Urban League v. New York*, 71 F.3d 1031,

1038 (2d Cir. 1995); *Elston*, 997 F.2d at 1407. Title VI disparate impact claims are analyzed using principles similar to those used to analyze Title VII disparate impact claims. *Young by and through Young v. Montgomery Cty. (Ala.) Bd. of Educ.*, 922 F. Supp. 544, 549 (M.D. Ala. 1996).

[15] The discussion of legal standards in this document focuses on Title VI because the majority of complaints received by ECRCO allege discrimination based on race, color, or national origin. Importantly, the analyses under other civil rights laws are not always the same. For example, section 504 requires "reasonable accommodation," an obligation not discussed in this chapter. 40 C.F.R. § 7.60.

[16] 38 Fed. Reg. 17968 (1973), as amended by 49 Fed. Reg. 1656 (1984) (codified at 40 C.F.R. Part 7).

[17] Specifically, the regulation states:

> No applicant, recipient, nor other person shall intimidate, threaten, coerce, or discriminate against any individual or group, either:
> (a) For the purpose of interfering with any right or privilege guaranteed by the Acts or this part, or
> (b) Because the individual has filed a complaint or has testified, assisted or participated in any way in an investigation, proceeding or hearing under this part, or has opposed any practice made unlawful by this regulation. 40 C.F.R. § 7.100

EPA plans to issue further information on the prohibition of retaliation and intimidation in the future.

[18] *See* 40 C.F.R. § 7.100. Any individual alleging such harassment or intimidation may file a complaint with EPA. EPA would investigate such a complaint if the situation warranted.

Georgia*, 775 F.2d 1403 (11th Cir. 1985); *Larry P. v. Riles*, 793 F.2d 969 (9th Cir. 1984). United States v. Maricopa Cty, 915 F. Supp. 2d 1073, 1081 (D. Ariz. 2012) (plaintiff properly stated a disparate impact claim where limited-English proficient Latino inmates had diminished access to jail services such as sanitary needs, food, clothing, legal information, and religious services). In addition, by memorandum dated July 14, 1994, the Attorney General directed the Heads of Departments and Agencies to "ensure that the disparate impact provisions in your regulations are fully utilized so that all persons may enjoy equally the benefits of [f]ederally financed programs." Attorney General Memorandum on the use of the Disparate Impact Standard in Administrative Regulations under Title VI of the Civil Rights Act of 1964 (July 14, 1994) (Attorney General July 14, 1994 Memorandum on the use of the Disparate Impact Standard in Administrative Regulations Under Title VI | AG | Department of Justice).

[40] 40 C.F.R. § 7.35(b).

[41] Adversity exists if a fact specific inquiry determines that the nature, size, or likelihood of the impact is sufficient to make it an actionable harm.

[42] In analyzing disparity, EPA analyzes whether a disproportionate share of the adversity/harm is borne by individuals based on their race, color, national origin, age, disability or sex. A general measure of disparity compares the proportion of persons in the protected class who are adversely affected by the challenged policy or decision and the proportion of persons not in the protected class who are adversely

affected. *See Tsombanidis v. W. Haven Fire Dep't*, 352 F.3d 565, 576-77 (2d Cir. 2003). When demonstrating disparity using statistics, the disparity must be statistically significant.

[43] *See N.Y.C. Envtl. Justice All. v. Giuliani*, 214 F.3d 65, 69 (2d Cir. 2000) (plaintiffs must "allege a causal connection between a facially neutral policy and a disproportionate and adverse impact on minorities").

[44] *Lau v. Nichols*, 414 U.S. 563, at 568 (1974).

[45] If as part of a recipient's permitting of a facility, a recipient makes a decision with respect to the siting of a facility; such decision may not intentionally discriminate or have a discriminatory effect on a protected population. The regulation states:

> A recipient shall not choose a site or location of a facility that has the purpose or effect of excluding individuals from, denying them the benefits of, or subjecting them to discrimination under any program or activity to which this part applies on the grounds of race, color, or national origin or sex; or with the purpose or effect of defeating or substantially impairing the accomplishment of the objectives of this subpart. 40 C.F.R. § 7.35(c).

[46] *See, e.g., Maricopa Cty.*, 915 F. Supp. 2d at 1079 (disparate impact violation based on national origin properly alleged where recipient "failed to develop and implement policies and practices to ensure [limited English proficient] Latino inmates have equal access to jail services" and discriminatory conduct of detention officers was facilitated by "broad, unfettered discretion and lack of training and oversight" resulting in denial of access to important services).

[47] *Georgia State Conf.*, 775 F.2d at 1417.

[48] *Wards Cove Packing Inc. v. Antonio*, 490 U.S. 642, 659 (1989); *Griggs v. Duke Power Co.*, 401 U.S. 424, 433-36 (1971). Notably, the concept of "business necessity" does not transfer exactly to the Title VI context because "business necessity" does not cover the full scope of recipient practices that Title VI covers, which applies far more broadly to many types of public and non-profit entities. *See Texas Dept. of Hous. and Cmty. Affairs v. Inclusive Communities Project*, 135 S. Ct. 2507, 2522-24 (2015) (recognizing the limitations on extension of the business necessity concept to Fair Housing Act complaints).

[49] *Elston*, 997 F.2d at 1413 (emphasis added); *See* EPA Draft Revised Guidance for Investigating Title VI Administrative Complaints Challenging Permits, 65 Fed. Reg. 39,667, 39683 (2000) (Draft Revised Investigation Guidance) ("Determining what constitutes an acceptable justification will necessarily be based on the facts of the case. Generally, the recipient would attempt to show that the challenged activity is reasonably necessary to meet a goal that is legitimate, important, and integral to the recipient's institutional mission.") (https://www.epa.gov/sites/production/files/2013-09/documents/frn_t6_pub06272000.pdf).

[50] Georgia State Conf., 775 F.2d. at 1418.

[51] *Elston*, 997 F.2d at 1407.

[52] In its 2000 *Draft Revised Investigation Guidance*, EPA stated that a demonstration in the permitting context that construction of a stationary source will not cause a violation of health-based NAAQS creates a rebuttable presumption that no adverse impacts are caused by the environmental permit at issue with respect to the relevant NAAQS pollutant for purposes of Title VI. That presumption could be overcome with other relevant information about the area. *See* Draft Revised Investigation Guidance, 65 Fed. Reg. at 39,680-81. Stakeholders raised concerns that EPA should more clearly distinguish between environmental compliance and civil rights compliance. Consequently, in 2013, EPA proposed to clarify that the Agency would no longer apply a rebuttable presumption in such a context and instead would consider whether an area was attaining NAAQS concurrently with other information, such as the

presence of "hot spots." *See* Adversity and Compliance with Environmental Health-Based Thresholds, 78 Fed. Reg. 24,739 (2013) (https://www.gpo.gov/fdsys/pkg/FR-2013-04-26/pdf/2013-09922.pdf). Following its review of comments on the 2013 draft, as well as subsequent external engagement with interested stakeholders, EPA will apply the approach described here. This approach supersedes the corresponding discussions in the two prior Federal Register notices and eliminates application of the rebuttable presumption.

Both prior positions and the approach described here are predicated on the application of health-based environmental standards such as the NAAQS. Under the Clean Air Act, a primary NAAQS must, in the judgment of the Administrator, protect public health with an adequate margin of safety. This judgment is based on a thorough review of the available scientific literature, including assessments of sensitive sub-populations. The NAAQS and its underlying science are then reviewed periodically to ensure that they remain sufficiently protective. Implementation of a NAAQS requires proper characterization of air quality, generally involving the use of ambient monitors over time, in order to determine whether the NAAQS are being met.

[53] Separately, complainants who believe the permits were issued in error may seek to appeal those permit decisions under administrative or judicial procedures applicable under a state permitting program. In addition, parties may petition EPA to object to a Title V operating permit. These procedures and remedies are distinct from a complaint under civil rights laws, and they are not addressed in the Toolkit.

[54] *See, e.g.*, 78 Fed. Reg. at 24,742; 65 Fed. Reg. at 39,680 (2000).

[55] EPA will exercise its reasonable enforcement discretion to determine whether a violation has occurred.

[56] In evaluating and receiving a complaint and supporting information from complainants, ECRCO will assist the complainant in understanding ECRCO's jurisdiction and the complainant's nondiscrimination rights under the statutes and regulations enforced by ECRCO according to its Role of Complainants and Recipients in the Title VI Complaints and Resolution Process policy paper (May 4, 2015) (https://www.epa.gov/ocr/epas-title-vi-policies-guidance-settlements-laws-and-regulations) and Case Resolution Manual (https://www.epa.gov/sites/production/files/2017-01/documents/final_epa_ogc_ecrco_crm_january_11_2017.pdf).

[57] This example addresses how compliance with environmental health-based thresholds relates to "adversity" in the context of disparate impact claims about environmental permitting. The approach described here does not address allegations about intentional discrimination, allegations about pollutants that are not addressed by NAAQS, most non-permitting fact patterns, or technology- and cost-based standards. However, the principle described here or another similar approach may apply in other contexts where appropriate. Furthermore, this approach in no way diminishes EPA's emphasis on informal resolutions of federal civil rights complaints, which may be undertaken before completion of the analysis described here. In addition, as outlined above, adversity is only one part of the disparate impact analysis.

[58] ECRCO may give due weight to relevant adverse impact analyses and disparity analyses submitted by recipients or complainants that, at a minimum, generally conform to accepted scientific approaches. The weight that ECRCO gives to any evidence and the extent to which ECRCO may rely on it in its decision will likely vary depending upon:

- relevance of the evidence to the alleged impacts;
- the validity of the recipient's methodologies;
- the completeness of the documentation that is submitted by the recipient;
- the degree of consistency between the methodology used and the findings and conclusions; and
- the uncertainties of the input data and results.

Consequently, EPA experts would undertake a scientific review of submitted materials. If the analyses submitted meet the factors above, ECRCO will not seek to duplicate or conduct such analyses, but instead will evaluate the appropriateness and validity of the relevant methodology and assess the overall reasonableness of the outcome or conclusions at issue.

If ECRCO's review reveals that the evidence contains significant deficiencies with respect to the factors above, then the analysis will likely not be relied upon in ECRCO's decision.

[59] EPA has substantial discretion to determine the types of harms, on a case by case basis, that warrant investigatory resources and are sufficiently harmful to violate Title VI: "Title VI had delegated to the agencies in the first instance the complex determination of what sorts of disparate impact upon minorities constituted sufficiently significant social problems, and were readily enough remediable, to warrant altering the practices of the federal grantees that had produced those impacts." *Choate*, 469 U.S. at 293–94; *see also Alexander v. Sandoval*, 532 U.S. 275, 306 (2001) (Stevens, J., dissenting). And lower courts have consistently recognized and deferred to agency interpretations of the disparate impact standard. *See, e.g.*, *United States v. Maricopa Cty*, 915 F. Supp. 2d 1073, 1080 (D. Ariz. 2012) (citing *Auer v. Robbins*, 519 U.S. 452, 461 (1997)) (agency interpretation of its own regulations "controlling unless plainly erroneous or inconsistent with the regulations"). Historically, EPA has focused primarily on those impacts that could fall under a recipient's authority.

January 18, 2017

FREQUENTLY ASKED QUESTIONS (FAQs) FOR CHAPTER 1 OF THE U.S. EPA'S EXTERNAL CIVIL RIGHTS COMPLIANCE OFFICE COMPLIANCE TOOLKIT

1) Why is EPA issuing a Civil Rights Compliance Toolkit ("Toolkit")?

The overall purpose of the Toolkit is to support and advance the External Civil Rights Compliance Office's (ECRCO) proactive compliance and enforcement efforts. ECRCO ensures that applicants for and recipients of EPA federal financial assistance comply with federal civil rights laws[1] in their programs or activities in several ways –through complaint investigations, compliance reviews, technical assistance, community engagement, and policy formulation. Accordingly, EPA is issuing the Toolkit to clarify existing law and policy and to provide guidance to promote and support applicant and recipient compliance with federal civil rights laws.

In issuing the Toolkit, EPA affirms its commitment to work with its financial assistance applicants and recipients to help achieve their compliance with federal civil rights laws, that is, that applicants for and recipients of financial assistance operate and administer their programs and activities in a manner free from discrimination. The Toolkit also provides members of the public with information about the civil rights laws and implementing regulations that ECRCO enforces and how those laws are enforced.

2) What does the Toolkit contain?

The Toolkit contains information and policy guidance to inform recipients about how EPA evaluates whether they are complying with their legal obligations pursuant to federal civil rights laws,[2] including through discussion and clear examples of the application of foundational civil rights legal standards (*i.e.*, intentional discrimination and disparate impact) used in investigating and resolving civil rights complaints at EPA.

The Toolkit is a "living document." EPA may revise it from time to time to make improvements, reflect emerging case law or reflect policy changes in EPA's approach to implementing federal civil rights laws.

3) Who is covered by federal civil rights laws?

Federal civil rights laws apply to the programs and activities of applicants for and recipients of federal financial assistance[3] as well as any subrecipients[4] who receive funds from a recipient to carry out its programs and activities. EPA's nondiscrimination regulation defines a recipient to include both public and private entities, including any State, public or private agency, institution, organization, or other entity or person to which federal financial assistance is extended.[5]

4) What is covered by federal civil rights laws?

Civil rights laws prohibit discrimination in "any program or activity" of recipients of federal financial assistance. With regard to certain recipients, such as public institutions, the "program or activity" that Title VI covers encompasses the entire institution and not just the part of the institution that receives the federal financial assistance.[6] For example, many state environmental agencies receive federal funding for their regulatory and environmental protection functions. Those agencies should be aware that all actions, not just permitting decisions, taken by state agencies funded by EPA are subject to federal civil rights laws.

5) What conduct is prohibited by federal civil rights laws and EPA's nondiscrimination regulation?

Recipients of EPA financial assistance are prohibited from taking actions in their programs or activities that are intentionally discriminatory and/or have a discriminatory effect. Violations of federal civil rights laws can result not only from intentional discrimination, but from discrimination based on disparate impact, *i.e.*, policies and practices that are neutral on their face, but have the effect of discriminating.[7] In addition, recipients may not intimidate, threaten, coerce, or engage in other discriminatory conduct against anyone because he or she has either taken action or participated in an action to secure rights protected by the non-discrimination statutes ECRCO enforces.[8]

6) What is intentional discrimination?

Intentional discrimination (or different treatment) occurs when a recipient intentionally treated individuals differently or otherwise knowingly cause them harm because of their race, color, national origin, disability, age or sex. Intentional discrimination requires a showing that a challenged action was motivated by an intent to discriminate but does not require showing bad faith, ill will, or evil motive.

7) What is disparate impact?

Disparate impact (or discriminatory effect) results when a recipient uses a facially neutral procedure or practice that has a significantly adverse (harmful) and disproportionate effect based on race, color, or national origin. In a disparate impact case, the focus is on the consequences of the recipient's policies or decisions, including the failure to take action, rather than the recipient's intent.

If there is evidence of adverse disparate impact, EPA must then determine whether the recipient has asserted a "substantial legitimate justification" for the challenged policy or practice. "Substantial legitimate justification" in a disparate impact case, is similar to the Title VII concept of "business necessity," which requires a showing that the policy or practice in question is demonstrably related to a significant, legitimate employment goal.[9] The analysis requires balancing recipients' interests in implementing their policies with the substantial public interest in preventing discrimination. If there is no such showing, EPA would likely find that the recipient has engaged in discrimination. If the recipient makes such an assertion, EPA must also determine if there are any "equally effective alternative practices" that would result in less adverse impact and/or whether the asserted justification is not just an excuse for discrimination. If EPA makes such a determination about available alternatives or finds pretext, it would likely find that discrimination occurred.

8) What legal standard does EPA apply in its civil rights investigations?

EPA utilizes the "preponderance of the evidence" (more likely than not) standard in its investigations to determine whether or not a recipient has violated federal civil rights laws.

9) Does compliance with environmental laws in a given situation equate to compliance with federal civil rights laws?

No. If in a given circumstance a recipient is in compliance with applicable environmental laws that fact alone does not necessarily mean that the recipient is in compliance with federal civil rights laws.

10) Does the EPA apply a "rebuttable presumption" to the adversity prong of its disparate impact analysis?

EPA addresses this issue directly in the Toolkit through an example involving issuance of permits authorizing construction and operation of a power station. To put this question in context, EPA, in its 2000 *Draft Revised Investigation Guidance*, stated that a demonstration in the permitting context that construction of stationary source will not cause a violation of the health-based National Ambient Air Quality Standards (NAAQS) creates a rebuttable presumption that no adverse impacts are caused by the environmental permit at issue with respect to the relevant NAAQS pollutant for purposes of Title VI.[10] In 2013, EPA proposed to clarify that the Agency would no longer apply a rebuttable presumption in such a context and instead would consider whether an area was attaining NAAQS concurrently with other information, such as the presence of "hot spots."[11]

Following its review of comments on the 2013 draft, as well as subsequent external engagement with interested stakeholders, EPA will apply the approach to adversity that is discussed in the Toolkit. Specifically, EPA will examine whether site-specific information demonstrates the presence of adverse health effects from NAAQS pollutants, even though the area is designated attainment for all such pollutants and the facility recently obtained a construction and operating permit that ostensibly meets applicable requirements. EPA's assessment would seek to establish whether a localized adverse health impact, as indicated by the NAAQS, exists in the area at issue and has been (or will be) caused by the emissions from the power station even though the impact of the facility had previously been modeled to demonstrate that the source met the criteria for obtaining a construction permit. As stated previously, compliance with environmental laws does not necessarily constitute compliance with federal civil rights laws.

While the adversity example in the Toolkit involves permits authorizing construction and operation of a power station, the approach described here or another similar approach may apply in other contexts where appropriate. Ultimately, this approach supersedes the corresponding discussions in the two prior Federal Register notices and eliminates application of the rebuttable presumption.

11) What types of harm does EPA consider when determining whether there has been an adverse and disproportionate impact on individuals?

EPA's nondiscrimination regulation does not define discriminatory effects but simply states that a recipient may not administer its program or activity in a manner which has the effect of subjecting individuals to discrimination because of their race, color, national origin, age, disability status, or sex.[12] This language encompasses a broad range of effects caused by a recipient's administration of its program. Therefore, in analyzing a claim of disparate impact, EPA will consider environmental harms and adverse health effects (*e.g.*, asthma and other respiratory illnesses, cancer, cardiac disease, stroke, allergies, *etc.*) that have allegedly been caused disproportionately based on race, color, or national origin, by a recipient's policy or practice. EPA will also consider non-health harms, including, among other things, economic (*e.g.,* depressed property values), nuisance odors, traffic congestion, noise and vermin. With respect to the non-health harms alleged (*e.g.*, economic, traffic, noise), Title VI allows agencies to consider whether these effects are occurring and, if so, whether they are sufficiently harmful to support a violation finding.[13]

[1] EPA's ECRCO is responsible for enforcing several civil rights laws which, together, prohibit discrimination on the basis of race, color, national origin (including on the basis of limited-English proficiency), sex, disability, and age, by applicants for and recipients of federal financial assistance from EPA.

[2] Note: The Toolkit is a guidance document and does not add requirements to applicable federal civil rights laws. The Toolkit is not a rule; it is not legally enforceable; and it does not create or confer legal rights or legal obligations upon any member of the public, recipient, the EPA, state and local governments, tribes, or any other agency. For instance, it includes references to statutes, regulations and case law, but it does not change or substitute for any legal requirements contained in those sources. While EPA has made every effort to ensure the accuracy of the information discussed in the Toolkit, the relevant statutes, regulations, and other legally binding requirements determine your obligations as a recipient. In the event of a conflict between the discussion in the Toolkit and any statute or regulation, the Toolkit would not control.

The Toolkit does not address every scenario that may arise under federal civil rights laws; nor does the Toolkit come with a guarantee that you will not receive a civil rights complaint if you abide by and implement the guidance contained within it. The Toolkit may not apply in a particular situation based upon the circumstances, and EPA retains discretion to adopt approaches on a case-by-case basis that differ from those discussed in the Toolkit where appropriate. Importantly, the Toolkit does not change in any way, your obligation to comply with applicable environmental laws.

[3] 40 C.F.R. § 7.15.

[4] The term "subrecipient" generally refers to an entity that receives federal financial assistance from EPA through a primary recipient. *See* http://www.grants.gov/web/grants/learn-grants/grant-terminology.html#S (definition of subrecipient).

[5] *See* 40 C.F.R. § 7.25.

[6] *Id.*

[7] The discussion of legal standards in this document and the Toolkit, generally, focuses on Title VI because the majority of complaints received by ECRCO allege discrimination based on race, color, or national origin. Importantly, the analyses under other civil rights laws are not always the same. For example, section 504 requires "reasonable accommodation," an obligation not discussed in this chapter. 40 C.F.R. § 7.60.

[8] *See* 40 C.F.R. § 7.100.

[9] *Wards Cove Packing Inc. v. Antonio*, 490 U.S. 642, 659 (1989); *Griggs v. Duke Power Co.*, 401 U.S. 424, 433-36 (1971). Notably, the concept of "business necessity" does not transfer exactly to the Title VI context because "business necessity" does not cover the full scope of recipient practices that Title VI covers, which applies far more broadly to many types of public and non-profit entities. *See Texas Dep't of Hous. and Cmty. Affairs v. Inclusive Communities Project*, 135 S. Ct. 2507, 2522-24 (2015) (recognizing the limitations on extension of the business necessity concept to Fair Housing Act complaints).

[10] *See* Draft Revised Guidance for Investigating Title VI Administrative Complaints Challenging Permits, 65 Fed. Reg. 39,667, 39,680-81 (June 27, 2000).

[11] *See* Adversity and Compliance with Environmental Health-Based Thresholds, 78 Fed. Reg. 24,739 (April 26, 2013).

[12] 40 C.F.R. § 7.35(b).

[13] EPA has substantial discretion to determine the types of harms, on a case by case basis, that warrant investigatory resources and are sufficiently harmful to violate Title VI: "Title VI had delegated to the agencies in the first instance the complex determination of what sorts of disparate impact upon minorities constituted sufficiently significant social problems, and were readily enough remediable, to warrant altering the practices of the federal grantees that had produced those impacts." *Alexander v. Choate*, 469 U.S. 287, 293-94 (1985); *see also Alexander v. Sandoval*, 532 U.S. 275, 306 (2001) (Stevens, J., dissenting). And lower courts have consistently recognized and deferred to agency interpretations of the disparate impact standard. *See, e.g.*, *United States v. Maricopa Cty*, 915 F. Supp. 2d 1073, 1080 (D. Ariz. 2012) (citing *Auer v. Robbins*, 519 U.S. 452, 461 (1997)) (agency interpretation of its own regulations "controlling unless plainly erroneous or inconsistent with the regulations"). Historically, EPA has focused primarily on those impacts that could fall under a recipient's authority.

<u>CONFIDENTIAL ATTORNEY WORK PRODUCT– DRAFT</u>
March 4, 2019
Via e-mail to Christine.Lawson@ncdenr.gov and Swinepermit.comments@ncdenr.gov
DWR Animal Operations
Attn: Swine General Permit
1636 Mail Service Center
Raleigh, NC. 27699-1636

Re: Draft Swine Waste Management System General Permit (AWG100000)

Dear DWR Animal Operations:

We submit these comments on the draft Swine Waste Management System General Permit (AWG100000) ("Draft Permit") on behalf of the North Carolina Environmental Justice Network ("NCEJN"), the Rural Empowerment Association for Community Help ("REACH"), Waterkeeper Alliance, Inc. ("Waterkeeper"), the Crystal Coast Waterkeeper and the North Carolina State Conference of the NAACP. To avoid redundancy, we incorporate by reference the attached comments submitted on our clients' behalf on December 21, 2018, as part of the stakeholder process.[1]

As an initial matter, and in connection with our representation of NCEJN, REACH and Waterkeeper in the 2014 administrative complaint alleging racial discrimination filed against DEQ with the U.S. Environmental Protection Agency (EPA) under Title VI of the Civil Rights Act of 1964 ("Title VI complaint"), we refer you to the "Background" section of those comments, which summarizes information provided to DEQ in 2013 concerning the racially discriminatory impacts of the current general permit.[2] Those impacts include air and water pollution emanating from the open pits of waste and sprayfields in which DEQ-permitted swine operations store and disperse billions of gallons of feces, urine and other waste. The consequences of this system are not just environmental, but also racially discriminatory, because they disproportionately burden non-white North Carolinians.

---

[1] *See NCEJN, REACH, and Waterkeeper Alliance Stakeholder Comments on General Permit (AWG 100000) (Dec. 21,*2018). These comments are herein incorporated by reference and attached hereto as Exhibit 1. *See also Sound Rivers, Cape Fear River Watch, Winyah Rivers Foundation, Crystal Coast Waterkeeper, Crystal Coast Riverwatch, White Oak-New Riverkeeper Alliance, Haw River Assembly, Yadkin Riverkeeper, Catawba Riverkeeper Foundation, Broad River Alliance, and Mountain True, Stakeholder Comments on General Permit (AWG 100000) (Dec. 21, 2018); National Resources Defense Council and Center for Biological Diversity, Stakeholder Comments on General Permit (AWG 100000)* (Dec. 21, 2018), which are herein incorporated by reference and attached hereto as Exhibits 2 and 3.
[2] *See* Complaint by NCEJN, REACH, and Waterkeeper Alliance Against North Carolina DEQ (EPA File No. 11R-14-R4), September 3, 2014 (hereinafter, "Complaint," attached hereto as Exhibit 4).

DEQ continues violating Title VI because the agency has failed to exercise its authority to provide adequate protections for the health and welfare of surrounding communities and, knowing the risks and impacts of the lagoon and sprayfield system in eastern North Carolina, failed to exercise its duty to include terms to identify and protect those communities in the draft Swine General Permit.We urge DEQ to begin planning now for the transition of North Carolina's swine industry from the antiquated lagoon and sprayfield system to a more sustainable foundation for farming in the state; at a minimum, though, the Draft Permit must comply with the mandates of Title VI, and should be changed to include the following:

1) At page 1, an additional provision should be added to the new section listing the "[r]easons for requiring application for an individual permit," that expressly recognizes the agency's mandate to comply with Title VI, as follows:
   - Subsection (h) "*a determination that the operation contributes to cumulative and/or discriminatory impacts on communities of concern.* [3]

2) Also at page 1, the permit duration period should be shortened from 5 to 2 years ("*This General Permit shall be effective from October 1, 2019 until September 30, 2021*"). This change is necessary given DEQ's public representation that the Environmental Justice geographic mapping tool ("EJ Tool") it is developing will not be ready to conduct a disparate impact and cumulative impacts analysis of facilities operated by applicants for the 2019 General Permit. Limiting the permit's duration to two years would demonstrate DEQ's bona fide commitment to implement the EJ Tool and conduct the necessary analyses within the next two years, make appropriate changes to the 2021 General Permit, and require swine operators to adopt less discriminatory alternative means of waste disposal within a reasonable timeframe. The 2-year time period would also afford the opportunity for DEQ to consider additional evidence of impacts by considering PLAT and groundwater monitoring data envisioned in this draft permit, as well as water monitoring data now collected pursuant to the Settlement Agreement DEQ reached with NCEJN, REACH, and Waterkeeper.[4]

---

[3] Our definition of "communities of concern" is based upon EPA guidelines, which refer to "populations of concern" and "vulnerability" defined by "characteristics of individuals or populations that place them at increased risk of an adverse health effect.*" See Risk Assessment Forum, U.S. Envtl. Prot. Agency, Framework for Cumulative Risk Assessment*, EPA/630/P-02/001F (2003). EPA considers a number of factors to determine vulnerability: susceptibility/sensitivity, differential exposure, differential preparedness, and differential ability to recover. *Id.,* at 39. In the North Carolina context, these factors would include the density of hog operations and proximity to other polluting sources, such as poultry operations.
[4] *See* Settlement Agreement, Case 11R-14-R4, attached hereto as Exhibit 5; DEQ, Stocking Head Creek Watershed Study, https://deq.nc.gov/about/divisions/water-resources/water-resources-data/water-sciences-home-page/shc-study.

In addition to and in support of the above requests, and in light of DEQ's response to the changes we requested during the stakeholder process to protect communities of concern, the pork industry's responses to those requests, and the subsequent changes in the Draft Permit, we direct DEQ's consideration to the following:

1. **EPA's "Letter of Concern"**

In January 2017, the EPA issued a "letter of concern" to DEQ as part of its investigation of our clients' Title VI complaint.[5] The 23-page letter describes results not only from EPA's site visits to Duplin, Sampson, Northampton and Pender Counties, where it interviewed "over 60 residents living near industrial swine operations permitted under the Swine Waste General Permit,"[6] but also its assessment of over two decades of scientific research and "reports published by or with federal agencies."[7] The EPA notes that the

> adverse impacts on nearby residents from the lagoon spray field method of treatment and disposal of waste from industrial swine operations are documented in numerous peer reviewed scientific studies, including more than thirty conducted in North Carolina.... [T]he reports provide consistent support for the occurrence of potential health hazards (e.g., eye, nose, and throat irritation; headaches; respiratory effects including asthma exacerbation; waterborne disease) at industrial swine operations and in their waste. Even while there is significant uncertainty regarding the levels of exposure in nearby communities to the identified contaminants and the risk of health effects attributable to those exposures, the risk for specific health effects in communities near industrial swine operations is a concern.
>
> North Carolina's 1994 Swine Odors Task Force stated "It is not surprising to learn that living near a swine operation can affect mental health" when discussing a Duke University study of "the moods of people exposed to odors from commercial swine operations in North Carolina. Forty-four neighbors of hog operations ... had less vigor and were significantly more tense, depressed, angry, fatigued, and confused.[8]

The letter then describes the EPA's consideration of the disparate impact analysis conducted by Drs. Steve Wing and Jill Johnston.[9] EPA warned DEQ of its "deep concern about the possibility that African Americans, Latinos, and Native Americans have been subjected to discrimination as the result of NC DEQ's operation of the Swine Waste

---

[8] *Id.* at 6.
[9] *See* Steve Wing and Jill Johnston, *Industrial Hog Operations in North Carolina Disproportionately Impact African-Americans, Hispanics and American Indians* (rev. Oct. 19, 2015), submitted to EPA in Case-11R-14-R4 (attached hereto as Exhibit 7).

General Permit program" in violation of Title VI and EPA's ensuing regulations.[10] EPA also expressed "grave concern" that our clients' members and staff had suffered intimidation from pork industry representatives in their efforts to get DEQ to address the harmful impacts from swine operations.[11]

EPA's letter concludes with seven sets of "preliminary" recommended actions. While all seven are critical, these three most directly relate to our requests:

- Conduct an assessment of current Swine Waste General Permit to determine what changes to the Permit should be made in order to substantially mitigate adverse impacts to nearby residents. Determine which changes are currently within NC DEQ's authority to make and develop a timetable for adopting them. For Permit changes necessary to substantially mitigate the adverse impacts that NC DEQ cannot adopt, determine the source of the impediment to their adoption.

- Conduct an assessment of current regulations applicable to facilities operating under the Swine Waste General Permit to determine what if any changes to the regulations would be required to substantially mitigate adverse impacts to nearby residents. Determine which changes are currently within NC DEQ's authority to make and develop a timetable to adopt them. For regulatory changes necessary to substantially mitigate the adverse impacts that NC DEQ cannot adopt, determine the source of the impediment to their adoption.

- Conduct an assessment of current mitigation technologies that would satisfy NC DEQ' s performance criteria for new or expanding industrial swine operations and what if any impediments exist to adopting those technologies.

It has been more than two years since EPA made the above recommendations. It has been more than a decade since such "mitigation technologies" were identified. It is unacceptable for DEQ to refuse to comply with its obligations under Title VI for another five years.

2. **The Title VI Settlement**

As part of the May 2018 settlement reached with DEQ, the agency agreed to a number of provisions to comply with its obligations under Title VI, including establishment of an effective Title VI program, improvements in environmental and public health protections in the Draft Permit, inclusion of impacted community members in the stakeholder input process, and development of an Environmental Justice geographical information tool ("EJ tool") to "allow DEQ programs to conduct environmental justice analyses" as a part of

[10] *See* Exh. 6 at 1.
[11] *Id.* at 8.

permitting.[12] At DEQ's February 4, 2019 public meeting regarding the EJ tool, the Department's Title VI Administrator, Sarah Rice, indicated that the tool will not be ready for implementation as part of the 2019 General Permit renewal.

It is necessary to address some apparent misunderstanding about the General Permit's discriminatory nature. During the Draft Permit public hearing on February 19, 2019, N.C. House Representative Jimmy Dixon incorrectly stated that claims of racially discriminatory impacts from "our animal facilities" are "misrepresented facts" because "if you take our animal facilities and you measure one half mile from them, it is 62% white." We set aside for the moment questions regarding what Rep. Dixon meant by "our animal facilities." We also question the relevance of Rep. Dixon's selection of a half mile as the appropriate metric for consideration, given that:

1) Significantly fewer people (less than one tenth as many) live within a half mile of a permitted swine operation than live within three miles. People living between a half mile and three miles away from any one CAFO are impacted by a higher concentration of CAFOs (sometimes dozens at once) than those living within a half mile of their closest CAFO;[13]

2) Decades of scientific research demonstrates air (including odor) and water pollution and concomitant adverse health effects experienced by residents within a radius greater than one-half mile of swine CAFOs in eastern North Carolina;[14]

[12] *See* Exh. 5. The agreement also contains other steps that DEQ must take, including a proposed implementation rule for the Violation Points System (see below at 26)(Exh. 5 at 5) and terms regarding acceptance of third-party data (*See*, *Letter from Sheila Holman to Complainants*, May 3, 2018, attached hereto as Exhibit 8).

Epidemiol. 174 (2017); Julia Kravchenko et al, *Mortality and Health Outcomes in North Carolina Communities Located in Close Proximity to Hog Concentrated Animal Feeding Operations*, 79 N.C. Med. J. 278 (2018).

3) Complaints of horrible odor, flies, buzzards and other burdens from neighboring CAFOs have been made by the REACH members who live more than a half mile from multiple CAFOs (both swine and poultry); and

4) All four nuisance cases tried so far against Smithfield (which resulted in multi-million- dollar jury verdicts) involved residents living more than a half mile from swine operations covered under DEQ's General Permit.

It is, however, critical to address a more fundamental misrepresentation underlying Rep. Dixon's statement. Latino, Native American and African Americans constitute a minority of North Carolina's population as compared to whites and as explained in the methodology section of Drs. Wing and Johnston's analysis (see Exhibit 7), "a larger *proportion* of non-Hispanic Whites in North Carolina live in remote rural areas than do Blacks."[15] However, the "percentages of [people of color, defined as everyone other than non-Hispanic whites], Blacks, Hispanics, and American Indians living within 3 miles of [an industrial hog operation] are 1.38, 1.40, 1.26 and 2.39 times higher than the percentage of non-Hispanic Whites, respectively."[16] These disparities are "highly statistically significant,"[17] which means they are not by chance or random.

So while it is correct that most people living near swine CAFOs in North Carolina are white—because whites are still the racial majority in the state and a larger proportion of that white population lives in rural areas—it is incorrect to conclude that there is no racially disparate impact from these facilities. Such a statement ignores the analysis and methodology required to determine disparate impact,[18] as well as the fact that although non-whites make up a minority of the total population, the communities living near permitted hog operations have disproportionately high percentages of black, Latino and Native American residents. Furthermore, the fact that there are also white people living in those communities does not contradict or rebut the statistical evidence presented by our clients to DEQ and acknowledged by the EPA that these operations disproportionately burden communities of color. Indeed, white residents living in proximity to hog operations would also benefit from cleaner air and water if DEQ required Permittees located near communities of concern to employ stronger protections and superior waste disposal technologies, but the agency's legal obligation under Title VI is to mitigate the demonstrated disparate impact on North Carolinians of color.

Given these facts and DEQ's obligation to comply with Title VI, the EJ tool must be designed, developed and deployed not only to identify whether a permit applicant's barns, lagoons and sprayfields are in close proximity to vulnerable populations (as measured by those neighbors' demographic and health indicators) and to a cluster of

[17] *Id.*
[18] *Id.*

other facilities and other sources of pollution, but also to assess potential cumulative impacts from other polluting operations within the three-mile radius.[19]

The EPA has defined "cumulative impacts" as the "[t]otal exposure to multiple environmental *stressors* . . . , including exposures originating from multiple *sources*, and traveling via multiple pathways over a period of time."[20] Incorporated here by reference and attached as Exhibit 10 is our September 2, 2016 letter brief to the EPA on cumulative impacts from hog CAFOs covered by DEQ's General Permit, which addresses with supporting research three stressors that contribute to the General Permit's cumulative adverse impact:

> First, EPA must account for the cumulative impacts of more than 2,000 IHOs [industrial hog operations] in a relatively small geographic area. Eastern North Carolina is more densely populated with hogs than anywhere else in the United States. Second, EPA must analyze the environmental contamination and associated risks to human health stemming from the cumulative impacts of IHOs and the many industrial poultry operations clustered in this same region. Finally, any analysis of the adverse impacts of IHOs in eastern North Carolina would be grossly inadequate without consideration of the affected community's pre-existing vulnerability, which results from racial discrimination, poverty, and other factors.[21]

Consideration of cumulative impacts is particularly critical given the co-location of the swine and poultry industries in the state. As of 2018, there were 516 million birds confined in industrial operations in North Carolina, up from 147 million in 1997, according to a recent report by the Environmental Working Group and Waterkeeper Alliance.[22] The report found that industrial hog and poultry farms in the state are highly concentrated together, with 93 percent of poultry operations located within just three miles of 20 or more other poultry and swine operations.[23] Pollution from both swine and poultry

[23] *Id.*

facilities is now contaminating the same waterbodies,[24] which are already suffering from high nutrient loads. Poultry manure, which is often applied as fertilizer, contains many of the same nutrients as hog manure, including nitrogen and phosphorus. At this point, statewide, industrialized poultry operations cause even more nutrient pollution than hogs.[25] The presence of both poultry and hog facilities in the same areas raises the risks of harms to water quality. Therefore, the co-location of industrial hog and poultry operations demands that the permit require the assessment of cumulative impacts from both kinds of operations – to ensure that decisions take account of real-world conditions.

In sum, in order to comply with Title VI, DEQ must take significant steps in the 2019 General Permit to address the permit's discriminatory and cumulative impacts. The above requested changes on page 1 of the Draft Permit are two necessary steps.

As described in our December 21, 2018 stakeholder comments, important recent events make this the most critical time for major changes in the Swine General Permit, including Smithfield's announcement of its plans for methane recapture at many of its operations; the increased frequency and severity of storms and rainfall; and the growing body of scientific literature that demonstrates that industrial hog operations using the lagoon and sprayfield system threaten human health and the environment. We applaud the positive changes that DEQ has made in the Draft Permit, and offer the following concerning other specific conditions and terms:

Condition I.1: Definition of Discharge and Storm Standards

We support DEQ's effort to update the definition of the 25-year, 24-hour rainfall event from reliance on an outdated 1960's era bulletin to more recent NOAA standards. However, the Draft Permit undercuts DEQ's recognition that the science and the facts have evolved since the 1990s by allowing facilities to be "designed, constructed, operated, and maintained to contain all waste plus the runoff from a 25-year, 24-hour rainfall event ***at the time of construction for the location of the facility***" (emphasis added). As storms hit North Carolina more frequently and more severely, the state needs to ensure that it updates its interpretation of the standard to protect the environment and communities from harmful manure waste runoff. In addition, DEQ must follow the science and require all operations to adhere to the same updated and uniform storm standard rather than outdated definitions established "at the time of construction."[26]

[24] *Id.*
[25] *Id.*
[26] Given the effects of climate change and the increasing frequency of even 100-year storms, if lagoons were to be built today, they should meet the even stricter standards of 100-year/24-hour rainfall events. As indicated above, however, we are not requesting the significant investment that this standard might require. We call on DEQ to plan for the transition from lagoons and sprayfields and in the meantime, recognize that a standard developed for a 25-year/24-hour storm event is grossly inadequate and not sufficiently protective of the waters or people of the state.

Hurricanes, storms, and extreme precipitation events in North Carolina have increased in both severity and frequency due to climate change.[27] Researchers project that average winter precipitation in North Carolina will increase up to 25% in the next 50 years at the current rate of warming.[28] The number of "heaviest 1%" rainfall events along the Mid-Atlantic coast rose nearly 30% from 1958 to 2016.[29] Since 1999, North Carolina endured at least four hurricanes or tropical storms that qualify as 100-year storms: Floyd in 1999,[30] Irene in 2011,[31] Matthew in 2016,[32] and Florence in 2018.[33] During Hurricane Floyd, Wilmington experienced a 24-hour record of 15.06 inches of rain.[34] Even according to updated NOAA rainfall standards, this exceeds the 100-year, 24-hour rainfall frequency of 12.7 inches.[35] Hurricane Irene produced enough rain over the northeast portion of the state to exceed a 25-year rainfall event.[36] Hurricane Matthew, which hit North Carolina just 15 years after Floyd, resulted in record levels of precipitation. Rainfall in Fayetteville, in the region of the state most concentrated with swine CAFOs, exceeded the town's 1000-year, 24-hour rainfall event of 8.6 inches by 6 inches.[37] Most recently, Hurricane

Florence dumped 8.84 inches of rain within 24-hours in Fayetteville, also exceeding the current storm definition.[38]

The heavy rainfall associated with extreme storms cause severe flooding. For example, multiple rivers and streams in North Carolina reached 100-year flood volumes during both Hurricane Floyd[39] and Hurricane Matthew.[40] During Hurricane Floyd, there were 14 distinct 500-year or greater floods in the eastern part of the state.[41] Sudden inundation of rainfall into uncovered swine manure lagoons caused the volume of waste to exceed the facilities' holding capacity, leading to structural failures and overflowing of waste matter onto flooded fields and into waterways. Hurricane Floyd flooded 45 swine lagoons, causing algal blooms and mass fish die-offs.[42] In 2016 with Hurricane Matthew, at least 14 hog lagoons flooded and two breached. After Hurricane Florence, North Carolina DEQ reported that 6 lagoons experienced structural damage and 33 lagoons overtopped, with an additional 10 lagoons operating at a level where overtopping was likely because the structure had no room to store additional liquid.[43] Overall, the agency reported hundreds of incidents representing environmental threats at animal operations due to flooding and inundation in the wake of the storm.[44]

With heavy rainfall, nutrients and disease-causing agents from sprayfields enter nearby streams through surface and subsurface runoff.[45] These pollutants, such as phosphorus and nitrogen, already have caused significant damage in streams and other water bodies

in eastern North Carolina.[46] In addition, pathogens and bacteria from the runoff fecal matter contaminate drinking water sources and threaten human health. In the weeks following Hurricane Florence, nearly 30% of tested drinking water wells contained fecal coliform bacteria at levels above the EPA health-based standard.[47] Drinking water with elevated levels of bacterial contaminants increases the risk of infection and illness.

Extreme rainfall in the future will cause even more runoff from swine waste management systems, polluting the environment and harming public health. DEQ's interpretation of the requirement that lagoons must meet a 25-year/24-hour storm event must keep up with the science and ensure that animal operations are prepared for the increasing severity of rainfall events.

It is inappropriate to ask only that facilities comply with historic standards from ten or twenty years ago when a lagoon was built, because these facilities were not designed to sustain the magnitude of extreme storms today. Prior to the adoption of the 25-year, 24-hour rainfall event developed by the National Oceanic and Atmospheric Administration in 2004, the General Permit used a definition from a 1960's technical bulletin.[48] This standard would have applied to any operation constructed prior to the adoption of the NOAA 2004 definition. A comparison of the precipitation quantities at various storm frequencies demonstrates the increasing probability of experiencing extreme rainfall events. The 1960's rainfall frequency atlas defines a 50-year, 24-hour rainfall event in Fayetteville, NC as just under 7 inches of rain.[49] In the updated atlas, a rainfall event producing between 6.16 to 7.19 inches is predicted to occur every 25 years rather than every 50 years.[50] A 25-year storm standard that would have applied to past permitted facilities now reflects the maximum amount of rain from a 10-year storm.

Operating and maintaining facilities based on historic standards and climate conditions is no longer adequate to limit waste runoff. In Fiscal Year 2017-2018, the large majority of permit violations discovered during Division of Water Resources (DWR) and Division of Soil and Water Conservation (DSWC) inspections related to manure management

issues.[51] 20% of all permit violations at swine operations (24 out of 121) were due to discharges from animal waste management systems; 83% of these discharges reached state surface waters.[52] Another 29% of violations documented "inadequate freeboard," in which lagoon structures held waste volumes above the maximum operating level.[53]

Condition I.4: Amendments

We support the new requirement that amendments be included as part of the CAWMP and be submitted to the Division's Central Office within 30 days. Under the 2014 permit, Permittees were not required to submit an amendment to the Division Office "unless specifically requested." This change will lead to greater transparency and accountability by allowing public access to records of amendments, which will no longer be kept only at the facility. This additional transparency is crucial, allowing community members who are affected by pollution to access information on changes to waste management activities, including land application, and to learn of any changes in a reasonable time. This will reduce the likelihood that amendments will lead to adverse effects on the environment.[54]

Condition I.12: Setbacks

We encourage DEQ to adopt stronger setbacks for land application of waste. The current requirements contained in the Draft Permit continue to be inadequate for protecting human health and the environment. DEQ should act on its authority to implement more protective standards for land application than those specified by statute.[55]

Abundant scientific research has demonstrated that land application of waste impairs water quality, supporting the need for strong setbacks.[56] Overapplication and application to saturated soils can cause contaminants to enter waters through runoff. [57] Significantly, even when waste is applied at recommended application rates, contamination can still

occur.[58] Research has also linked land application to the presence of antimicrobial residues in stream water,[59] and surface waters near sprayfields have been found to contain high concentrations of fecal indicator bacteria.[60] A study in North Carolina revealed that 22% of the nitrogen in waste applied to sprayfields was lost to offsite transport, suggesting that nitrogen could be contaminating nearby water resources.[61] As mentioned in previous comments, North Carolina needs particularly stringent requirements for setbacks due to its high concentration of industrial animal operations and its unique hydrological and geological features.[62] Porous soil and high water tables increase the risk that nutrients from waste application will contaminate water sources, including drinking water.

Despite its need for especially strong protections for water resources, North Carolina's requirements for setbacks are lower than in other states. In this Draft Permit, setbacks for wells remain only 100 feet, which is significantly lower than other states' requirements. For example, as mentioned in past comments, South Dakota requires setbacks of at least 250 feet from private wells,[63] South Carolina requires a 200-foot setback from any drinking well,[64] and Wisconsin requires a 1,000-foot setback from community wells.[65] In addition, Indiana recently required that CAFO waste management systems be located a minimum of 1,000 feet from public water supply wells.[66] Due to the vulnerability of drinking water sources in many areas of North Carolina, land application should only be allowed to occur a minimum of 500 feet from wells, rather than only 100 feet. North Carolina, with its particularly vulnerable water resources, should have even stricter standards than these other states.

While we welcome the inclusion of specific setbacks for land application from water bodies in this Draft Permit, the distances fall far short of what is necessary. The setback requirements prior to 1997 have been recognized to be inadequate; therefore, older facilities should not continue to be held to these weaker standards. The setbacks should

equal the distance necessary for preventing contamination of waterbodies, which is DEQ's obligation. Older facilities should not be given more leeway at the expense of environmental quality and impacts on nearby community residents. In addition, having one standard for land application for all facilities will make compliance and enforcement more straightforward.

Even a 75-foot setback from surface waters for all facilities would be inadequate. The EPA NPDES manual requires that setbacks for manure application for large CAFOs must be "a minimum" of 100 feet "from surface waters and conduits to surface waters."[67] Some states have recognized the need for even greater protections. For example, Indiana requires setback distances of 300 feet from surface waters, as of 2018.[68]

Condition II.4: Nutrient Management Plan

We strongly support the new language clarifying that agronomic rates for land application must account for "all nutrient sources," rather than only nutrients from the swine waste being applied. This change will help ensure that land application does not occur at greater than agronomic rates, since analyses prior to land application should account for all potential nutrient sources, including commercial fertilizer, effluent, sludge, and waste from other animals.

Preventing excessive application of nutrients is critical since the watersheds impacted by land application already suffer from high nutrient loads. For example, nutrient enrichment has been highlighted as the primary threat to water quality in both the Tar Pamlico River Basin and the Neuse River Basin.[69] Excessive nutrient enrichment harms the environment by contributing to fish kills, algal blooms, and contamination of drinking water.[70] High nutrient loads in surface and groundwater indicate that land application has failed to occur at proper agronomic rates, leading to excess nutrients being leached into waterways.[71] Moreover, ensuring proper land application practices, and

[71] The nutrient load in waterways is also affected by the deposition of volatilized ammonia. Calculations of agronomic rates will be grossly inadequate until they take into account this significant nutrient source. It is vital that DEQ require facilities to do so in the next permit.

thus preventing water contamination from leached nutrients before it occurs, is especially critical due to the lack of comprehensive water monitoring requirements for CAFOs.

This proposed change is especially important given the rapid rise in the number of poultry operations in the same areas where hog operations are located, discussed above.[72] Under these conditions, application rates must take into account potential impacts of the co-location of poultry and swine facilities. The revision to Condition II.4 is a welcome move in that direction, since it will require that all nutrient sources be accounted for when determining agronomic rates for land application.

Condition II.7: Operator in Charge ("OIC")

We support the clarification regarding the OIC's responsibilities, which are reasonable measures to ensure that all land application is properly inspected, monitored, documented, and supervised in a timely manner. The additional requirement that if neither the OIC nor designated back-up is present during land-application of waste then the OIC or designee must inspect the application site within 24 hours of the application, should be amended to require not just inspection but completion of the requisite inspection records within that time period. Inclusion of OIC oversight in the permit, and the removal of the overbroad affirmative defense "loophole" is necessary to reduce the risk of discharge and other permit violations and will improve accountability and transparency.

Condition II.10: Disposal of Mortalities

We applaud DEQ's decision to clarify that "burial is not recommended for disposal of dead animals." This provision of the Draft Permit is consistent with guidance published by the North Carolina Department of Agriculture and Consumer Services ("DACS"), which deems burial a "limited on site disposal option due to flooded conditions and often minimal depth to seasonal high water table."[73] However, we urge DEQ to impose meaningful safeguards to protect public health and the environment in situations in which burial occurs.

---

[72] *See supra* n. 20-22.

[73] N.C. Depart. of Agric., *Mass Animal Mortality Management Plan for Catastrophic Natural Disasters,* 2 (2016), http://www.ncagr.gov/disaster/documents/massmortalityguicanceplan.pdf. In emergency conditions that require burial, DACS recommends that operators maintain at least 12 inches of soil between the bottom of the burial hole and the seasonal high water table; maintain at least 3 feet of soil covering any buried animal; maintain at least 300 feet from any existing stream, public body of water, or public water supply well, and at least 100 feet from any other type of existing well; and locating a burial site "so as to minimize the effect of stormwater runoff." N.C. Depart. of Agric., *Animal Burial Guidelines During a Declared Emergency*, 2 (2011), http://www.ncagr.gov/oep/Storms/ANIMAL_BURIAL_GUIDELINES_April_2011.pdf.

Burial of dead animals can significantly impair water quality.[74] Indeed, burial pits often release more pollution than municipal and industrial sewage plants.[75] As animal carcasses decay, they release nutrients (nitrogen and phosphorus), chloride, disease-causing agents present in animal waste, ammonia, and nitrates into the environment—potentially rendering groundwater unsafe to drink.[76] This pollution continues until carcasses delay completely, a process that can take up to two years.[77]

Improper burial also reduces the quality of life and threatens the health of those living nearby. Areas surrounding industrial animal facilities already host high numbers of flies, birds, and rodents—all of which may feed on improperly buried carcasses.[78] Because animal carcasses can carry antimicrobial-resistant pathogens,[79] improper burial facilitates the movement of these pathogens into nearby communities and may lead to the development of antibiotic-resistant bacteria.[80]

We urge DEQ to impose groundwater-monitoring requirements near burial sites, as discussed below. Hurricane Florence recently caused the deaths of more than 5,500 hogs, nearly double the number killed during Hurricane Matthew.[81] Given the increasing frequency and intensity of extreme weather events due to climate change,[82] severe storms and mass mortalities are likely to continue in the future.

[82] Cynthia Rosenzweig et al., *Climate Change and Extreme Weather Events; Implications for Food Production, Plant Diseases, and Pests,* 2 Global Change & Human Health 89, 89-104 (2001).

Operators likely require more than 24 hours to develop an appropriate plan for managing mass mortalities. During Florence, high levels of precipitation and flooding continued long after initial hog deaths occurred. As a result, operators who planned to bury dead animals were likely unprepared to take prompt and responsible action, since burying dead animals in flooded soil directly contributes to release of pollutants into groundwater.

To protect public health and the environment, DEQ should work with the State Vet pursuant to its authority under N.C. Gen. Stat. 106-403 to prohibit mass burials during rainfall events and within floodplains. In addition, DEQ should increase the minimum distance of the burial site to the nearest groundwater well to a quarter mile (1,320 feet).[83] Information about mortalities should be added to the annual certification form. Additional challenges associated with mass burial should be addressed on a case-by-case basis.[84]

Condition II.19: Application of Waste in Wind Conditions

We applaud DEQ's decision to prohibit facilities from applying waste in wind conditions that cause or might reasonably be expected to cause waste to reach surface waters or wetlands or cross boundary lines or field boundaries. The Draft Permit provides an objective standard for land application and clarifies that operators are responsible for ensuring that waste does not in fact reach surface waters or wetlands or cross property lines or field boundaries. This provision is particularly important because certain wind conditions can carry mist containing disease-causing agents into vulnerable ecosystems, including surface waters and wetlands, and across property lines threatening human health.

Livestock waste contains harmful bacteria, viruses, and other pathogens that can infect humans and cause serious illness. In CAFO waste slurries, these disease-causing microbes can survive for weeks at a time.[85] Surface applications of bacteria-rich wastes to nearby fields are imprecise, leading to deposition of fecal matter and associated microbes and contaminants downstream. In the days following applications, harmful microbes have

---

[83] The Washington State General Permit prohibits natural decomposition within 1,320 feet or less from any groundwater well, spring, sinkhole, or body of surface water, and in an area that has a seasonally high water table, seasonal floods, or within a hundred-year floodplain. We urge DEQ to implement similar restrictions on mass burial during a catastrophic mortality event to prevent environmental and health harms. *See* Wash. State Dept. of Ecology, *Response to Comments for the Concentrated Animal Feeding Operation National Pollutant Discharge Elimination System and State Waste Discharge General Permit and Concentrated Animal Feeding Operation State Waste Discharge General Permit*, 47 (Jan. 18, 2017), available at: https://ecology.wa.gov/DOE/files/5f/5f39ec9a-7687-442e-b8f1-1376ba2a4687.pdf.
[84] *Id.*
[85] Jane L. Mawdsley et al., *Pathogens in Livestock Waste, Their Potential for Movement Through Soil and Environmental Pollution*, 2 Applied Soil Ecology 1, 1–15 (1995).

been detected in groundwater and streams far from the site of application.[86] The area of potential exposure is much larger than the immediate area surrounding the site of application.

People living and working near application sites suffer exposure to these microbes and pollutants for extended periods, putting them at higher risk of health complications. Researchers have found swine fecal particles inside residential homes located near swine facilities in eastern North Carolina.[87] Contact with and consumption of food in contact with fecal particles containing bacteria and viruses can lead to infections. Wind-dispersed ammonia and the associated odor also pose significant threats to human health and wellbeing, causing symptoms that include headaches, nausea, hives, anxiety, irritated and dry eyes and throat, and depression.[88] Requiring facilities to limit and prevent spreading of airborne fecal matter and pollutants from spray mist is crucial to protect community health.

Condition II.23: Ceasing land application after storm warnings/watches
The Draft Permit expands land application up to 12 hours after storm watches and warnings, rather than four hours as in the stakeholder draft permit and the current permit. We oppose this change and urge the Department to revert to the original 4-hour window after which to cease land application following issuance of a National Weather Service (NWS) Hurricane Warning, Tropical Storm Warning, or a Flood Watch/Flash Flood Watch. It appears that the window was expanded from 4 to 12 hours at the swine industry's request, based only on industry's unsubstantiated claim that the NWS has begun issuing warnings and watches 36 hours in advance of a storm's arrival. This condition must ensure that waste has enough time to incorporate into the soil before precipitation in order to prevent waste from entering storm runoff from fields. Given the increasing intensity and severity of storms and rainfall, and the overwhelming impacts from flooding from Hurricanes Matthew and Florence in 2018, any reduction in the amount of time that sprayed waste can be absorbed by crops before a significant rain event is unconscionable and ignores scientific climate evidence described in our comments on Condition I.1. above. While storm watches and warnings might now be issued 36 rather than 24 hours in advance, this is not necessarily always the case, as the National Weather Service says warnings are "generally within 36 hours" and "are expected within 36 hours."[89] Requiring cessation of land application within 4 hours of the NWS

watch or warning is a critical safeguard to prevent runoff and discharge. This change should be reversed.

Conditions II.18, II.24, III.2, and III.3: Requirements for Installation of Automated Technology

In North Carolina, antiquated, lower-tech systems for managing swine waste continually lead to permit violations that jeopardize public health and environmental quality. Automated technology that is affordable and widely available could help address these pervasive and severe violations.
We again encourage DEQ to plan now for the transition to more sustainable alternatives to the lagoon and sprayfield system. While the agency continues authorizing the use of the lagoon and sprayfield system, however, we support new language in Conditions II.18, III.2.c., and III.3 clarifying when the Division will use its authority to require automatic flow monitoring equipment, automated waste-level monitors and recorders, and automated rain gauges and recorders are necessary, though these provisions don't go far enough. The permit should require that all Permittees install these devices, instead of requiring them only on a case-by-case basis. Mandatory installation of these three kinds of devices would improve Permittees' ability to comply with several permit provisions. Automatic flow meters improve the quality of recordkeeping and calculations needed for proper maintenance of lagoons and sprayfields. Automated waste-level monitors and recorders enable Permittees to monitor and record lagoon waste levels with greater accuracy and consistency. The increasing frequency of severe weather events makes the use of these devices all the more important, since they enable data collection during storms, when it is most crucial. Similarly, automatic rain gauges are a simple, inexpensive way to improve the accuracy of records of precipitation events. These devices leave less room for human error and intentional non-compliance from self-monitoring and self-reporting.

At minimum, if installation of automatic flow monitoring equipment, automated waste-level monitors and recorders, and automated rain gauges and recorders continues to be on a case-by-case basis, the permit should state that circumstances beyond those explicitly listed in these conditions can lead DEQ to require these technologies. Language should be added to Conditions II.18, III.2, and III.3 to make clear that devices can be required as deemed necessary by the Director.

Furthermore, Condition II.24 should be modified to require that all Permittees install devices to stop irrigation during precipitation events. We are opposed to Permittees being given the choice between installing automated equipment and committing to the presence of an Operator in Charge (OIC) during land application of waste. These two options do not provide equivalent protections, since the written commitment to have an OIC present does not address the possibility for willful noncompliance. It is already a permit violation to land apply waste during precipitation events. Under the current permit, Permittees already have an obligation to avoid this practice and the OICs, their backups, or someone under their supervision is already required to inspect "the land application site as often as necessary to insure that the animal waste is land applied in accordance with the CAWMP."[90] This human element has proven repeatedly inadequate to prevent violation of the permit. Requiring installation of devices to automate compliance for all Permittees would help combat violations of the prohibition on land application during precipitation, which have been widely observed by Waterkeeper Alliance and community members. In addition, for those Permittees who elect to or are required to install these devices, they should be required to complete installation within six months, instead of 12 months. This shorter timeframe would ensure that devices to stop irrigation during precipitation events would be in place prior to the hurricane season of 2020. It is bad enough that the industry will enter the 2019 hurricane season without such technology in place.

In addition, all Permittees should be required to notify DWR in writing when devices covered by Conditions II.18, II.24, III.2, and III.3 have been installed. Finally, Condition II.18 on flow monitoring equipment should contain language similar that in Conditions II.24, III.2, and III.3 requiring that devices be properly maintained in line with the manufacturer's instructions and warranties.

Condition II.28: Crop Removal

Although we support the effort to clarify crop removal requirement, 24 months is far too long to adequately protect against decomposition and the return of nutrients into the soil. As discussed below, we support a more reasonable time-frame for the removal of hay bales (either in the form of actual removal or, absent a reasonably short time frame for actual removal, then for proper storage) on/near CAWMP fields.[91]

Timeline for Harvesting

Allowing cut crops to lie on the land results in decomposition. As crop residues decompose, nitrogen and phosphorus are released back into the soil through N mineralization and then nitrification, becoming available for leaching in the process.[92]

---

[90] Permit AWG 100000, II.17.

Mineralized N becomes available to plants for uptake or to leaching through nitrification or, particularly in areas with high-water-table soils, enters the atmosphere as gaseous nitrous

Crops and soil conditions found in eastern North Carolina where the highest concentration of these operation are located lend themselves to increased N mineralization of decomposing crop residues.[93] In the 24 months that the current provision language allows crop residues to remain after cutting, significant amounts of nitrogen and phosphorus once stored in crops will leave the decomposing plant residues and return to the soil in a leachable form.[94] If the objective of applying waste to crops is to take up nutrients from the soil to prevent leaching and to remove these nutrients from the system, this provision should be amended to clarify that the harvest of cut residues must be completed within 1 to 2 weeks.[95]

A more appropriate time frame in which to harvest cut crops would be 1-2 weeks, and not more than 6 months.[96] The shorter time period would also improve hay and silage

---

oxide (a greenhouse gas) through denitrification. P in crop residues is mostly in forms already bioavailable to plants and will likely join the soil solution or become adsorbed to soil particles upon decomposition from crop residues; P in the soil solution or adsorbed to soil particles is available for leaching or loss to water through erosion).

[93] Baoqing Chen et al., *Soil Nitrogen Dynamics and Crop Residues. A review*, 34 Agron. Sustain. Dev. 429–442 (2014) (N mineralization, and therefore the risk of leaching, is impacted by crop composition and soil type. Even during decomposition of crops like hay with high C:N ratios, microbes might at first immobilize N, but decomposition process eventually lead to a net N mobilization for these crop residues); T. M. Egelkraut, D. E. Kissel & M. L. Cabrera, *Effect of Soil Texture on Nitrogen Mineralized from Cotton Residues and Compost*, 29 J. of Envtl Quality; Madison 1518 (2000) (sandier soils like those in eastern North Carolina mineralize more N than soils comprised of higher percentages of silt and clay, possibly because sandy soils have less aggregate protection of decomposing organic matter, freeing up more of the crop residues to decomposition and, consequently, N mineralization and leaching).

[94] I. K. Thomsen et al., *Net Mineralization of Soil N and 15N-ryegrass Residues in Differently Textured Soils of Similar Mineralogical Composition*, 33 Soil Biology and Biochemistry 277–285 (2001) (N mineralization of decomposing crop residues can begin on day one of cutting and contact with the soil and continue, though at a decreasing rate, until the residues are completely decomposed. Ryegrass decomposition studies show continued N mineralization during the entire study period of seven months, at which time, as much as 36% of N from the ryegrass residues was recovered in the soil as mineral N); H. Shindo & T. Nishio, *Immobilization and Remineralization of N Following Addition of Wheat Straw into Soil: Determination of Gross N Transformation Rates by 15N-ammonium Isotope Dilution Technique*, 3 Soil Biology and Biochemistry 425–432 (2005) (wheat straw decomposition can transition from immobilization to mineralization in a matter of weeks, if not sooner. The N remineralisation rates of wheat straw have been documented at 0.71, 0.55 and 0.29 mg N kg–1 day–1 after 7, 28 and 54 days, respectively—indicating a faster rate of return occurs in the first week).

quality. Most growers harvest and remove hay and other feed crops after cutting within a week, if not much sooner.[97] Furthermore, research from USDA Extension programs advocates for "Haylage in a Day" practices that consolidate cutting, drying, and removal steps within a single day to allow for enough drying out time to avoid rot while maximizing the amount of total digestible nutrients in the hay or silage.[98]

Timeline for Removal after Harvesting
Once crops on land application sites have been harvested, they should be removed from contact with the land and, if kept onsite, stored in such a way that minimizes the chance of decomposition and return of nutrients to the soil in order to guarantee compliance with the CAWMP. At a minimum, this Condition should clarify that if harvested crops are not physically removed from the land application site then operators must remove harvested crops from contact with the ground when stored on the land application site. The same timeframes for decomposition of crop residues described above applies to harvested crops. Therefore, crops should be removed according to the definition described above within 1-2 weeks of harvest, and at the very least no later than 6 months after harvest. Again, this timeline is reasonable, as most growers now cut, harvest, and remove their hay all in a week, if not in a day.

Conditions for Proper Removal via Onsite Storage
The closer in contact soil particles and plant residues are, the faster decomposition occurs.[99] The optimal conditions for decomposition are high water content, small residue size with high surface area for soil contact, and high temperatures. Therefore, to minimize the chance of returning nutrients to the soil—and to improve the quality of stored hay—the permit provision should specify the conditions for storing hay as a form of "removal" after it has been cut and harvested from the land application site.

Hay exposed to moisture and/or sunlight will decompose faster. Contact between hay and soil is the most critical aspect of hay decomposition and spoilage and should be eliminated.[100] Bales stored outside, exposed to the elements, on the ground and without a cover can see a sharp increase in moisture content, as much as 120% for the outer 3 inches, which can speed up weathering and decomposition of the hay.[101] In areas of high precipitation or humidity, improper storage can lead to greater than 50% loss of dry

---

P during decomposition processes predominantly span just 2-6 months, during which time decomposition processes occur most rapidly with significant initial nutrient losses).

[101] *Id.*

matter, which is detrimental to forage quality and efforts to prevent leaching.[102] Over the course of just several months, storing bales outside unprotected in the eastern United States can lead to decomposition and extensive and costly loss of feeding value for at least the outer 5-6 inches of hay, with greater losses at the bottom of bales due to contact with the soil.[103]

To avoid speeding up decomposition, the permit should require that hay be stored either 1) offsite or 2) if onsite, on pallets, pads 4-8 inches deep of rocks 1-3 inches in diameter, concrete, or some other base to raise the hay off of bare ground; securely covered as a group or as individual bales with a woolen blanket, flannelette sheet, plastic sheeting at least 6 mil. thick, net wrap, tarp, or other cover that protects bales from moisture while ideally letting the hay breath; and in high density bales of at least 10 pounds per cubic foot if a round bale. Even bales individually wrapped in covers should not be stored directly on the ground.[104] Bales stored outside in rows should run up and down well-drained, gentle slopes to avoid trapping water, should be stored with ends of bales butted tightly together, and should have at least three feet between the rows.[105] These conditions are in line with best storage practices for preserving hay and silage quality and are widely recommended by extension agencies and industry entities to improve crop quality during storage.[106]

In addition to these criteria for any storage on site, the permit should set a limit for how long bales can be stored onsite. Even with the best practices described above, nutrient loss from bales stored for 12-18 months can be double that of bales stored for less than 9 months.[107] Therefore, this permit should limit onsite storage of hay bales to a maximum of one year.

Condition III.2, 3b: Criteria for Monitoring and Recording Waste Levels

We urge DEQ to make automated monitoring/recording of waste levels mandatory for all facilities, instead of requiring it on a "case by case" basis. Given the increase in extreme

[107] Huhnke, *supra* n.106.

weather events due to climate change, the accuracy and precision of waste levels are increasingly important and time-sensitive. Automatic monitors make information available when it matters most. They are also more accurate and can store data, which can simplify the Permittee's job, while providing an accurate record at relatively low cost.

We appreciate the Division's removal of the freeboard violation pre-condition from III.2(c) as a step in the right direction. We note what appears to be an inadvertent failure to delete this sentence from III.2(c): "The Director may determine that installation of automated waste level monitors is not required if the Permittee can demonstrate that preventative measures were taken to avoid the violations and that the violations resulted from conditions beyond the Permittee's control." Because of the elimination of the freeboard violation requirement, this sentence makes no sense here.

Condition III.8: Mortality Records

Increasing the regularity of recordkeeping from monthly to weekly is an important step towards more effective oversight and, when necessary, investigation relating to the mortality and disposal of animals. The particular odors, vermin, pestilence, and other adverse impacts from the collection and disposal of dead hogs continue to be a central element in complaints from residents and were raised in the Title VI complaint.[108] Additionally, this increased oversight of animal mortality at permitted facilities is consistent with DEQ's new provisions in Condition II.10 regarding disposal of dead animals, which incorporate specific record-keeping and reporting requirements, and help improve oversight and transparency.

Condition III.9(f): Waste Samples Following Discharge

This Draft inexplicably deletes the provision requiring facilities to obtain waste samples within 48 hours after first knowledge of a discharge from a lagoon to surface waters.[109] This provision needs to be restored, as it is fundamental to ensuring accountability and transparency to the public, as well as to securing accurate and timely data regarding the potential impact of any discharge, which becomes more difficult to assess if sampling is delayed. During the stakeholder process, industry representatives objected to requiring sampling within 48 instead of 72 hours on the grounds that labs are not open on weekends. We requested sampling happen within 24 hours of knowledge of discharge.

---

[109] *See* Draft Swine Waste Management System General Permit for Stakeholder Process, III.9(f)(48 hour standard); Swine Waste Management Permit (2014), III.9(f) (72 hour standard).

Condition III.10-III.14: Groundwater Monitoring

These provisions reaffirm the Division's existing regulatory authority to require a Permittee to undertake any necessary monitoring and reporting to protect surface water, groundwater, and wetlands. By its express terms, this provision requires individualized assessment and provides an important "first-line" of defense from any actual or potential adverse off-site impacts of permitted operations. The Division must retain the full range and scope of potential monitoring and reporting requirements, since this provision is designed to identify possible impacts, and any necessary monitoring, testing, or mitigation, as early as possible.

Support for Groundwater Monitoring in the 100-year Floodplain

We strongly support the additional provisions in Condition III.10-III.11 that require on-site groundwater monitoring at facilities with structures in the 100-year floodplain. The high-water table, low organic matter content, and sandy nature of these soils create conditions in which lagoon pits and spray field manure applications can leach nitrogen, phosphorus, and bacteria into groundwater and surface waterways. Studies have repeatedly found elevated nutrient levels below spray fields and downstream from lagoons in North Carolina, not just in the 100-year floodplain.[110] North Carolina watersheds with CAFOs have significantly higher concentrations of ammonium, nitrate, and total N than those without CAFOs.[111]

Facilities operating in the 100-year floodplain are more vulnerable to the risks of groundwater contamination due to flooding and high water tables. The Legislature recognized this risk in 1995, when it passed N.C. Gen. Stat. § 106-802(a2), prohibiting construction of new animal waste management systems in the 100-year floodplain, and again in 2007 when it amended N.C. Gen. Stat. § 143-215.10I to establish superior technology performance criteria and the Lagoon Conversion Program which came with significant financial investment.[112] In the last two decades, the risks associated with operating a facility in the 100-year floodplain have only increased. In light of climate change and more intense and frequent severe weather, CAFO operations in the 100-year floodplain are even more vulnerable to flooding and the surrounding area will be more at risk of groundwater and surface water contamination.[113]

Conditions to Trigger Groundwater Monitoring Outside of the 100-year Floodplain

The groundwater monitoring proposals in this Condition are a necessary step toward improved monitoring and enforcement to support the health and well-being of North Carolinians. However, the permit should specify additional key conditions that will trigger groundwater monitoring of facilities outside the 100-year floodplain, and these triggers should target the CAFOs most at risk of polluting and the areas most at risk of being polluted. Such triggers should include the following:

1. *Operations that employ burial as a mortality management strategy* – We applaud that this permit disfavors burial of mortalities, discussed above regarding Condition II.10. If facilities are still using burial, they should monitor groundwater for relevant contaminants. Livestock burial sites produce leachate that can contaminate groundwater, especially in areas with elevated water tables and sandy soils.[114] Complete decomposition of animal carcasses can take two years, and even as long as ten years depending on environmental conditions.[115] During the period of decomposition, animal carcasses can release greenhouse gases and leachates containing high levels of chemical contaminants including high electrical conductivity, turbidity, biochemical oxygen demand, ammonium-nitrogen, total dissolved solids, and Cl^- and SO_4^{2-} concentrations.[116] Elevated chloride levels in particular are good indicators of burial-related groundwater contamination. Burial sites can also lead to groundwater contamination from pathogens and bacteria including fecal coliform, *C. perfringens*, and, especially, *E. coli*.[117] Additionally, bacteria like sulfate-reducing bacteria can also serve as indicators of groundwater contamination from livestock burial sites. [118] Lastly, antibiotics are also likely present in the leachate from decomposing carcasses.[119]

2. *Scale and environmental context of a facility* – Studies indicate that the concentration of facilities in a given area, the amount of area covered by wetlands, and the amount of land under a sprayfield system together correlate with measurable effects of CAFO waste manures on surface water quality. In the shallow aquifer system of the North Carolina Coastal Plain, groundwater discharge

to receiving streams contributes about 50-60 percent of the annual stream flow in the region.[120] Therefore, not only do the findings of groundwater studies bear weight in considering the impacts of CAFOs on groundwater quality, surface water studies in the region hold relevance, as well, as proxy indicators of groundwater quality. Watersheds with lower percentages of wetlands and higher swine barn densities and/or higher total acres of land application area have the most significant measurable impacts on surface water quality.[121] Therefore, groundwater-monitoring requirements should be triggered in watersheds with 1) a high concentration of CAFOs or a high amount of land area sprayed with animal waste *and* 2) a low percentage of wetland area.[122] This requirement should be triggered by a facility's proximity to a community of concern, discussed above at 7-8.

3. *Lagoons with a bottom elevation less than a minimum of 2 feet above the seasonal high water table* –These facilities are not compliant with the Natural Resources Conservation Service Waste Storage Facility Pond Criteria (313-Practice Standard), which requires that all ponds have a bottom elevation that is a minimum of 2 feet above the seasonal high water table.[123] Such lagoons are more at risk of leaching of nutrients and bacteria with little barrier between the waste they contain and the shallow aquifer systems in the Coastal Plains.[124] Therefore, triggering monitoring for these facilities would ensure that their operations are not endangering the health of communities who depend on water downstream for drinking water.

4. *Facilities upstream from drinking water sources* – Given the abundance of scientific evidence that waterways in watersheds dense with CAFOs have measurable negative nutrient and bacterial characteristics resulting from CAFO operations, facilities operating in close proximity upstream from drinking water sources should have to monitor their impacts on water quality.[125]

5. *Non-compliance history* – As directed by NC Gen Stat § 143-215.6E (2014), the North Carolina Environmental Management Commission under DEQ has the authority and obligation to develop a Violation Point System applicable to permits for animal waste management systems for swine farms that monitors permit violations and considers the relative threat of each violation to groundwater and

---

[120] Harden, *supra* n. 111.
[121] *Id.*
[122] *Id.* DEQ could readily operationalize these standards by adopting a groundwater monitoring trigger for facilities in watersheds with 1) less than 14% wetland cover and 2) greater than 3 barns/mile or 52 total acres to which swine waste is applied.

[125] *See supra*, n. 110-111.

surface water quality, public health, and environment.[126] Violations that harm one of these three factors "shall receive the most points and shall be considered significant violations."

In the May 2018 settlement, DEQ agreed to draft a proposed implementation rule for the Violation Points System by May 3, 2019.[127] Consistent with a Violation Points System, this permit should require facilities with more than one significant permit violation or a certain number of violation points in the permit timeframe to monitor their facilities for the duration of the permit according to the standards in this Draft Permit.[128] Facilities that have non-compliance issues and acquire a high number of violation points have an elevated risk of contaminating groundwater as the conditions of this Draft Permit and, eventually, the point system are in place to protect environmental quality. Violating these regulations, therefore, is accompanied by an increased risk of negative impacts on environmental and water quality. Monitoring groundwater quality provides an avenue for protecting human health near non-compliant facilities and ensuring a transition to robust compliance.

6. <u>*Documented impacts on groundwater quality*</u> – DEQ should require groundwater monitoring at facilities where there is documentation that operations have impaired groundwater. At minimum, this permit should retain language proposed in the stakeholder process requiring groundwater monitoring "when any of the following conditions exist, including but not limited to: a. evidence that groundwater impacts to public or private water wells are occurring off-site; b. evidence of migration of contaminated groundwater to off-site property or properties; c. evidence of surface water impacts via groundwater."[129]

   For the Violation Points System to yield its intended results, DEQ must detect and enforce non-compliance issues negatively impacting water, health, and environmental quality. Of the 177 violations found during FY 2017-18, only 20 resulted in the initiation of an enforcement action.[130] Unpermitted discharges from the systems and evidence of over application were two of the three most common violations, both of which can degrade groundwater quality. The Wilmington Regional Office staff only had the capacity to spend an average of 56 minutes on each inspection, which is insufficient given the necessary inspection components.

---

[126] *See* 15A NCAC 02T.0120(a) ("The Division shall consider an applicant's compliance history in accordance with G.S. 143-215.1(b)(4)b.2 and with the requirements contained in this Rule for environmental permits and certifications issued pursuant to Article 21.").
[127] *See* Exh. 5 at 5.
[128] Groundwater monitoring should be tied to significant violations, *see* GS 143.215.6E(a)(1) ("violations that involve the greatest harm to … groundwater"), as well as the accumulation of lesser violations that heighten the risk to groundwater resources.
[129] Draft Swine Waste Management System General Permit for Stakeholder Process, III.10.
[130] Dept. of Envtl. Quality, *supra* n.51.

In light of DEQ's stretched capacity for enforcement and recent budget cuts,[131] in the event that a third party can demonstrate acceptable evidence of offsite impact on groundwater quality, groundwater monitoring should be triggered. The Division should always assess the credibility of evidence of groundwater contamination, but when credible evidence is presented, it should be considered regardless of who presents it. Additionally, absent comprehensive groundwater monitoring by the regulating agency, the evidence necessary to trigger groundwater monitoring will be impossible to obtain unless rigorous, credible third-party evidence collected via approved sampling protocols is accepted.

7. *Covered Lagoons/Digesters* –N.C. Gen. Stat. § 143-215.10I(b) prohibits issuance or modification of a permit "to authorize the construction, operation, or expansion of an animal waste management system that serves a swine farm that employs an anaerobic lagoon as the primary method of treatment and land application of waste by means of a sprayfield as the primary method of waste disposal." As should be made clear by attached Exhibits 11 and 12[132], this would apply to lagoon covers and digesters, which would have to comply with the following:

> The Commission may issue a permit for the construction, operation, or expansion of an animal waste management system that serves a swine farm under this Article only if the Commission determines that the animal waste management system will meet or exceed all of the following performance standards: (1) Eliminate the discharge of animal waste to surface water and groundwater through direct discharge, seepage, or runoff. (2) Substantially eliminate atmospheric emission of ammonia. (3) Substantially eliminate the emission of odor that is detectable beyond the boundaries of the parcel or tract of land on which the swine farm is located. (4) Substantially eliminate the release of disease-transmitting vectors and airborne pathogens. (5) Substantially eliminate nutrient and heavy metal contamination of soil and groundwater.

N.C. Gen. Stat. § 143-215.10I(b) (2007-523, s. 1(a).) We note that this statute has already been violated where DEQ has allowed Permitees to install lagoon covers and digesters that fail to comply with these statutory performance criteria. DEQ must require those operations to undertake

[131] Will Doran, *As NC Pollution Concerns Grow, so do Environmental Budget Cuts*, Raleigh News & Observer, https://www.newsobserver.com/news/politics-government/state-politics/article174769781.html (last visited Feb 27, 2019).

[132] *See Smithfield Swine Farm Biogas Strategy*, admitted on Feb. 22, 2019 as Defendant's Exhibit 707 in *McGowan et al v. Murphy-Brown LLC d/b/a/ Smithfield Hog Production,* (E.D.N.C. Southern Division, 7:14-cv-00182), attached hereto as Exhibit 10; and attached Exhibit 11, the December 2, 2018 testimony of Kraig Westerbeek, Vice President Environment and Support Operations, Murphy-Brown LLC from *Gillis et al. v. Murphy-Brown*, LLC, E.D.N.C. No. 7:14-cv-00185 (Exh. 9 referenced at 281).

groundwater monitoring and forbid any further covers or digesters under the General Permit.

Anaerobic digestion makes nutrients more bioavailable to plants, increasing the content of leachable nitrogen in effluent and leading to a greater risk of groundwater contamination.[133] After anaerobic digestion, less effluent needs to be applied to the land to achieve the same fertilization effects since more of the nutrients are usable for plant uptake. Bioavailable nutrients are not locked up in microbes or absorbed to soil, making them likely to leach if not taken up by plants. Plant uptake of nutrients is relatively inefficient.[134]

Anaerobic digestion increases the nitrogen load in effluent by inhibiting ammonia off-gassing from the lagoon. Therefore, if a lagoon and sprayfield system with a digester continues to spray the same amount of waste on a field as before installing a digester (which often already occurs in amounts exceeding the soil's and plants' capacities to hold onto the nutrients), more bioavailable nutrients will be introduced into the system, increasing the amount of nutrients that can be leached out of the system. Furthermore, any leaching directly from the lagoon into the soil or groundwater will contain more bioavailable nutrients that stimulate eutrophication and result in negative health consequences.

Likewise, since the digester system increases the concentration of ammonium and ammonia in the lagoon, these systems produce an increase in ammonia volatilization from CAFO waste that can increase the risk of groundwater contamination nearby.[135] Digestate slurry volatilizes—and therefore redeposits—more ammonia than regular swine slurry.[136] Scientists estimate that 80-90% of total ammonia emitted from livestock operations is redeposited within roughly 6 miles of the source, and 20% is redeposited within roughly a half a mile.[137] Ammonia can be dry deposited on soil and plant surfaces or dissolved in water particles and precipitated back to land and waterways. In both cases, this increased volatilization not only presents atmospheric emissions concerns, but also represents an additional source of nitrogen entering waterways adjacent to CAFO operations with digesters. For the reasons described above, facilities with digesters pose an elevated risk of surface and groundwater nutrient contamination.

[133] Joe Harrison et al., *Transformation and Agronomic Use of Nutrients From Digester Effluent*, eXtension.org (2013), https://articles.extension.org/pages/67900/transformation-and-agronomic-use-of-nutrients-from-digester-effluent (last visited Feb 20, 2019).
[134] For example, in North Carolina, average nitrogen losses are roughly 50% of the total amount applied to the land due to leaching, volatilization, and denitrification. Osmond and Kang, *supra* n.130.
[135] Mallin et al., *supra* n.110; Robert Nkoa, *Agricultural benefits and environmental risks of soil fertilization with anaerobic digestates: a review*, 34 Agronomy for Sustainable Development 473–492 (2014).
[136] Nkoa, *supra* n.134.
[137] *Id.*

Therefore, installing a covered lagoon/anaerobic digester system should trigger groundwater-monitoring requirements.

Sampling Parameters for Groundwater Monitoring

We strongly support quarterly sampling of monitored facilities described in Attachment B referred to in Condition III.13, as seasonality in both environmental conditions and CAFO activities influences detected impacts, with samples in winter or early spring significantly underestimating impacts from swine CAFO lagoon and sprayfield systems.[138] Additionally, we support the proposed monitoring parameters specified in Attachment B. While the specified parameters will provide DEQ with the necessary information to monitor CAWMP outcomes and ensure compliance with the General Permit, these parameters alone limit DEQ's ability to link swine operations to water quality indicators.

We propose expanding the parameters to include sodium, potassium, and nitrite-N concentrations, which can be used in combination with nitrate-N concentrations to isolate the impacts of swine CAFOs as opposed to poultry CAFOs or other agricultural activities.[139] Likewise, the use of genetic markers and isotope tracers would improve groundwater monitoring with respect to isolating the impacts of a particular operation. Furthermore, groundwater-monitoring parameters should include Total Kjeldahl Nitrogen so that sample results enable calculation of total nitrogen levels using nitrate-N, nitrite-N, and Total Kjeldahl N. We also recommend adding more up-to-date pathogen indicators—including the *E. coli* or *enterococci* standards, which EPA recommended replace fecal coliform indicators three decades ago[140]—as well as parameters to detect antibiotic resistant bacteria.

Lastly, we encourage DEQ to clarify the sampling procedures and standards necessary to obtain accurate and high-quality groundwater monitoring data. For instance, facilities directed to monitor water quality on a case-by-case basis should also install monitoring wells both upstream and downstream from each lagoon/storage pond. The National *Field Manual for the Collection of Water Quality Data* published by the U.S. Geological Survey is a good blueprint for standardizing appropriate groundwater monitoring protocols.[141] Groundwater quality data and water level data should be entered into DEQ's GIS database and made available to the public.

---

[138] Michael A. Mallin & Matthew R. McIver, *Season Matters When Sampling Streams for Swine CAFO Waste Pollution Impacts*, 16 J. of Water and Health; London 78–86 (2018).

[139] Harden, *supra* n. 111 (swine CAFOs in North Carolina tend to have higher sodium + potassium concentrations (commonly between 11 and 33 mg/L) and δ15N values of nitrate + nitrite (commonly between 11 and 26 ‰) relative to streams that have general, non-CAFO agricultural inputs).

[140] U.S. Environmental Protection Agency, *Ambient Water Quality Criteria for Bacteria*, 5 (1986).

[141] Franceska Wilde, *Collection of Water Samples (ver. 2.0): U.S. Geological Survey Techniques of Water-Resources Investigations* §4.2 (2006), http://pubs.water.usgs.gov/twri9A4/ (last visited Feb 24, 2019).

Although there is room to go farther, DEQ has made significant improvements to monitoring groundwater quality that will provide needed information and help protect human and environmental health.

Condition III.15: Facility Record Keeping

Lengthening the record retention period at facilities from 3 to 5 years is consistent with terms agreed upon in the Title VI settlement and with practices in other states. This expansion will improve accountability and transparency and make possible a more complete and longitudinal history to evaluate permit compliance. For these reasons, it is also vital that these provisions apply to all Permittees. DEQ should also facilitate more online record-keeping and allow for Permittees to convert these records from paper to digital and for the records to be filed with the Agency rather than exclusively stored on site. These changes would ease the compliance burden operators bear, while also greatly improving transparency and enhancing accessibility to information that impacts the environment and public health.

Condition III.18: Annual Certification

We strongly support the requirement that the annual certification be filed by all Permittees. This was also a core element of the Title VI settlement and is designed to increase accountability, oversight, and transparency, and minimizes any reporting burden. However, the proposed Certification form should be revised to require additional basic information about each permitted operation, including:

(a) each manure hauler by name and address;
(b) which and how much additional nutrient loads were added (including but not limited to, sludges, unused feedstuff, leachate, milk waste, septage, and commercial fertilizer); and
(c) the number of animal mortalities at each operation.

The requirement that these Annual Certifications be kept on file at the Department and made available to the public will ensure that the information most important to the public—relating to potential environmental and public health impacts of permitted operations—is up-to-date, complete, and readily accessible. We also support any effort to streamline or expedite the production, collection, dissemination, and availability of these records through digital or online methods.

Conditions III.17, 19-21: Notices to DWR and to the Public after Discharges

We appreciate the clarification that the larger discharges trigger all the requirements of lesser discharges. However, Condition III.17 should be changed to require facilities to contact DWR within a shorter time—12 as opposed to 24 hours. Other states have even stricter requirements for reporting dangerous events. In Ohio, permittees must report potentially dangerous spills and discharges within 30 minutes of discovery, and in Illinois, permittees must report discharges into the waters of the state to a hotline "immediately upon discovery." Given that the heaviest concentration of swine operations are in eastern North Carolina—where drainage conditions and other access to surface waters increase the contamination risks substantially in the event of a lagoon breach, overflow, or spill—and given the high number of lagoons and sprayfields in the floodplain, these changes to the public notice provisions are critical for DEQ to ensure transparency and accountability.

We also urge DEQ to require issuance of the press release within 24 as opposed to 48 hours after a discharge of 1,000 or more gallons of waste reaches surface waters. Two days is too long for the public to have to wait to obtain information of this magnitude, particularly given the speed and ease of using of digital media to distribute this information. We also urge DEQ to include the additional provision included in the stakeholder draft that the press release reference actions taken to prevent further discharge and a facility contact person and phone number. That information would ensure greater transparency and direct accountability to the public.

Condition IV.1: Unannounced Inspections

This new language is an important clarification of DEQ's existing authority and aligns with best practices used in other states to incentivize compliance.[142] This change is also consistent with the broader goals expressed by communities of concern and other environmental advocates throughout the stakeholder process for greater oversight and monitoring of permitted operations by DEQ.

Thank you for your consideration.

Abstract

OBJECTIVES—Little is known about the health effects of living in close proximity to industrial swine operations. We assessed the relationship between estimated exposure to airborne effluent from confined swine feeding operations and asthma symptoms among adolescents who were aged 12 to 14 years.

METHODS—During the 1999–2000 school year, 58 169 adolescents in North Carolina answered questions about their respiratory symptoms, allergies, medications, socioeconomic status, and household environments. To estimate the extent to which these students may have been exposed during the school day to air pollution from confined swine feeding operations, we used publicly available data about schools (n = 265) and swine operations (n = 2343) to generate estimates of exposure for each public school. Prevalence ratios and 95% confidence intervals for wheezing within the past year were estimated using random-intercepts binary regression models, adjusting for potential confounders, including age, race, socioeconomic status, smoking, school exposures, and household exposures.

RESULTS—The prevalence of wheezing during the past year was slightly higher at schools that were estimated to be exposed to airborne effluent from confined swine feeding operations. For students who reported allergies, the prevalence of wheezing within the past year was 5% higher at schools that were located within 3 miles of an operation relative to those beyond 3 miles and 24%

higher at schools in which livestock odor was noticeable indoors twice per month or more relative to those with no odor.

CONCLUSIONS—Estimated exposure to airborne pollution from confined swine feeding operations is associated with adolescents' wheezing symptoms.

asthma; environmental health; epidemiology; school age children; school health

During the past 2 decades, the process of raising swine and other livestock has grown into a major industry in the United States. Production has shifted from smaller, family-owned farms to larger, industrialized confined animal feeding operations (CAFOs). Animals in North Carolina's industrialized operations are raised in confinement buildings, housing hundreds to thousands of hogs per operation. Residues of food additives, bedding, dried waste, and animal dander are vented from confinement buildings, and animal waste from the confinement houses is flushed into on-site cesspools, where it begins to decompose and aerosolize anaerobically before being sprayed onto nearby land. There are concerns about the health impacts of exposure to particulate matter, antibiotic residues, volatile organic compounds, and bioaerosols that are present in air that is downwind from confinement buildings, waste lagoons, and spray fields.[1–4]

In occupational settings, adverse respiratory symptoms and changes in bronchial responsiveness and lung function have been observed among confinement building workers.[5–12] Studies that have compared swine CAFO neighbors with other rural residents showed that neighbors reported more frequent respiratory symptoms and mucosal membrane irritation.[13] This literature about health impacts of residential exposures that arise from CAFOs focuses on adults[2,13–15] and may describe inadequately the potential respiratory health effects among children, who may experience notably different physical, educational, and social impacts from such exposures. We designed this research to assess the relationship between self-reported wheezing symptoms among adolescents who were aged 12 to 14 years and estimated exposure to airborne effluent from swine CAFOs.

METHODS

This study combined data about adolescents' respiratory health symptoms, data from a survey of school environments, and location data about swine CAFOs and public schools in North Carolina. Random-intercepts binary regression models were used to estimate prevalence ratios (PRs) that assessed the association between airborne swine pollutants and the prevalence of wheezing symptoms.

North Carolina School Asthma Survey Data

During the 1999–2000 school year, the North Carolina Department of Health and Human Services conducted a statewide respiratory health surveillance project to assess the prevalence of respiratory symptoms among middle school–aged children.[16] Approximately 67% (128 568 of 192 248) of all eligible students participated in the survey, which included core wheezing questions from the International Study of Asthma and Allergies in Childhood questionnaire, a standardized and validated instrument that combines a traditional written questionnaire with a series of video scenes that show children with asthma symptoms.[17–20] To complete the video-based survey questions, students viewed a sequence of video vignettes that showed adolescents experiencing asthma-related symptoms; each scene was followed by time to complete a written survey question, allowing each student to indicate whether he or she had experienced symptoms like those illustrated in the scene.[19,20] We analyzed the prevalence of any wheezing symptoms within the past year ("current wheezing"), as determined by responses to questions about wheezing at rest, waking at night as a result of wheezing, exercise-induced wheezing, and severe wheezing attacks. The definition of current wheezing used here is consistent with that applied in previous analyses of the North Carolina School Asthma Survey (NCSAS) data.[16,21–23]

To evaluate whether the estimated exposure had an impact other asthma-related outcomes, we assessed "severe wheezing" using responses to survey questions about waking at night as a result of wheezing and having a severe wheezing attack during the past year; considered the severe wheezing symptoms to be frequent when they occurred at least once per month ("frequent severe wheezing"); and evaluated physician-diagnosed asthma, medical care, and behavioral consequences of asthma-related symptoms.

Each adolescent also answered questions about age, race, Hispanic ethnicity, allergies, socioeconomic status, cigarette smoking history, and home environment. We included age as a continuous variable (centered at 13) and categorized all other variables: race (black/white); Hispanic ethnicity (yes/no); allergies to cat, dog, dust, grass, or pollen (yes/no); ever smoked cigarettes (yes/no); number of other smokers in household (0, 1, 2, or ≥3); and use of a gas stove at home (<1 time per month vs ≥1 times per month). Socioeconomic status was assessed using responses to a question about payment for lunch at school, with lower economic status designated by receiving free or reduced-price lunch at school compared with paying full price for lunch or bringing lunch to school.

School Environment Data

During the 2003–2004 school year, we mailed 4 copies of a survey to principals of 337 public schools and asked each to distribute the surveys to current school employees. More than 800 anonymous survey respondents, employed in 265 (79%) of the targeted schools, answered questions about their observations of the environmental conditions in and around the school buildings. The survey responses indicated whether there was visible evidence of the presence of cockroaches, rodents, or mold and noticeable odors from indoor (eg, mold) and outdoor (eg, nearby industries) sources of airborne pollutants. Responses were used to create school-level indicator variables for the presence of indoor respiratory irritants and sources of outdoor air pollution from agriculture and industries that are located near the school. Because of concerns about response bias resulting from social and political conflict surrounding industrial swine production in North Carolina, we asked survey respondents to answer a question about livestock odor generically rather than about odor specifically arising from swine operations. When we received >1 survey from a single school, schools were categorized as positive for a given survey question when any respondent reported the given condition.

Swine CAFO Exposure Estimates

Estimates of exposure to airborne pollution from 2343 swine CAFOs were generated using data from permits that were issued by the North Carolina Division of Water Quality to all CAFOs that house at least 250 animals and use a liquid waste management system. Records contained mandatory information about each CAFO facility, including geographic coordinates and the number, type, and weight of animals (called steady-state live weight [SSLW]) at each operation.[3,24] CAFO operators who filed applications for liquid waste management permits with the state agency provided latitude and longitude coordinates of their operations; the coordinates were verified and corrected, when necessary, when state inspectors visited the operations, although the extent to which the information was corrected by agency inspectors was not recorded in the data (S. Lewis, personal communication, 2002).

Separate exposure estimates were developed on the basis of distances between schools and swine CAFOs and of survey responses about noticeable odors from livestock farms. Distances and geographic directions between schools and CAFOs were calculated using the formulas given by Goldberg et al[25] and Sinnott,[26] respectively. We used calculations of proximity to create 3 metrics of potential exposure for each school: (1) distance to the nearest operation; (2) SSLW within 3 miles; and (3) a weighted SSLW based on the distance between the school and nearby swine CAFOs, the SSLW of each operation, and the proportion of wind measurements in the direction from the operation to the school. We obtained measurements of wind speed and direction recorded at 16 automated weather stations located throughout the state from the State Climate Office of North Carolina (Raleigh, NC). Hourly averages from January 1999 through December 1999 and from the weather station located nearest each school–CAFO pair were used to compute the proportion of time when the wind was blowing from the operation to the school. Weighted SSLW values for each CAFO within 3 miles of a school were the product of the squared inverse of the distance between the school–CAFO pair, the operation's SSLW value, and the proportion of time that regional wind measurements indicated that wind was blowing from the operation toward the school. For each school, weighted SSLW values were summed and the schools were assigned categories of low, medium, and high exposure on the basis of tertiles of the distribution of values among schools with 1 or more swine CAFOs located within 3 miles. A 3-mile radius was selected on the basis of previous research about the impacts of swine CAFOs on health and quality of life among neighbors who live within a 2-mile radius[2,13]; for this research, we expanded the potential zone of exposure to 3 miles because odors from swine CAFOs sometimes are reported at distances of >2 miles.

Study Population

Students in 499 public schools participated in NCSAS, and each student provided data about his or her respiratory health. Schools in 14 counties that did not contain a swine CAFO or border a county with at least 1 swine CAFO (*n* = 45), schools within the city limits of the 6 cities with populations >100 000 (*n* = 61), schools within 5 miles of the state border (*n* = 18), schools with <25 students surveyed (*n* = 34), schools that had closed or relocated since 2000 (*n* = 11), and schools that did not respond to the survey about in-school environmental conditions (*n* = 72) were excluded from our study. The remaining 265 public schools were included in our study. From these 265 schools, a total of 73 305 boys and girls who were aged 12 to 14 years responded to NCSAS. Of those, 58 169 (79%) who reported black or white race and provided complete data for all asthma survey variables of interest constituted our final study population.

Statistical Analyses

Multivariate analyses were conducted separately for individuals with and without self-reported allergies to cat, dog, dust, grass, and/or pollen. To assess the relationship between the prevalence of wheezing symptoms and the estimates of in-school exposure, we used random-intercepts binary regression. This method accounted for the hierarchical clustering of student-level data within schools. Specifically, we used a variation of the generalized linear mixed model $E(Y x) = \exp(\alpha + \Sigma\beta x)$ similar to those described by Singer[27] and McLeod,[28] in which the student's outcome is modeled by a combination of student-level (level 1) and school-level (level 2) models. The student-level model was defined as

$$\log_e(P_{ij}) = \beta_{0j} + \beta_1 x_{1j} + \beta_2 x_{2j} + \ldots + \beta_n x_{nj}, \quad \text{(level 1)}$$

where P_{ij} is the probability of outcome y = 1 for individual i in school j, p_{ij} ~ binomial; β_{0j} is school-specific intercept (intercept for school j); and β is the effect of individual-level predictor x_{ij}. Level 1 models included student-level variables for age, gender, race, Hispanic ethnicity, economic status, allergy status, cigarette smoking experience, number of other smokers in the household, and use of a gas kitchen stove at home. The school-level (level 2) model was defined as

$$\beta_{0j} = \beta_0 + \mu_1 z_1 + \mu_2 z_2 + \ldots + \mu_n z_m + \mu_{0j}, \quad \text{(level 2)}$$

where β_0 is the mean of school-level means for outcome y (ie, fixed intercept); μ is the effect of school-level predictor z_j; z_j is the school-level predictor for school j; $\mu_{0j} \sim N(0, \tau_{00})$; and τ_{00} is between-school variance. The level 2 models included main exposure variable(s) and indicator variables for rural school locale, survey-reported presence of indoor respiratory irritants (cockroaches, rodents, mold visible, mold odor, or flooding of school buildings within the past 5 years), and survey-reported industry other than a swine CAFO located near the school. The level 2 model, substituted into the level 1 model, results in a final 2-level random-intercepts model,

$$\log_e(P_{ij}) = \beta_{0j} + \beta_1 x_{1j} + \beta_2 x_{2j} + \ldots + \beta_n x_{nj} + \mu_1 z_1 + \mu_2 z_2 + \ldots + \mu_n z_m + \mu_{0j},$$

where μ_{0j} is the random intercept term. Associations were estimated as PRs (exp[μ]) using SAS statistical software version 8.2 (SAS Institute Inc, Cary, NC).

RESULTS

More than 26% (15 250 of 58 169) of students who participated in NCSAS during the 1999–2000 school year reported wheezing during the past year (ie, current wheezing). Table 1 shows adjusted PRs for individual-and school-level characteristics. Of the individual-level characteristics, the highest PR was observed for self-reported allergy status (PR: 2.20; 95% confidence interval [CI]: 2.14–2.27). Variations in the prevalence of current wheezing by school-level characteristics and indicators of school-specific environmental health conditions were less pronounced.

Of the 265 schools, 66 (25%), including 10 518 (18%) surveyed students, were located within 3 miles of at least 1 (range: 1–27) swine CAFO. More than 50% of the schools were within 7 miles of the nearest operation (median: 6.7 miles; range: 0.22–42.0 miles). The average SSLW capacity of operations that were located within 3 miles of a school was slightly lower than that of operations that were located beyond 3 miles (556 283 lb vs 605 139 lb), and, overall, the SSLW capacity of swine CAFOs increased with increasing distance from the nearest surveyed school (β [SE] per mile = 15 948 [4791]). On the basis of the environmental health surveys and according to survey respondents, livestock odor was noticeable outside buildings in 86 (33%) schools and inside the buildings in 39 (15%) schools.

Table 2 presents adjusted PRs for wheezing using each exposure measure separately for students with and without allergies. PRs were 1.05 (95% CI: 1.00–1.10) and 1.02 (95% CI: 0.94–1.11) for adolescents who did and did not have allergies, respectively, and attended schools that were located within 3 miles of the nearest swine CAFO. PRs were approximately unity for schools that were closer than 2 miles, compared with schools with no nearby swine CAFOs, and were 1.12 (95% CI: 1.04–1.19) and 1.08 (95% CI: 0.95–1.21), respectively, for students who did and did not have self-reported allergies and attended schools that were located between 2 and 3 miles from the nearest operation. Associations with SSLW and the weighted SSLW exposure categories also tended to be highest for the low exposure groups and closer to unity for higher exposure groups compared with schools with no nearby swine CAFOs. Basing potential exposure estimates on survey-reported livestock odor resulted in 20 fewer schools' and 3315 fewer adolescents' being considered unexposed. The prevalence of current wheezing was 24% and 21% higher among allergic and nonallergic students, respectively, at schools in which livestock odor was noted inside the school building 2 or more times per month relative to the prevalence at schools without any survey reports of livestock odor.

Table 3 presents adjusted associations between school proximity within 3 miles of a swine CAFO and alternative asthma outcomes as well as functional consequences of asthma-related symptoms. Results indicate that larger proportions of adolescents who attended school near at least 1 swine CAFO experienced respiratory symptoms, physician diagnosis, asthma-related medical treatment, activity limitations, and missing school because of their symptoms. In the population of all students, the largest PRs were observed for physician-diagnosed asthma (PR: 1.07; 95% CI: 1.01–1.14), medication use (PR: 1.07; 95% CI: 1.00–1.15), and visit to a physician or an emergency department or hospitalization (PR: 1.06; 95% CI: 1.00–1.12). Most associations were slightly higher in adolescents with self-reported allergies; however, the PR for physician-diagnosed asthma was higher among students without (PR: 1.14; 95% CI: 1.01–1.26) compared with those with (PR: 1.06; 95% CI: 0.99–1.12) self-reported allergies. Adjusted associations between these outcomes and the presence of livestock odor in and around the schools indicate only slightly elevated proportions of wheezing symptoms, physician diagnosis, use of asthma-related medical care, activity limitations, and missed school among students in schools where employees reported noticeable livestock odor (Table 4). When school-level exposures were assigned on the basis of reported livestock odor (Table 4), the PRs for severe wheezing (PR: 1.05; 95% CI: 1.00–1.10) and frequent severe wheezing (PR: 1.06; 95% CI: 0.98–1.14) were higher than when exposure was assigned on the basis of distance to the nearest swine CAFO (severe wheeze, ≤3 miles: 1.02 [95% CI: 0.97–1.07]; frequent severe wheeze, ≤3 miles: 1.01 [95% CI: 0.92–1.09]; Table 3).

DISCUSSION

We observed elevated prevalences of current wheezing among 12- to 14-year-old students who attended public schools near swine CAFOs, especially among students with self-reported allergies. Such associations are plausible, given that swine CAFOs are sources of bioaerosols, endotoxins, and other airborne asthma triggers. The availability of standardized symptom data and the independence of symptom and exposure data strengthen confidence in the validity of our findings. Overall, estimates of excess current wheezing symptoms among students who attended schools nearby swine CAFOs are as high as 24% among students who attended schools where livestock odor was reported outside as well as inside 2 or more times per month. Excess prevalence of current wheezing tended to be greater among students who reported allergies. Although the majority of the estimates are small in relative terms, the increases are important in absolute terms because of the high prevalence of asthma-related symptoms in this age group; the impact that symptoms have on adolescents' ability to attend school and participate in social, recreational, and physical activities; and the costs and burdens of symptom-related medical care. In these data, the effect estimates for swine CAFO exposures are of similar magnitude to the effects that have been estimated for established risk factors for wheeze, such as age, race, gender, economic status, Hispanic ethnicity, exposure to secondhand cigarette smoke, and use of a gas stove at home.

We estimated potential exposure on the basis of distance and a mailed survey. Although distance is a crude measure of exposure, our findings suggest a consistent trend toward higher symptom prevalence, especially among adolescents with allergies, at schools that were between 2 and 3 miles of a swine CAFO. The finding that schools that were located within 2 miles had a lower prevalence of current wheezing may reflect the lack of a direct relationship between exposure to etiologically active agents and distance. Use of distance and SSLW as exposure measures does not take account of waste management and sanitation practices of swine CAFOs, ages and conditions of the facilities' equipment, localized weather patterns, topography surrounding the school, school building structure, and ventilation practices, all of which may affect the quantity and the duration of the exposures. In addition, swine CAFO practices such as waste and sanitation procedures may be influenced by population density, land availability, and other features of the communities in which the operations are located, although we do not know the extent to which this occurs. Indeed, results of analyses that used exposure metrics of increasing complexity failed to show a monotonic dose-response relationship between the exposure and current wheezing, further suggesting that if the exposure is associated with an increase in respiratory symptoms, then relevant exposure may not correlate directly with the factors that we used for our distance-based exposure categories.

The higher prevalence of current wheezing among students who attended schools that were located 2 to 3 miles from the nearest swine CAFO compared with the prevalence among students who attended schools within 2 miles also may be attributable to exposures that were experienced at home, in the communities where students lived, and in other locations that could not be assessed in our study. In many of the rural areas in North Carolina, students may live many miles from the public schools that they attend. As the distance between the school and the CAFO becomes small, few homes can be equally close or closer to a CAFO; as the distance increases, more of the students' homes can be located closer to a CAFO than the distance between the CAFO and the school, and school-based exposure estimates will underestimate students' total swine CAFO exposures. In addition, reports of odor from swine CAFOs tend to be more common in early morning and evening hours rather than in the daytime, when students are in school. Although this phenomenon may not affect exposures in geographic areas where both schools and homes are far from CAFOs, identifying exposure as the distance between a school and a CAFO may be more problematic in regions where schools are located very near or within several miles of CAFOs if exposure varies throughout the day. Previous research that was conducted in a rural population of school-aged children who may have experienced swine farm exposures at home indicated a higher prevalence of asthma-related symptoms among children who lived on farms where swine were raised than among children who lived on farms where swine were not raised and among children who did not live on farms,[29] although the extent to which exposures that resulted from residence on a swine farm were attributable to performing chores or occupation-like tasks, rather than simply living close to swine, are unknown. Although information about adolescents' household farming exposures are unavailable in our study population, the majority of swine in North Carolina are raised in nonresidential, factory farm settings; therefore, the proportion of children who perform chores or live on swine farms is expected to be low.

Results of analyses of the distance-based measures of each exposure suggest lower prevalence of wheezing among students who attended schools that were located nearest to CAFOs and located in areas with the highest density of swine compared with those in the highest exposure categories. To assess potential misclassification of exposure, we excluded from all analyses schools with reported livestock odor from the unexposed distance-based categories, schools that were located beyond 3 miles of swine CAFO from the exposed survey-based categories, and schools for which survey respondents specifically identified livestock odor as arising from poultry and found no notable differences in the direction, magnitude, or precision of the PRs generated. An alternative explanation for the lower prevalence of wheezing among students in schools that were located nearby swine CAFOs may be the hygiene hypothesis, which postulates that early-life exposures and childhood infections may confer protection against hay fever, atopy, and asthma.[30,31] Specifically, rural living and early-life exposures to allergens, irritants, and other bioaerosols on farms may be associated with lower rates of atopy and asthma.[29,32–38] In our study, the prevalence of wheezing was slightly lower (−1.2%) in rural compared with non-rural schools. Although we could not assess early-life exposures, higher exposures to animal dander and bacterial endotoxin during early developmental stages among individuals who attend schools closest to swine CAFOs and therefore often live in rural areas could provide some resistance to exposures later in childhood and lead to lower prevalence of wheezing during adolescence compared with students who attend schools farther away.

Twenty-one percent (*n* = 72) of schools were excluded from our final analysis because of nonparticipation in our mailed survey about in-school environmental conditions. When we compared the populations of schools that participated and those that did not, we found differences in mean distance to the nearest swine CAFO (participating schools: 8.7 miles; nonparticipating schools: 8.0 miles), percentage of nonwhite enrollment (participating schools: 36%; nonparticipating schools: 42%), and percentage of enrolled students who received subsidized school lunches (participating schools: 48%; nonparticipating schools: 51%). Systematic differences between participating and nonparticipating schools in levels of exposure and prevalences of asthma-related symptoms could have influenced our findings.

We received up to 7 completed surveys per school, and for each survey question, we assigned an exposure to a school when any respondent indicated the presence of the exposure. This method of classifying schools' environmental conditions and, in particular, the presence of livestock odor at the school was sensitive to the number of surveys completed and returned from each school and did not take into account the variation in survey responses from a single school. Our intention was to survey employees in several occupations who would be familiar with different aspects of the school building and students' behaviors: teacher, administrator, maintenance or custodial staff, and school nurse or health care personnel. Previous literature about the economic, political, and social impacts of a strong swine industry presence in communities in Iowa and North Carolina suggested that residents who live near swine CAFOs may be reluctant to voice their concerns for fear of social ostracism or conflict in their communities.[39–42] Although our school survey was anonymous and designed to minimize risks for deductive disclosure of respondents' identities, we recognize the possibility that respondents may have underreported livestock odor out of concern for expressing their opinions, and we cannot know fully the extent to which our survey reports were influenced by the social and political context in the communities in which the schools were located.

Lack of data on medical risk factors, environmental asthma triggers, and classification of allergic status on the basis of survey reports rather than of a clinical assessment of atopy are limitations of this study. Because students self-identified asthma-related symptoms, our current wheezing variable may include other respiratory symptoms that the respondents experience and mistake for the symptoms that were illustrated in the video scenes. Cross-sectional asthma-related symptom data and survey-based exposure data prohibit specific assessment of temporal relationships between the symptoms and exposures evaluated here. Our findings are vulnerable to systematic error if students with asthma-related symptoms changed their environments or behaviors because of symptoms that were caused by exposure to airborne pollution that arose from swine CAFOs; such a systematic error would lead to underestimation of associations between swine CAFOs and asthma symptoms.

CONCLUSIONS

This research was designed to estimate exposures to a source of air pollution that is of great concern to swine CAFO neighbors and to investigate relationships between school exposures and respiratory health of middle school–aged children. Our findings identify a plausible association between exposure to airborne pollution from swine CAFOs and wheezing symptoms among adolescents. Environmental pollution measurement and standardized clinical information about asthma symptoms and atopic status could help to determine better the magnitude and the temporality of the relationships between swine CAFO emissions and respiratory symptoms. Our findings should be used by public health personnel who are interested in understanding possible adverse respiratory health consequences of an important rural environmental exposure.

Lung function
Allergies
Asthma

ABSTRACT

Background: Air emissions from concentrated animal feeding operations (CAFO) have been associated with respiratory and allergic symptoms among farm workers, primarily on swine farms. Despite the increasing prevalence of CAFOs, few studies have assessed respiratory health implications among residents living near CAFOs and few have looked at the health impacts of dairy CAFOs.
Objectives: The goal of this study was to examine objective and subjective measures of respiratory and allergic health among rural residents living near dairy CAFOs in a general population living in the Upper Midwest of the United States.
Methods: Data were from the 2008–2016 Survey of the Health of Wisconsin (SHOW) cohort (n = 5338), a representative, population based sample of rural adults (age 18 +). The association between distance to the nearest CAFO and the prevalence of self-reported physician-diagnosed allergies, asthma, episodes of asthma in the last 12 months, and asthma medication use was examined using logistic regression, adjusting for covariates and sampling design. Similarly, the association between distance to the nearest CAFO and lung function, measured using spirometry, was examined using multivariate linear regression. Restricted cubic splines accounted for nonlinear relationships between distance to the nearest CAFO and the aforementioned outcomes.
Results: Living 1.5 miles from a CAFO was associated with increased odds of self-reported nasal allergies (OR = 2.08; 95% CI: 1.38, 3.14), lung allergies (OR = 2.72; 95% CI: 1.59, 4.66), asthma (OR = 2.67; 95% CI: 1.39, 5.13), asthma medication (OR = 3.31; 95% CI: 1.65 6.62), and uncontrolled asthma, reported as an asthma episode in last 12 months (OR = 2.34; 95% CI: 1.11, 4.92) when compared to living 5 miles from a CAFO. Predicted FEV1 was 7.72% (95% CI: −14.63, −0.81) lower at a residential distance 1.5 miles from a CAFO when compared with a residence distance of 3 miles from a CAFO.
Conclusions: Results suggest CAFOs may be an important source of adverse air quality associated with reduced respiratory and allergic health among rural residents living in close proximity to a CAFO.

1. Introduction

Over the last several decades, large livestock farms, including concentrated animal feeding operations (CAFOs), have increasingly replaced small farms across the globe. The change in normative agricultural practices from smaller farms to large-scale farming productions, while more efficient for meat production, may also increase risk of adverse respiratory health or other outcomes among communities living in rural communities. CAFOs increase both the quantity and concentration of airborne particulates, gases, and vapors associated with farming (Schiffman et al., 2001). More than 400 compounds have been found in and around CAFO facilities, including volatile organic compounds (VOCs), endotoxins, ammonia, and hydrogen sulfide (Schiffman et al., 2001). While respiratory health effects among CAFO farm workers are well documented (Douglas et al., 2018; Kirkhorn and Garry, 2000; Radon, 2006), less is known about the extent to which CAFO air emissions affect the health of nearby residents.

Beyond increasing air emissions, potential for increased exposure to emerging antibiotic resistance microorganisms and outbreaks of zoonotic viral and bacterial pathogens have drawn attention to potential health risks among residents living near CAFOs (Gilchrist et al., 2007; Li et al., 2015; Rogers and Haines, 2005). Several agents, such as ammonia, hydrogen sulfide, endotoxins, and viral and bacterial pathogens from animal manure can be absorbed by dust particles and stay

airborne for long periods and travel several miles, potentially exposing nearby residents to elevated levels of livestock-related agents (Cole et al., 2000; Omland, 2002; Dungan, 2010).

Three studies in the United States (U.S.) found the prevalence of asthma to be higher among children and adolescents attending schools (Mirabelli et al., 2006; Sigurdarson and Kline, 2006), and living (Pavilonis et al., 2013), near swine CAFOs. Studies among adults have found more mixed results. Two ecological studies among adults in the Netherlands (Hooiveld et al., 2016) and Greece (Michalopoulos et al., 2016) found null results when assessing residential proximity to livestock farms with allergy and asthma outcomes. Yet, an ecological study in North Carolina, U.S. found the prevalence of wheezing to be higher among adults living near swine CAFOs (Wing and Wolf, 2000). Two studies in rural Germany found the number of animal houses near a residence and measured ammonia levels to be associated with decreased lung function in adults (Radon et al., 2007a; Schulze et al., 2011). However, only measured ammonia levels were associated with sensitization of allergies (Schulze et al., 2011).

Three Netherlands studies found mixed results using general practice electronic medical records (EMR) to identify cases and controls of asthma and allergies. Inverse associations were found between distance to the nearest farm and asthma, allergies, and COPD (Borlée et al., 2015; Smit et al., 2014) and negative associations between the numbers of livestock farms within 1000 m of residence and lung function (Borlée et al., 2017). Yet living within 1000 m of > 11 farms had increased odds of wheezing and COPD (Borlée et al., 2015), and measured ammonia was associated with decreased lung function (Borlée et al., 2017). The only adult study in the U.S. to use EMR found living near a CAFO was associated with increased odds of asthma medication use and asthma-related hospitalizations (Rasmussen et al., 2017).

Several of the aforementioned studies (Sigurdarson and Kline, 2006; Wing and Wolf, 2000; Michalopoulos et al., 2016) consisted of people living near 2–3 identified livestock operations, small regions consisting of a few rural towns in Germany (Radon et al., 2007a; Schulze et al., 2011) or a rural county in the U.S. (Pavilonis et al., 2013). While studies in the Netherlands (Borlée et al., 2015, 2017; Smit et al., 2014) have used population-based study samples using electronic medical records from general practices, only one study in the United States has attempted to done so by using asthma hospitalization, emergency, and medication data from Geisinger Clinic in Pennsylvania (Rasmussen et al., 2017). Generating generalizable results from clinic data in the United States can be challenging as those who do not seek medical care due to inconvenience, cost, or lack of insurance go unreported.

The number of studies on the effect of CAFO air emissions exposure on respiratory health among nearby residents is limited and results are inconsistent. Furthermore, many prior studies have grouped exposure to CAFOs, removing individually variability. This study advances understanding of public health implications of CAFOS by using cubic spline regression to examine the association between residential proximity to CAFOs and respiratory health effects in order to account for non-linearity and retain individual levels of exposure. This study uses a well-characterized, rural sample of Wisconsin residents. Wisconsin ranks second after California as the state with the largest number of dairy cows (USDA, 2017); over 90% of its CAFOs being dairy CAFOs (WDNR, 2016). To our knowledge, no studies to date have looked at respiratory effects among residents living near dairy CAFOs.

2. Materials and methods

2.1. Study sample

Data came from the 2008–2016 Survey of the Health of Wisconsin (SHOW) state-wide sample of adults ages 18 and older ($n = 5338$). SHOW participants are randomly selected using a probability sampling proportion to size with replacement (PPSWR) approach (Nieto and Peppard, 2010). Between 2008 and 2013, a two-stage probability-based cluster sampling was used to randomly select census block groups (stage 1) and household addresses (stage 2) annually within strata of region and poverty level (Nieto and Peppard, 2010). SHOW 2014–2016 cohort was designed as a three-year sample instead of an annual sample as in prior years. A three stage cluster-sampling approach was employed. One county per strata was randomly selected within strata of county mortality rates, followed by random selection of census block groups by poverty status strata. Then 30–35 residential households were randomly selected via US postal service listings.

SHOW recruits 400–1000 participants every year. Across all years of the study, on average 67% of individuals who screen eligible complete each study component (interview and exam). However, participation rates vary from 47% in some urban communities to > 80% in some rural communities.

Fig. 1 describes the analytic sample selected for this study which includes a subset of 1856 (35%) rural participants among the 5338 SHOW subjects. Participants were considered rural if their residence was located in rural census block group defined by the U.S. Census Bureau as having fewer than 2500 people (U.S. Census Bureau, 2015). Additionally, 32 subjects who reported farming as their current occupation were excluded due to increased likelihood of occupational contact with livestock. While livestock contact could be assessed as a surrogate of a higher level of exposure to CAFOs, the number of individuals with occupational exposure was too small to examine this sub-population separately. Since those with livestock contact may or may not live near a CAFO, they were excluded to reduce confounding. Subjects with missing data on any of the respiratory outcomes or confounders of interest were also excluded from analyses, resulting in a final sample size of 1547 for asthma and allergy outcomes, and 1395 for objectively measured lung function outcomes. Detailed allergy data was only collected for 2008–2013 SHOW cohort, resulting in $n = 1019$ for detailed allergy analyses. All residential household addresses were geocoded using CENTRUS software (Pitney Bowes Inc., Stamford, CT) and linked to the nearest CAFO using ArcGIS v10.3 software (ESRI, Redlands, CA).

2.2. Concentrated animal feeding operations (CAFOs)

Data on CAFO location, type (dairy cow, hog, chicken, or turkey), years of operation and total animal units are maintained by the Wisconsin Department of Natural Resources' (WDNR) and Department of Agriculture, Trade and Consumer Protection (DATCP) under the Wisconsin Pollutant Discharge Elimination System (WPDES) program. WPDES falls under the Clean Water Act (CWA) National Pollutant Discharge Elimination System (NPDES) which requires states to regulate point source pollution to waters of the entire United States. CAFOs are defined by the CWA [Section 502(14)] as point sources, thus requiring a discharge permit and monitoring by WPDES.

CAFOs are defined as an animal feeding operation (AFO) where the following conditions are met: 1) animals are confined for a total of 45 days or more in any 12-month period and 2) animals do not have access to crops, vegetation or forage growth in the normal growing season. AFOs that have 1000 or more animal units (1 animal unit = 1000 pounds of live animal weight) are considered a large CAFO (1000+ cattle, 700+ dairy cows, 2500+ swine, 55,000+ turkeys). Medium CAFOs (300–999 cattle, 200–699 dairy cows, 750–2499 swine, 16,500–54,999) are additionally regulated under WPDES if the facility has a manmade ditch or pipe that carries manure or wastewater to surface water or if the animals come into contact with surface water that passes through the area where they are confined (40 CFR § 122.23 (b), 2012).

According to publicly available data downloaded from WDNR WPDES program there were a total of 284 CAFOs operating in Wisconsin in 2016. Ninety percent (244 large, 2 medium) were dairy CAFOs, followed by swine (5 large, 9 medium), beef (10 large, 3 medium), poultry (1 medium, 10 small). Publicly available data were limited, therefore additional data including the location, start date, and end date of all permitted CAFOs established between 2007 and 2015 was obtained via an open records request to the Wisconsin DATCP. The DATCP data was used to ensure CAFOs were in existence during SHOW participants' year of participation in the study (when residential address and health data were collected). Supplementary Fig. 1 from the WDNR shows the proportion of CAFOs by animal type has remained stable over the last decade, with over 90% of the CAFOs in Wisconsin being dairy.

Residential proximity to the nearest CAFO was used as a proxy to estimate potential exposure to air emissions from CAFOs. Distance from a participant's residence to the nearest CAFO was calculated using the "Near" tool in ArcGIS (ESRI, Redlands, CA). Participants were linked by cohort year to the nearest CAFO, only including CAFOs that were in existence during both the year they participated AND the year prior.

2.3. Allergy, asthma, and lung function

Self-report history of respiratory allergies and asthma was collected during in-home interviews. Current allergies were defined as having reported "yes" to the survey question "Do you still have allergies or hay fever?" as a follow-up to the question "Has a doctor or other health professional ever told you that you had allergies or hay fever?" Allergy type was defined based on response to the question "Where do allergy symptoms occur?" For this analysis individual with nasal, sinus, lung, eye, and skin as sites of allergies most likely to be triggered by CAFO air emissions were included. Those reporting digestion, food, or insect allergies were unlikely to be related to proximity to CAFOs and were defined as not having respiratory allergies.

Participants were defined as having current asthma if they responded yes to the survey question "Do you still have asthma?" which is a follow-up to the question "Has a doctor or other health professional ever told you that you had asthma?" Those who report having current asthma are also asked "During the last 12 months, have you had an episode of asthma or an asthma attack?" and if they have taken prescription medication to prevent or stop asthma attacks within the last 30 days.

Forced expiratory volume in 1 s (FEV1) and forced vital capacity (FVC) were measured via spirometry using an electronic peak flow meter (Jaeger AM, Yorba Linda, CA), and validated protocol (Richter et al., 1998). Trained technicians gave study participants explicit directions on how to breathe into the spirometry device. Measurements were considered valid if two FEV1 and FVC readings were within 10% of the highest value measured. FEV1 to FVC ratio (Tiffeneau index) and percent predicted FEV1 (FEV1 divided by predicted FEV1) were also assessed to account for inter-individual variability in lung function measurement. Predicted FEV1 was calculated using sex, race, age, and height as defined by the NHANES general U.S. population (Hankinson et al., 1999).

2.4. Covariates and confounding

Self-reported demographic data including age (years), gender (male vs. female), education (high school or less, some college, and bachelor's degree or higher) and household income were gathered via personal interviews. Poverty to income ratios were calculated using U.S. Department of Health and Human Services poverty guidelines and the midpoint of the household income range identified by the participant. Body mass index (BMI) was calculated from measured weight and height as kg/m^2. Physical activity was defined as Metabolic Equivalent of Task (MET)-minutes/week of moderate or vigorous activity using self-report data from a modified International Physical Activity Questionnaire - IPAQ (Craig et al., 2003). Income, BMI and MET-minutes/week were used as continuous variables in all statistical models, but log transformed to adjust for skewness. Additional self-reported questionnaire items assessed as potential confounders include: home smoking policy, household pets, smell of mildew or mold inside, and the use of any pesticides inside the home in the last 12 months. Sensitivity analyses were also run to test for potential confounding by previously identified environmental sources of allergies and respiratory health in the population (Schultz et al., 2017) residential proximity to the nearest primary or secondary roadway and industry were also examined.

2.5. Statistical analysis

Restricted cubic splines functions were applied to the residential distance in order to account for nonlinear relationships between distance to the nearest CAFO and respiratory health. Knots were placed at the minimum, maximum, and 25th, 50th, 75th percentiles of the distance variable (0.24, 6.17, 9.07, 17.9, 69.9 miles). Univariate as well adjusted multiple linear (lung function outcomes) and logistic (allergic and asthma outcomes) regression models were used to examine associations between residential proximity to a CAFO and respiratory health. Potential confounders selected a priori from the literature. Covariates that did not change the main effect estimate by > 10% were excluded from the multivariate models. An adjusted odds ratio (OR) or an adjusted beta-coefficient value with two-sided p-value < 0.05 was regarded as statistically significant. To acquire estimates from the spline regression, comparisons were made between different residential distances, while holding confounders constant. Residential distances of interest were chosen a priori from literature estimating air pollution and distance from CAFOs (Schinasi et al., 2011; Williams et al., 2011; Wilson and Serre, 2007; Wing et al., 2013; Michalopoulos et al., 2016), and from univariate spline regression trends between distance to nearest CAFO and each outcome. SAS version 9.4 (SAS Institute Inc. Cary, NC) was used for all statistical analyses. All adjusted analyses included sampling weights to account for sampling design, response rates and spatial clustering.

3. Results

Descriptive characteristics of the study population by residential proximity to the nearest CAFO are presented in Table 1. The majority of the study population (72%) lived > 5 miles from a CAFO, 4% (n = 65) lived < 1.5 miles of a CAFO and 23% (n = 361) lived 1.5–5 miles from a CAFO. Those living near a CAFO (< 1.5 miles) were more likely to be males, never-smokers, younger, less educated and diagnosed with asthma when compared with those living middle-distance (1.5–5 miles) and far (> 5 miles) from a CAFO. Those living near a CAFO were also less likely to live near a major roadway and have allergies when compared to the populations living middle-distance and far from a CAFO (Table 1). Unadjusted cubic spline plots revealed the log odds of asthma and allergy outcomes decreased, and lung function increased, as distance from a CAFO increased, leveling off at around 5 miles (Supplementary Fig. 2). Therefore, results include comparisons between distances of 1–3 miles compared with 5 miles from a CAFO.

Close residential proximity to a CAFO (living within 1–3 miles) remained positively associated with reporting any allergy symptoms even after controlling for gender, age, BMI, smoking status, education, income, pet ownership (Fig. 2). Mold in the home, smoking policy in the home, indoor chemical use, and residential proximity to an industrial site and roadway did not change the main effects and were not included in final models. Odds of allergies was > 2-fold when comparing living 1 and 1.5 miles from a CAFO to 5 miles from a CAFO (OR = 2.55; 95% CI: 1.49, 4.36 and OR = 2.02; 95% CI: 1.33, 3.08) and decreased as distance from a CAFO increased. Similar associations were seen among those with nasal- and lung-specific allergies, with the strongest associations seen with lung allergies. The adjusted odds of lung allergies was consistently > 2-fold higher among those living 1–3 miles from a CAFO when compared to those living 5 miles from a CAFO. Supplementary Tables 1 and 2 show results of all distance comparisons made for the previously mentioned allergy outcomes, along with current allergies assessed with the entire 2008–2016 cohort. While results indicate residential proximity is associated with eye and dermal allergies, none of the results were statistically significant (Supplemental Table 2).

Residential proximity to a CAFO was similarly associated with asthma and asthma control measures, including one or more asthma attacks in the last 12 months or taking asthma medication. Reporting current asthma was consistently about 1.8–1.9 times greater among those living 1–3 miles versus 5 miles from a CAFO (Fig. 3). The odds of ever being diagnosed with asthma was 3.11 (95% CI: 1.49, 4.36) and 2.67 (95% CI: 1.33, 3.08) when comparing 1 and 1.5 miles from a CAFO to 5 miles from a CAFO. Similar to the associations seen with current and nasal-specific allergies, the odds of doctor diagnosed asthma and asthma medication use decreased as distance from a CAFO increased. Those living 1, 1.5, 2, 2.5 miles from a CAFO, asthma medication was 4, 3, 2.5, and 2 times greater, respectively, when compared to those living 5 miles from a CAFO; all associations statistically significant. Odds of an asthma attack were consistently 2-fold higher at 1–3 miles versus 5 miles from a CAFO, with the odds being 2.34 (95% CI: 1.11, 4.92) times higher at 1.5 miles versus 5 miles from a CAFO.

Among the SHOW 2008–2013 cohort, the odds of reporting both allergies of nose or lungs and current asthma was 2.67 (95% CI: 0.97, 6.38) times greater and 2.14 times greater among those living 1 and 1.5 miles from a CAFO when compared to those living 5 miles from a CAFO (Fig. 2). Associations were lower at 2 and 2.5 miles but increased again to 2.74 (95% CI: 1.43, 5.23) when comparing 3 miles to 5 miles from a CAFO. This finding suggests that those in this study population with the presence of asthma or allergies may have allergic asthma. Results of all distance comparisons made with the aforementioned asthma outcomes can be seen in Supplementary Table 3. Similar directional associations are seen when distances of 1–3 miles are compared with 3, 4, and 6 miles as a reference value instead of 5 miles.

FEV1 percent predicted and FEV1/FVC were significantly lower among individuals living 1–3 miles from a CAFO when compared to those living5 miles from CAFO (Fig. 3).While not statistically significant, Fig. 4 shows FEV1 percent predicted was 11.31 L/s (95% CI: 0.51, 23.14) lower at 1 mile, and 7.00 L/s (95% CI: 2.26, 16.26) lower at 1.5 miles, when compared with 5 miles from a CAFO. The difference in FEV1 percent predicted decreased at 2 and 2.5 miles versus 5 miles until it reached 0 when comparing 3 miles versus 5 miles from a CAFO. FEV1/FVC was 0.039 (95% CI: 0.008, 0.07) lower at 1 mile, and 0.027

p-trend: statistical significance by Chi-square test.

(95% CI: 0.003, 0.051) lower at 1.5 miles, when compared with 5 miles from a CAFO. Results of all distance comparisons, including FEV1 and FVC outcomes, can be found in Supplementary Table 4.

4. Discussion

These findings add to the emerging body of literature regarding public health impacts of concentrated animal feeding operations among rural populations. Much of the existing research has been conducted in Europe. This one of the first studies to examine how rural respiratory health is potentially influenced by farming practices in a general population based sample of adults in the United States. Among this well-characterized population-based sample, household proximity to a CAFO was associated with numerous respiratory outcomes including increased odds of self-reported allergies and asthma, and decreased lung function.

The use of cubic splines to explore nonlinear relationships between proximity to a CAFO and respiratory health outcomes was a strength of this study. Associations between residential proximity within 3 miles of a CAFO and increased prevalence of allergies, asthma, and decreased lung function were observed. Each of the respiratory outcomes followed a similar nonlinear relationship with distance from CAFOs and a 5 mile reference cut point was determined based on visual plots of the cubic spline functions of distance to the nearest CAFO regressed by each respiratory outcome separately. The non-linearity relationship seen in respiratory outcomes is not surprising as levels of constituents from air emissions from point sources (i.e. airports, roadways, industries, livestock facilities) tend follow a similar exponential decay as distances from the sources increase (Batterman et al., 2014; Dungan, 2010; Hadlocon et al., 2015; Maantay et al., 2009; Moreira et al., 2005; O'Shaughnessy and Altmaier, 2011; Polidori et al., 2010; Zhou and Levy, 2007).

Study findings are consistent with, and add strength to other U.S.-based studies of asthma and allergy symptoms among people living near AFOs or CAFOs. Pavilonis et al. (2013) found cumulative exposure to AFOs < 3 miles from residence was associated with an increased odds of asthma (1.51 $p = 0.014$) and asthma medication or wheeze (1.38 $p = 0.023$) among school age children. Similarly, Rasmussen et al. (2017) found adult asthmatics recruited from a clinic based sample and living within 3 miles of a CAFO compared > 3 miles had increased odds of ordering asthma medications (OR = 1.11 (95% CI: 1.04, 1.19)) and asthma hospitalizations (OR = 1.29; 95% CI: 1.15, 1.46). The smaller farm sizes may have contributed to the smaller effect sizes seen in Pavilonis et al. (2013) study. Not to mention, diagnosis of pediatric asthma is based on symptoms, which vary throughout a child's life, and also day to day (Asher et al., 2012; Jacob et al., 2017; Yang et al., 2017). The focus on hospitalizations and emergency department visits (Rasmussen et al., 2017) may have underestimated asthma events by excluding those who live near CAFOs but do not seek medical care due to being uninsured, financially insecure, or far from services.

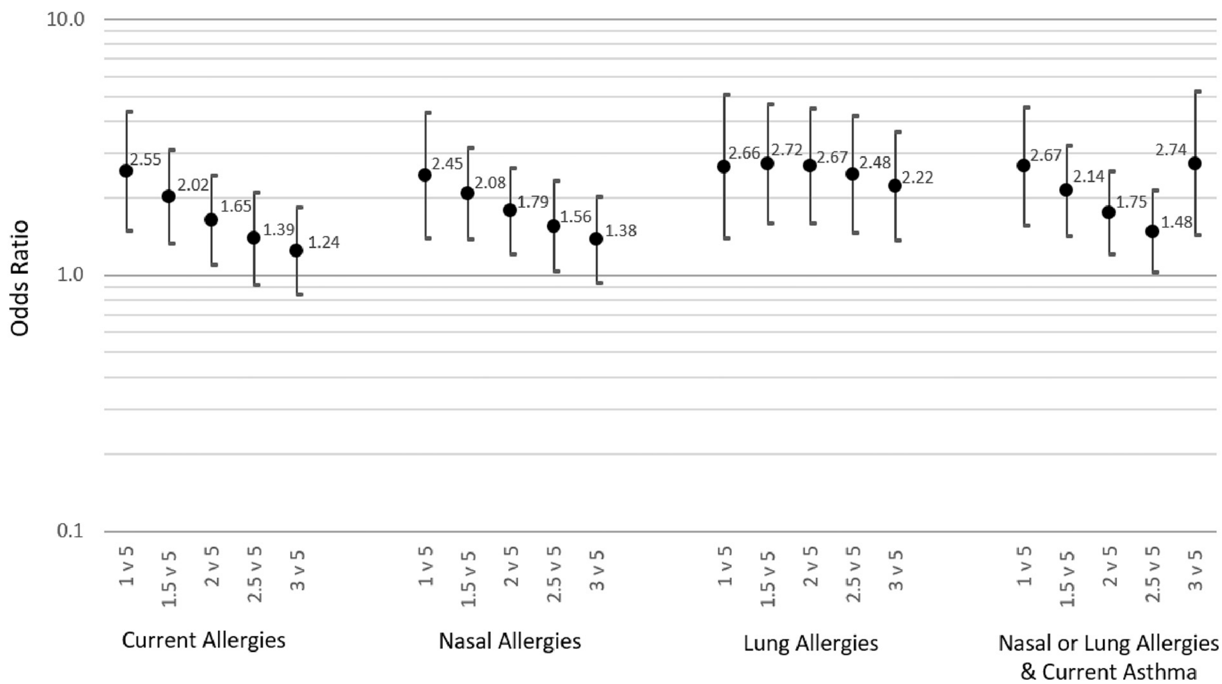

Fig. 2. Results of logistic regression assessing allergic outcomes by restricted cubic spline of residential distance to the nearest CAFO. Residential distances of 1, 1.5, 2, 2.5 and 3 miles (1.6, 2.4, 3.4, 4.0, 4.8 km) from a CAFO were compared with a residential distances of 5 miles (8.0 km) from a CAFO. Models are adjusted for gender, age, poverty to income ratio, education, BMI, smoking status, pet ownership and proximity to major roadways.

Results showed stronger associations with doctor diagnosed asthma than with current asthma. Discrepancies could be due to several factors, including a lack of clarity regarding the survey question assessing current asthma. Cross-tab frequencies on current asthma and asthma medication in the last 12 months revealed several participants reported not having current asthma because it is under control from taking asthma medication. Discrepancies between current asthma and doctor diagnosed asthma are not uncommon and can be due to several other factors including misdiagnosis, remission and relapse of asthma (Aaron et al., 2017).

Current allergies of any type and nasal allergies were 2.5 times higher at 1 mile from a CAFO, and decreased to 1.3 times higher at 3 miles from a CAFO when compared to 5 miles from a CAFO. Lung allergies remained 2.2–2.6 times higher at distances 1–3 miles from a CAFO when compared to 5 miles. The ability to assess allergy by type is a unique contribution, and something few studies have been able to do. Our study confirms findings from a few U.S. studies that have looked at proximity to CAFOs and allergies or allergy-like symptoms. Wing and Wolf (2000) found those living within 2 miles of a CAFO had increased prevalence of running nose, coughing, headache, itchy eyes, running nose, and sore throat. Mirabelli et al. (2006) found stronger associations with adolescents attending schools within 3 miles of a CAFO and asthma when stratified by those with allergies.

Findings in the U.S, are largely in contrast to those found in Europe,

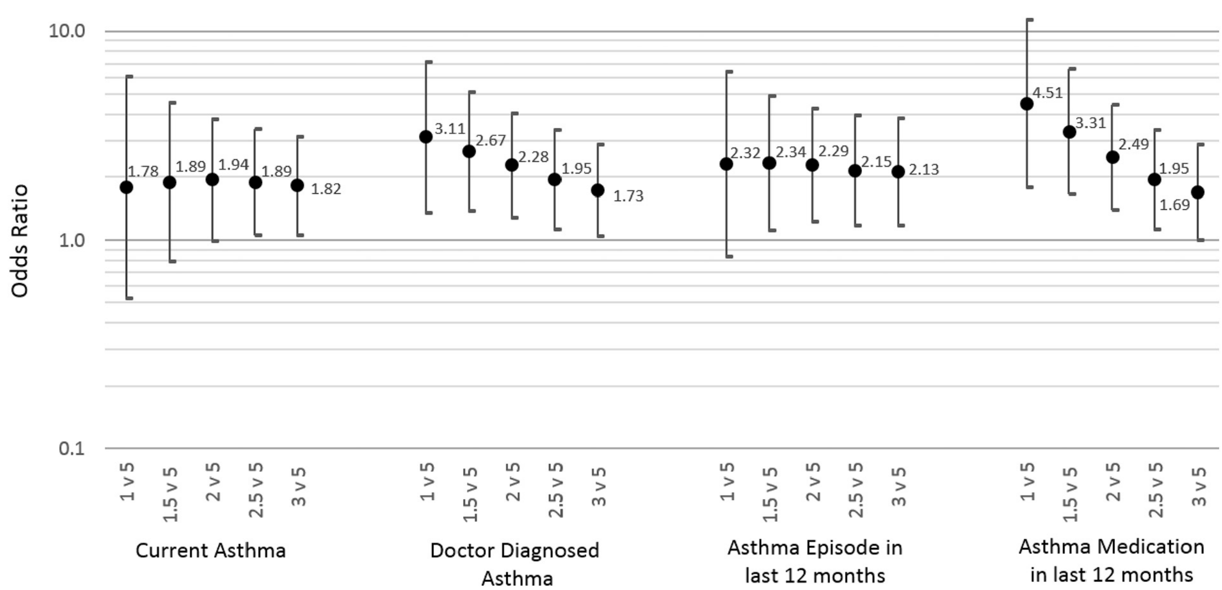

Fig. 3. Results of logistic regression assessing asthmatic outcomes by restricted cubic spline of residential distance to the nearest CAFO. Residential distances of 1, 1.5, 2, 2.5 and 3 miles (1.6, 2.4, 3.4, 4.0, 4.8 km) from a CAFO were compared with a residential distances of 5 miles (8.0 km) from a CAFO. Models are adjusted for gender, age, poverty to income ratio, education, BMI, smoking status, pet ownership and proximity to major roadways.

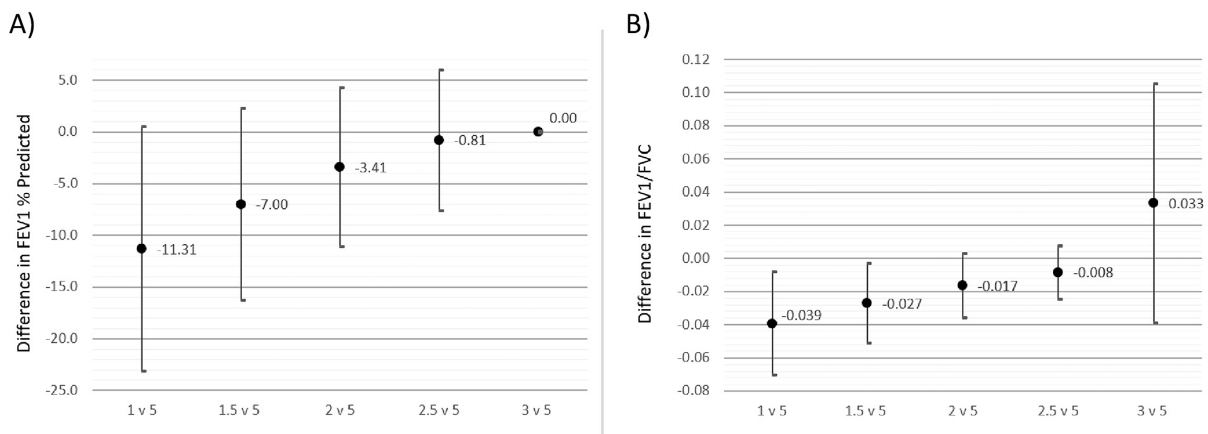

Fig. 4. Results of linear regression assessing (A) FEV1% predicted and (B) FEV1/FVC ratio by restricted cubic spline of residential distance to the nearest CAFO. Residential distances of 1, 1.5, 2, 2.5 and 3 miles (1.6, 2.4, 3.4, 4.0, 4.8 km) from a CAFO were compared with a residential distances of 5 miles (8.0 km) from a CAFO. Models are adjusted for gender, age, poverty to income ratio, education, BMI, smoking status, pet ownership, height, and physical activity.

particularly in Germany and Netherlands, where proximity cut points are typically at 500 m (0.31 miles) or 1000 m (0.62 miles). Several factors may contribute to this. For example, European confined livestock farms are generally smaller than in the U.S., densely clustered, and located in areas of higher population density. Thus, shorter distance cut points and livestock farm counts within 500 or 1000 m are more appropriate. Borlée et al. (2015, 2017) is one of the few studies to assess nonlinear associations using cubic splines of CAFO proximity and nasal allergies, finding inverse results to those seen in this study. Borlée et al. (2015) and Smit et al. (2014) both found inverse associations with doctor diagnosed asthma and allergies using EMR data in the Netherlands. Hooiveld et al. (2016), another Netherlands study which used EMR data found null results, but did not use individually measured exposure data as seen in the other two Netherlands studies. (Radon et al., 2007a) found self-reported asthma and nasal allergies were associated with increased livestock farm odor in Germany, but the number of animal houses near the home was not a predictor of allergies or specific sensitization. (Schulze et al., 2011) is one of the few European studies to find those exposed to higher ammonia levels from livestock farms to be 4.2 times more likely to be sensitized against ubiquitous allergens.

Findings from European studies largely suggest livestock farms provide a protective effect, if any, and support the hygiene hypothesis, specifically with allergy endpoints. The most comprehensive studies dedicated to disentangling the various factors of the protection against allergy provided by farming, such as ALEX, GABRIEL Advanced Surveys, and PASTURE, have been performed in European regions where dairy production is the main activity and where farming is not industrialized; (Alfvén et al., 2006; Genuneit et al., 2011; Riedler et al., 2001) rather in mid-mountain-altitude and among small cheese farms in areas like the Alps (Lis et al., 2008; Roque et al., 2016). In the ALEX and GABRIEL studies, the overall farm effect has been explained by specific and diverse exposure to types of livestock, crops, straw, fodder storage, manure, and unpasteurized milk (Vuitton et al., 2014; Vuitton and Dalphin, 2017). However, the industrialization of farming is thought to have decreased the microbial diversity and increased the abundance of specific bacterial genera which may induce inflammatory response (Kong et al., 2012; Powers et al., 2015; Schaeffer et al., 2017). This is further supported by studies showing household dust and the nasal microbiota from farm children to have higher alpha and beta diversity than those found from nonfarm children, and lower nasal microbiota diversity to be associated with asthma prevalence (Depner et al., 2015; Pekkanen et al., 2018).

However, protective or null effects have also been seen among adults living near non-traditional, industrialized confined livestock operations in Europe, which are generally smaller in size than CAFOs seen in the United States. (Borlée et al., 2015, 2017; Hooiveld et al., 2016; Radon et al., 2007b; Smit et al., 2014; Michalopoulos et al., 2016) This suggests that the dose of exposure to microbes, in combination with particulate matter, gases, and vapors emitted from livestock operations, may also play a role in the respiratory health effects seen among nearby residents. While it appears both the dose and type of exposure to microbial agents from livestock farms may be of importance, additional research is needed with attempts to identify etiological agents from livestock agents. Differences in the size and management practices of the livestock farms themselves, the microbial diversity emitted, the regulations imposed on them or the populations living near them are all factors which may have contributed to the different results seen in the European studies when compared to the U.S.

Discrepancy in findings across studies in Europe and the U.S. could also be due to varying ways in which asthma and allergies are diagnosed, or defined. Asthma diagnoses are often made based on symptoms and treatment based on severity of symptoms. However, asthma is a heterogeneous disease that manifests differently in different people, symptoms can vary over time and change day to day within the same person, and therefore diagnoses may vary by individual, doctor, or region. (Jacob et al., 2017) Previous studies have showed the challenges to accurately diagnosing asthma have resulted in over- or underdiagnosis of asthma. (Jacob et al., 2017) Furthermore, distinctions between allergic and non-allergic asthma can often not be made without a serological test. All these factors may also contribute to discrepancies in results across the literature.

Lung function was positively associated with proximity to a CAFO, with lung function improving as distance from a CAFO increased. The effect sizes, although most non-significant, were similar to results from European studies of adults in Germany and the Netherlands (Schulze et al., 2011; Radon et al., 2007a, 2007b). A distance of 1.5 miles was associated with −7.0% predicted FEV1 when compared with a distance of 5 miles from a CAFO. Schulze et al. (2011) found a −8.19% predicted FEV1 among those with average ammonia concentration greater than or equal to 19.71 $\mu g/m^3$ when compared to those with levels below. Similarly Radon et al. (2007a, 2007b) reported a −7.4% predicted FEV1 among those more than twelve animals houses within 500 m of home. While definitions of exposure to CAFO varied, the fact that all three studies found very similar results suggests residential proximity to a CAFO, or many AFOs, is likely associated with decreased lung function.

As one of the first studies in the U.S. to use a randomly selected statewide, population-based sample of rural adult residents to assess multiple respiratory health effects among people living in proximity to CAFOs, this study has numerous strengths. Prior U.S. studies have tended to rely on grouped exposures, removing individually variability among the exposure (Mirabelli et al., 2006; Rasmussen et al., 2017; Sigurdarson and Kline, 2006; Wing and Wolf, 2000). Our study was able to report on the nonlinear association between proximity to the nearest CAFO and respiratory health outcomes in the U.S., providing an important link between dispersion modeling of CAFO emissions and human health effects.

While utilizing a randomly selected statewide sample is a strength of this study, it is also a limitation. Rare exposures, such as living near a CAFO in the U.S., can result in low power and are best studied with cohort studies where subjects are selected by exposure status. Low power may have resulted in our inability to detect interaction with proximity to a CAFO and smoking status. Though we carefully controlled for multiple confounding factors, residual confounding or confounding by other unmeasured factors may affect estimated associations including individuals with potential higher livestock exposures via occupation. However, the number of subjects reporting livestock exposure was small and not sufficient to examine as a separate subpopulation. Similarly, residents in urban areas were not included to reduce bias and reduce potential unmeasured confounding introduced by air pollution sources unique to urban areas. The cross sectional nature of this study also limits conclusions regarding the temporal association between exposure and respiratory outcomes, particularly self-reported asthma prevalence. Self-report is not ideal and can lead to recall bias, however asthmatic and allergic symptoms may go clinically underreported in rural areas, where people may be less likely to seek medical care due to inconvenience, cost, or lack of insurance. While objective and self-report data on asthma was available, this study relied on self-report of allergies. Therefore, results cannot definitively tease out allergic and non-allergic asthma, something that would have strengthened the study and increased comparability with other studies. Furthermore, the lack of allergic sensitization data limits comparisons with other studies.

We were able to acquire retrospective CAFO data and ensure CAFOs linked to participant residences were in existence prior and during their study participation. However, the farm size and type could not be validated from this data. Additionally, we were unable to account for proximity to non-CAFO livestock farms. The assumption being made here is that the distribution of smaller farms is random throughout the study sample, resulting in non-differential misclassification bias. This assumption results in estimates biased towards the null.

5. Conclusion

In summary, residential proximity to a CAFO among individuals from a randomly sampled general population health survey was positively associated with self-reported nasal and lung allergies, asthmatic outcomes, and objectively measured lung function. This study provides evidence for respiratory health effects among residents living near dairy CAFOs. CAFOs may be an important source to regulate as current evidence suggests that large livestock farms may contribute to health disparities among rural residents. Building on findings from this observational study, future research should consider longitudinal study designs, more refined estimates of exposure source-apportioned air constituents in nearby homes, and more systematic tracking and validation of outcomes. More research is also needed to understand the mixtures of airborne agents from nearby livestock facilities in order to identify any etiological agents which may be associated with asthma, allergies, or lung function in residents living near large livestock facilities. Passive air pollution monitoring using filters or dust collection in homes would be useful to collect in order to better understand composition of air particles and how they may change over time. A cohort study which selects study participants by residential proximity and monitors respiratory health symptoms across multiple seasons should also be considered. Alternatively, a case-control study that recruits from hospitals and clinics in areas with a large concentration of CAFOs and could follow-up self-reported symptomology overtime could overcome some existing limitations of this work.

Sources of funding

Funding for SHOW comes from the Wisconsin Partnership Program (PERC) Award (223 PRJ 25DJ). This project was also supported by funding from the National Heart Lung and Blood Institute (1 RC2 HL101468) the National Institutes of Health's Clinical and Translational Science Award (5UL 1RR025011). Authors also acknowledge support from a core grant to the Center for Demography and Ecology at the University of Wisconsin-Madison (P2C HD047873), the National Institutes of Health, National Center for Advancing Translational Sciences CTSA award (UL1TR000427), and National Institute for Minority Health and Health Disparities award (1P60MD0003428).

Declaration of Competing Interest

None.

Acknowledgements

The authors thank the staff and graduate students at the Survey of the Health of Wisconsin (SHOW) for assistance in data processing and analysis. We would also like to thank the Wisconsin Partnership Program for continued funding of this work. We would also like to thank the SHOW participants for their time and contribution to this work.

Spatial and temporal variability in excessive soil phosphorus levels in eastern North Carolina

L.B. Cahoon[1,*] and S.H. Ensign[2]
[1]*Department of Biological Sciences, UNC Wilmington, Wilmington, NC 28403, USA;* [2]*Curriculum in Ecology, UNC Chapel Hill, Chapel Hill, NC 27599, USA;* [*]*Author for correspondence (e-mail: Cahoon@uncw.edu)*

Received 12 February 2003; accepted in revised form 28 January 2004

Key words: Agriculture, Land use, Manure, Phosphorus, Soil

Abstract

Numerous studies have shown that accumulation of excessive soil phosphorus raises the potential for phosphorus export and eutrophication of adjacent surface waters. Soil phosphorus data from the North Carolina Agronomy Division's database were analyzed for two-year periods spanning the decades of the 1980s and 1990s for 39 eastern North Carolina counties. Eastern North Carolina supported extensive row crop agriculture, rapidly growing intensive livestock industries, and a growing human population during these decades. Excessive soil phosphorus levels, defined as having a soil phosphorus index (P-I, based on Mehlich III testing) $>$ 100, occurred in over 40% of almost a million samples reported for the three two-year periods analyzed. Excessive soil P-I levels were most frequent in central eastern North Carolina, declined in the 1980s and rose again in the 1990s. The distribution of row crop area with excessive soil P-I levels was very similar in time and space. Increases in the area harvested for cotton (+635%) and pasture (+523%) with excessive soil P-I levels were particularly large during the 1990s, when crop areas harvested associated with excessive soil P-I levels for other major crops (corn, tobacco, peanuts) declined. Residential and recreational land uses were associated with similarly high frequencies of excessive soil P-I levels, but these land uses were relatively unimportant ($<$5% area) compared to agricultural land use (~34%) in the region. Recent increases in fertilizer shipments (approximately twofold in the late 1990s) likely reflected increased cotton production. Rapid growth in concentrated animal production (almost twofold increase in total animal units (AU) between 1992 and 2001), with accompanying land application of wastes, accounted for increases in soil P-I values in pasturelands in the 1990s, particularly in central eastern North Carolina, where these activities were concentrated. The potential threat to water quality from export of excessive soil phosphorus is therefore greatest in this region. North Carolina is currently developing a Phosphorus Loss Assessment Tool (PLAT) in an attempt to manage the challenge posed by excessive soil phosphorus levels.

Introduction

Phosphorus is generally considered the macronutrient most frequently responsible for eutrophication problems in freshwater and, to a lesser extent, in estuarine ecosystems (Vollenweider 1976; Hecky and Kilham 1988; Sundareshwar et al. 2003). Excess phosphorus loadings to aquatic ecosystems can drive algae blooms, stimulate bacterial growth, increase biological oxygen demand, and alter aquatic community structure (Correll 1998; Carlsson and Caron 2001; Mallin et al. 2001).

The importance of phosphorus loading from non-point sources, in addition to more well-regulated point source discharges, is widely recognized, e.g., Wanielista and Yousef (1993), Carpenter et al. (1998). Among non-point sources, agricultural sources of phosphorus, which include conventional fertilizers and land-applied animal manures, have received considerable attention, e.g., Sharpley et al. (1994), Daniel et al. (1998), Parry (1998), Sims et al. (1998), Sharpley and Tunney (2000). The relatively recent spread of intensive livestock production using concentrated animal feeding operations (CAFOs) has also led to research on the environmental effects of land-applied manures, with much research focused on phosphorus loading to aquatic ecosystems from land application of wastes from livestock in various countries (Austin et al. 1996; Liu et al. 1997; Sharpley 1997; Sims et al. 1998; Martinez and Peu 2000; Novak et al. 2000; Sauer et al. 2000; Schoumans and Groenendijk 2000; McDowell et al. 2001a, b, c).

Assessment of the risk posed to water quality by phosphorus application to the landscape is a complicated task (Sharpley et al. 1994; Edwards et al. 2000; Nash and Halliwell 2000; McDowell et al. 2001a, b, c). Phosphorus tends to associate strongly with soils, in contrast to more readily soluble nitrogen compounds. Soil erosion has, therefore, been considered a primary pathway of phosphate export. However, other mechanisms of phosphorus transport from landscapes into aquatic ecosystems have been documented, including surface transport of unincorporated materials containing phosphorus, loss of dissolved phosphorus in surface runoff, and leaching of phosphorus through the soil (Austin et al. 1996; Sharpley 1997; Sims et al. 1998; Leinweber et al. 1999; Turner and Haygarth 1999; Turtola and Yli-Halla 1999; Djodjic et al. 2000; Martinez and Peu 2000; Novak et al. 2000).

Soil phosphorus concentration is frequently assessed as a measure of the risk of phosphorus export from landscapes (Pote et al. 1996, 1999; Liu et al. 1997; Sharpley 1997; Sims et al. 1998; McDowell et al. 200la, b, c; Sharpley and Tunney 2000). Although other factors, including distance from water, precipitation/irrigation duration and intensity, water table depth, soil type, phosphorus sorption capacity, slope, tillage, phosphorus application rate and form, and plant cover, affect phosphorus export (Sharpley et al. 1994; Hooda et al. 2000), the concentration of soil phosphorus in excess of plant needs usually determines the potential for phosphorus export. Studies have shown that the amounts and concentrations of phosphorus in surface runoff and in water leaching downward increase significantly as soil phosphorus concentrations rise (Sims et al. 1998; Turner and Haygarth 1999; Novak et al. 2000). Recent studies have also shown that phosphorus export rises dramatically beyond a threshold soil phosphorus concentration or 'break point', which may vary among soil types (McDowell et al. 2001b). Guidelines for interpretation of soil test data on phosphorus concentrations have therefore highlighted the increased risk of phosphorus export above certain soil phosphorus levels, although actual export rates can vary with the factors listed above (Sharpley and Tunney 2000).

Excessively high soil phosphorus levels have been shown to arise from long-term application of commercial fertilizers and, more recently, from widespread land application of fecal wastes, both human and animal. The application of animal wastes at agronomic rates based on nitrogen content and the typically low nitrogen:phosphorus ratio in fecal wastes result in a high potential for accumulation of excess soil phosphorus (Carlile and Phillips 1976; Westerman and King 1983; Barker and Zublena 1995; Jongboeld and Lenis 1998). Regions where row-crop agriculture and/or CAFOs are particularly concentrated have shown significant increases in soil phosphorus concentrations to potentially problematic levels, and regulatory agencies have responded with various management measures (Schoumans and Groenendijk 2000; Sharpley and Tunney 2000).

Non-agricultural land uses, such as residential development (Schueler 1994) and recreational uses, e.g., golf courses (Mallin et al. 2002), can also contribute to phosphorus loading to aquatic ecosystems through fertilizer application, land disturbance, and changes in drainage. As shifts in the relative proportions of agricultural and other land uses occur with changing patterns of human population growth, it is important to consider the relative potential of these different land uses to cause impacts on phosphorus loading and impacts on aquatic ecosystems, particularly in coastal regions with extensive development activities and population shifts.

Eastern North Carolina now supports all of the activities potentially associated with increasing soil phosphorus concentrations. This low-lying, mostly flat portion of the coastal plain has extensive riverine and estuarine systems vulnerable to nutrient loading (Figure 1; Bricker et al. 1999). Eastern North Carolina has supported significant row crop production, particularly tobacco, corn, soybeans and small grains, for many years. Eastern North Carolina has also become a major center of intensive livestock production, especially swine and turkeys, in the last two decades (Cahoon et al. 1999). These agricultural activities have been particularly concentrated in eastern

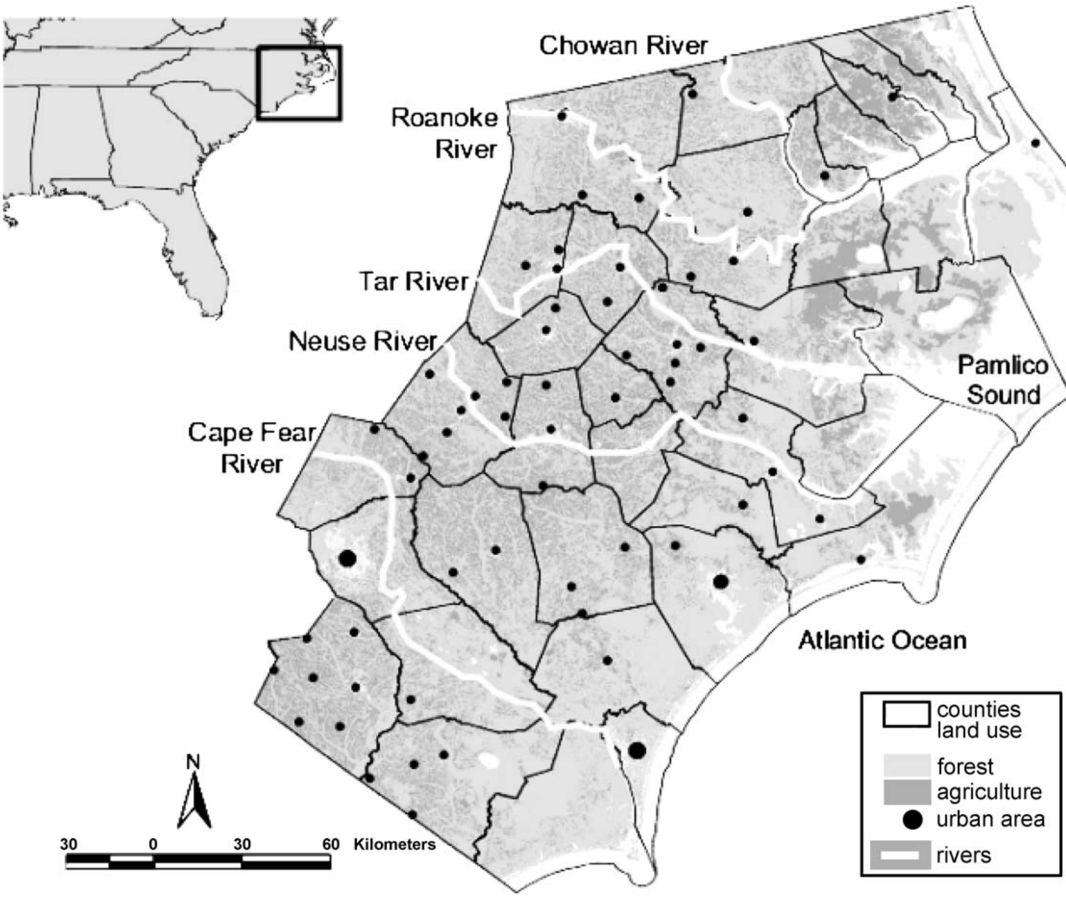

Figure 1. Map of the 39 counties of eastern North Carolina, illustrating county boundaries, major water bodies, and forested, agricultural, and urban areas. Large dots denote urban areas with populations $>50{,}000$, smaller dots denote towns with smaller populations. Land use data from U.S. Geological Survey (2000).

North Carolina. Finally, North Carolina experienced population growth of 21.4% during the decade 1990-2000, with even higher growth rates in coastal counties. Other states and countries, e.g., Maryland and the Netherlands, have experienced serious water quality problems arising from similar trends. The objective of this investigation was to determine the patterns of occurrence of excessive soil phosphorus levels in eastern North Carolina during the last two decades in relation to the major crop types and land uses.

Materials and methods

The North Carolina Department of Agriculture's Agronomy Division provides free soil testing services for state residents and maintains a publicly accessible database of soil test results. Results are compiled for each state fiscal year (FY, July 1 – June 30) with summary soil test data grouped by result ranges for each crop or land use type for each county. Results of individual sample submissions with numerical soil test data and accompanying information have also been posted on the Division's web page since 1998.

The N.C. Agronomy Division employs the Mehlich III extraction method followed by atomic absorption spectrometry to measure soil-P levels (Tucker et al. 1997). The Mehlich III method is considered to extract 'plant-available' phosphorus compounds ('M3P', primarily orthophosphate), providing a useful measure of soil phosphorus concentrations with respect to crop needs (N.C. Coop. Ext. Serv. 1997). Results are reported using a Phosphorus Index (P-I) system, which scales soil-P levels in terms of plant needs. P-I values can be converted into concentration units, e.g., kg P ha^{-1}, using appropriate factors. P-I values in the range 0-10 are considered very low, 11-25 low, 26-50 moderate, 51-100 high, and >100 very high (Tucker et al. 1997). Fertilization generally drives a positive plant response at P-I values <50. P-I values >100 ($=240$ kg P ha^{-1}) are considered excessive and are thought to indicate an increased risk of P export and water pollution (N.C. Coop. Ext. Serv. 1997).

Soil P-I data for 39 counties in eastern North Carolina were obtained for the years (FY) 1980 and 1981, 1990 and 1991, and 2000 and 2001, broken down into P-I ranges by crop or land use type, from the N.C. Agronomy Division. Data from two-year periods were averaged in order to provide larger data sets to analyze patterns over each decade and to mitigate year-to-year variability in soil testing. The limitations and assumptions involved in the soil P-I data summarized here must be considered before evaluating their full importance. North Carolina's soil test data were derived from samples collected by many individuals at different frequencies, times of year, and different densities per unit area across different land uses. The use of large data sets and two-year intervals may have reduced some of the variability otherwise expected, but sampling biases cannot be completely ruled out. Soil samples are supposed to be collected from the top 10 cm of soil and so represent only surface concentrations of phosphorus. Most phosphorus added to soils, i.e., as fertilizer or animal waste, is found in the top portion of the soil (Sims et al. 1998; Martinez and Peu 2000; Novak et al. 2000), so soil P-I data probably represented the bulk of the soil P content, certainly the fraction most labile to runoff and erosion losses (Liu et al. 1997). However, soil P-I data represent an underestimate of total P in the soil when incorporation into or leaching to deeper horizons is considered (Sims et al. 1998; Turner and Haygarth 1999; Novak et al. 2000), and because soil P-I levels determined by the M3P method are considered to indicate only extractable, 'plant available' P (N.C. Coop. Ext. Serv. 1997). The categorization of soil P-I data sets into classes, particularly the class considered here, 'P-I >100', likely also understates the magnitude of excessive soil P-I levels.

Harvested crop acreage, fertilizer shipment and livestock census data were obtained from the N.C. Department of Agriculture's annual statistics yearbooks and converted as appropriate into metric units (hectares and metric tons).

The frequency of excessive soil P-I values as a percentage of total row crop area per county was calculated using soil P-I data for crop types and data from the N.C. Department of Agriculture's annual statistics yearbooks (N.C. D.A. 1982, 1992, 2001) on harvested area for each crop type in each county for 1980, 1990, and 2000. Areas associated with 'home grounds' and 'turf' land uses were not assessed in these yearbooks. 'Miscellaneous' crop type samples were apportioned to each row crop type (according to area harvested data for those crop types in counties for which the summary soil reports did not report soil test results for that crop type) and used to calculate total area and area with excessive soil P-I levels for each crop type.

The intensity of fertilizer use was analyzed by comparing crop area harvested and fertilizer shipments using data from the N.C. Department of Agriculture's Agricultural Statistics yearbooks for the period 1980-1998 (Figure 10; N.C. D.A. 1981–1998). North Carolina's legislature abolished the requirement to report fertilizer shipments annually by county after 1997, so data for the eastern 39 counties were unavailable after that year.

Individual numerical soil test data from swine production operations for the period 1998-2001 were obtained using the N.C. Division of Water Quality's lists of permitted operations and the Agronomy Division's public web site. Soil P-I data were obtained from 1,670 soil reports with 14,125 individual samples. Approximately 500 of these reports and 4100 of the individual samples were from swine production operations owned by corporate integrators and the remainder from individual swine production operations contracting with an integrator.

The effects of residential and recreational land uses on the distribution of excessive soil P levels were assessed by estimating the frequency of excessive soil P levels for the 'home grounds' and 'turf' crop type designations in the N.C. Agronomy Division's database. 'Home grounds' included lawns, gardens, and other residential land uses. 'Turf' corresponded primarily to golf courses and turf farms. Owing to lack of these data for many counties in the period FY80-FY81, only data for the periods FY90-FY91 and FY00-FY01 were plotted for the eastern counties.

Results

Agricultural land uses dominated in eastern North Carolina, with harvested cropland averaging approximately 1.3 million ha between 1980 and 2000 (Figure 1). Total 'land in farms' was 34% of total land area of the 39 eastern North Carolina counties in 1997 (N.C.D.A. 1999). Forests, wetlands, and other undeveloped lands accounted for over 50% of the land area in eastern North Carolina, while 'urban' land cover was less than 5% of land area and golf courses accounted for much less than 1% of total land area (N.C. D.W.Q. 1996, 1997a, b, c, 1999a, b, c, 2000). Although silviculture is important in eastern North Carolina, there were very few soil test results reported for 'forestry' crop types and those values were very low.

Distribution of excessive soil P-I values through time

The N.C. Agronomy Division analyzed over 226,000 soil samples from 39 eastern counties in FY80+FY81 (Table 1). Sample numbers rose approximately 30% a decade later and then another 50% to approximately 450,000 by FY00+FY01. Larger counties and counties with extensive agriculture operations, e.g., Sampson, generated more samples than smaller counties and counties with little agriculture, e.g., Dare.

The frequency of excessive soil P-I values for all land use types was plotted by county for each of the three time periods assessed (Figure 2). The frequency of excessive soil P-I values generally declined (in 34 of 39 counties) between FY80-FY81 and FY90-FY91, but generally increased (in 35 of 39 counties) by FY00-FY01, with considerable variation among counties (Table 2). The highest frequencies of excessive soil P-I values ($>50\%$ of all samples) were consistently found in the central portion of eastern North Carolina at each time interval (Figure 2). The counties bordering estuarine or oceanic waters generally had lower frequencies of excessive soil P-I values (mean = 35% in FY00-FY01). One notable pattern was the declining frequency of excessive soil P-I values between FY80-FY81 and FY90-FY91 in the central region, followed by an increase during the interval between FY90-FY91 and FY00-FY01 in many of those counties, particularly Duplin, Greene, Lenoir, and Sampson counties (Figure 2).

Analysis of the percentages of samples with excessive soil P-I by land use type during the three time intervals revealed several patterns (Table 3). There was a general decrease in the percentages of excessive soil P-I values between FY80-FY81 and FY90-FY91 with an increase by FY00-FY01, except that values for 'pasture' increased and values for 'home grounds' declined steadily. Most ($>80\%$) excessive soil P-I values were associated with row crops, which may partially reflect greater use of soil testing

Table 1. Numbers of soil sample data reported by N.C. Agronomy Division in FY80-FY81, FY90-FY91, and FY00-FY01 for 39 eastern N.C. counties. County names in bold denote counties directly adjoining estuarine or ocean waters (Figure 2).

FY00-FY01	49.0	10.5	Carteret	75.4	Lenoir

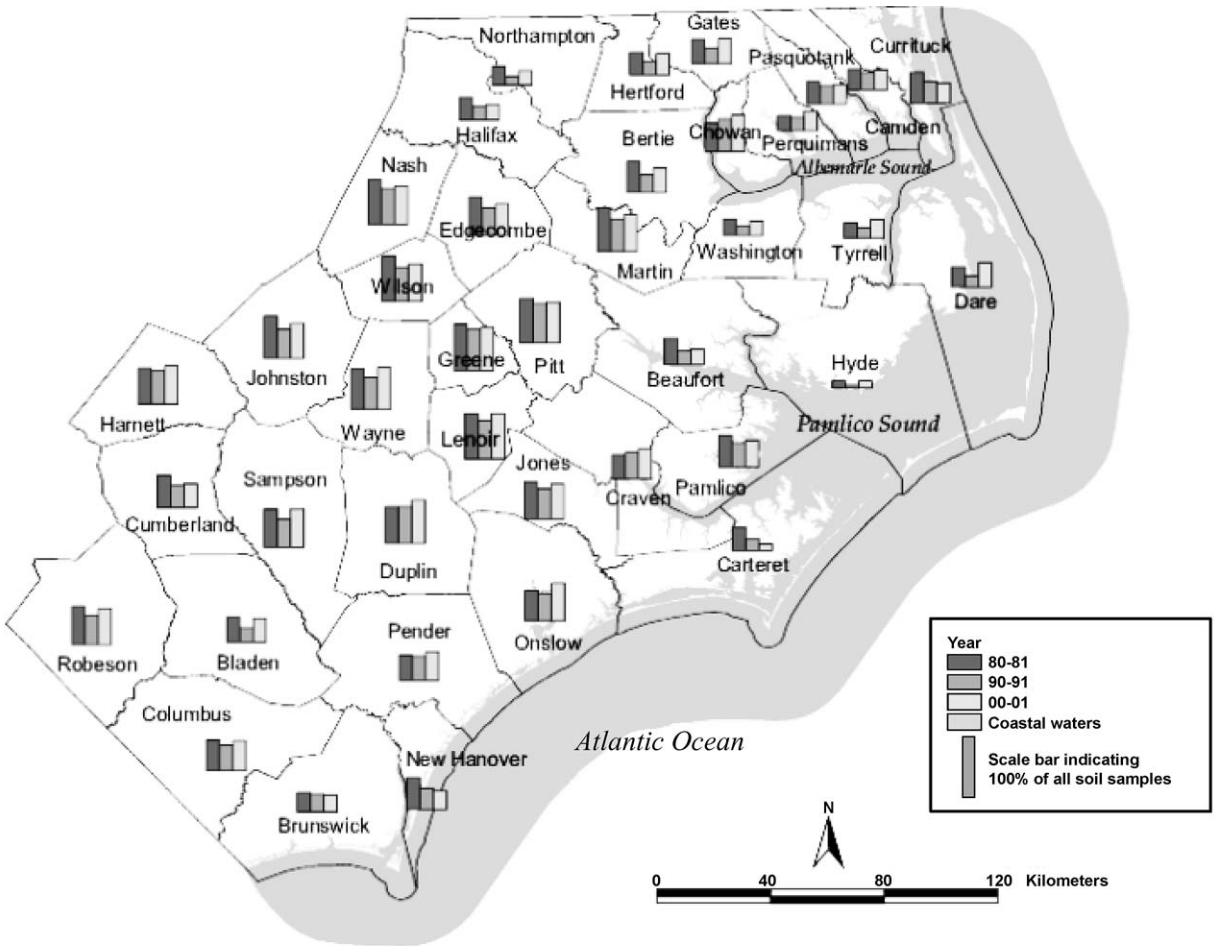

Figure 2. Map showing summary data for frequency of excessive soil P-I levels for the periods FY80-FY81, FY90-FY91, and FY00-FY01 for the 39 counties of eastern North Carolina for which soil P-I data and other information were obtained.

services by commercial farmers. A large proportion (>40%) of the samples with excessive soil P-I levels in FY00-FY01 was associated with cotton production, although the area of harvested cotton was only about 25% of total harvested area (Table 3; N.C. D.A. 2001). This observation suggested that the numbers of soil samples per crop ha harvested varied considerably among crop types.

Patterns of excessive soil P-I values by crop type

The percentage of row crop area with excessive soil P-I values was highest in central eastern North Carolina during each time period (Figure 3), with patterns very similar to those in the summary data set (Figure 2). The counties adjoining estuarine or oceanic waters had generally low frequencies of row crop area

Table 3. Total number (1,000) of soil samples reported and percent of samples with excessive soil P-I levels by land use type in eastern North Carolina for two-year periods, FY80-FY81, FY90-FY91, and FY00-FY01.

	FY80-FY81		FY90-FY91		FY00-FY01

Tobacco	92	84.4	67	71.6	44	78.5

harvested. The temporal patterns of row crop area with excessive soil P-I values were also very similar to those of the summary data set, with declines in 35 of 39 counties between 1980 and 1990 and increases in 34 of 39 counties between 1990 and 2000.

The changing frequencies and crop-specific patterns of excessive soil P-I levels associated with row crop agriculture during 1980, 1990 and 2000 were further examined by calculating the percent areas of each row crop type with excessive soil P-I levels in each corresponding FY (Table 4). The total area of row crops with excessive soil P-I levels in eastern North Carolina decreased about 30% during the 1980s from approximately 0.7 million ha, and then increased in the 1990s from about 0.48 million to over 0.64 million ha. The percentages of each row crop type with excessive soil P-I levels generally decreased between 1980 and 1990, but increased again by 2000. The crop types associated with excessive soil P-I levels changed significantly in their relative contributions to the total area figures in the intervals FY80 to FY90 to FY00. The largest change was the increase in cotton crop area harvested with excessive soil P-I levels (+279% between FY80 and FY 90, +635% between FY90 and FY00, to over 160,000 ha in FY 00), accounting for almost all the total increase. A smaller, but similarly impressive relative increase in crop area with excessive soil P-I occurred for pasture (− 30% between FY80 and FY90, but +523% between FY90 and FY00, to over 30,000 ha in FY00), which included various forage grasses planted on animal manure application fields. Soybeans were also associated with large areas with excessive soil P-I levels (at least 160,000 ha each year). On the other hand, the area with excessive soil P-I levels declined markedly over the interval FY80 to FY00 for peanuts, tobacco, and corn (from just over 0.4 million ha for the three crops in FY80 to just over 0.2 million ha in FY90 to approximately 0.14 million ha in FY00), with modest changes for other crop types.

Shifts in the crop types and acreages harvested associated with excessive soil P-I levels paralleled changes in total acreage harvested for those crops in eastern North Carolina during the intervals 1980 to 1990 and 1990 to 2000 (Table 4). Total crop area harvested declined from about 1.4 million ha in 1980 to 1.19 million ha in 1990, then increased to about 1.34 million ha in 2000. Area harvested for corn, tobacco, and peanuts declined significantly over this period, with a smaller decline in area harvested for soybeans. Area harvested for small grains increased somewhat. The largest increases in area harvested during the period 1980–2000 were for hay (equivalent to ‘pasture’ in soil reports; up over 300%) and cotton (up almost 20-fold).

Crop area harvested and fertilizer shipments declined generally during the 1980s and rose beginning in the early 1990s (Figure 4). These data showed an average ratio of fertilizer shipped per FY to ha harvested per year, e.g., FY82 and 1982, of 0.13 mt total fertilizer/harvested ha during the 14 years, 1982–1995. There was an increase in fertilizer shipments from almost 1 million mt per year as late as FY 1995 to over 1.8 million mt per year by FY97, yielding an average ratio of mt fertilizer shipped per harvested ha of 0.24 for 1996–1997. Fertilizer shipments to 35 of 39 eastern N.C. counties increased between FY95 and FY97 (N.C. D.A. 1996, 1998)

Excessive soil P-I values and CAFO distribution

Livestock inventories increased dramatically during the 1980s and 1990s, with the most dramatic increase driven by the growth of the swine industry in the 1990s, stabilizing at an inventory of over 8 million head in the 39 eastern counties of North Carolina when a legislative moratorium on new swine production facilities was enacted in 1997 (Mallin and Cahoon 2003). When expressed as ‘animal units’ (1 beef cow = 2.5 swine = 30 broiler chickens = 55 turkeys), total animal units in the eastern 39 counties of North Carolina increased rapidly during the 1990s, until the 1997 swine moratorium (Figure 5; N.C. D.A. 1993–2001). Data on turkey production, a significant fraction of animal unit totals, were reported only from 1992 onward. During the period 1992–2001 swine

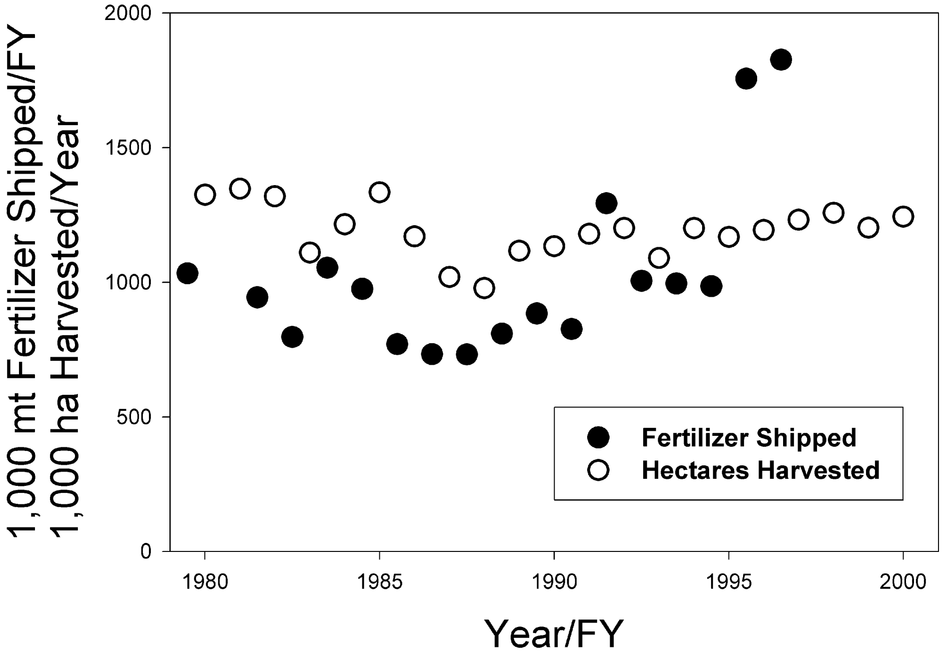

Figure 4. Fertilizer shipments (by FY) and crop area harvested (by calendar year) in eastern North Carolina, 1980–2000.

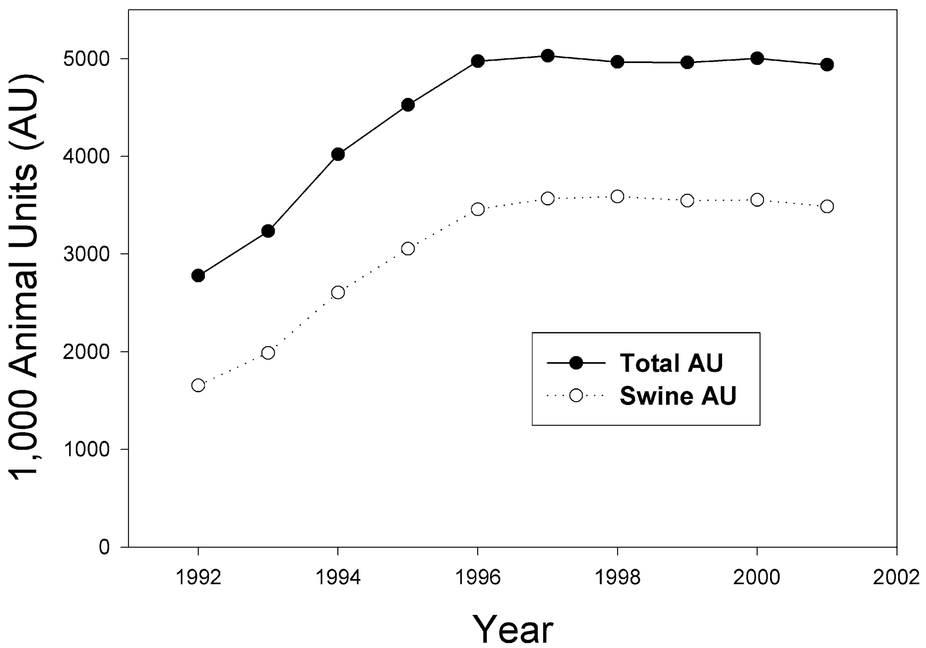

Figure 5. Changes in total animal units (beef cattle + swine + turkeys + broiler chickens) and swine animal units in eastern North Carolina, 1992–2001.

inventory increased from 60% of total animal units in the eastern 39 counties (1,655,000 AU in 1992) to approximately 71% of the total (3,490,000 AU in 2001). Broiler chickens and turkeys accounted for most of the remainder, with beef cattle accounting for only 76,000–92,000 animal units during the period.

Mean soil P-I values from swine CAFOs were 167 (400 kg P ha^{-1}) for all operations, 153 (368 kg P ha^{-1})

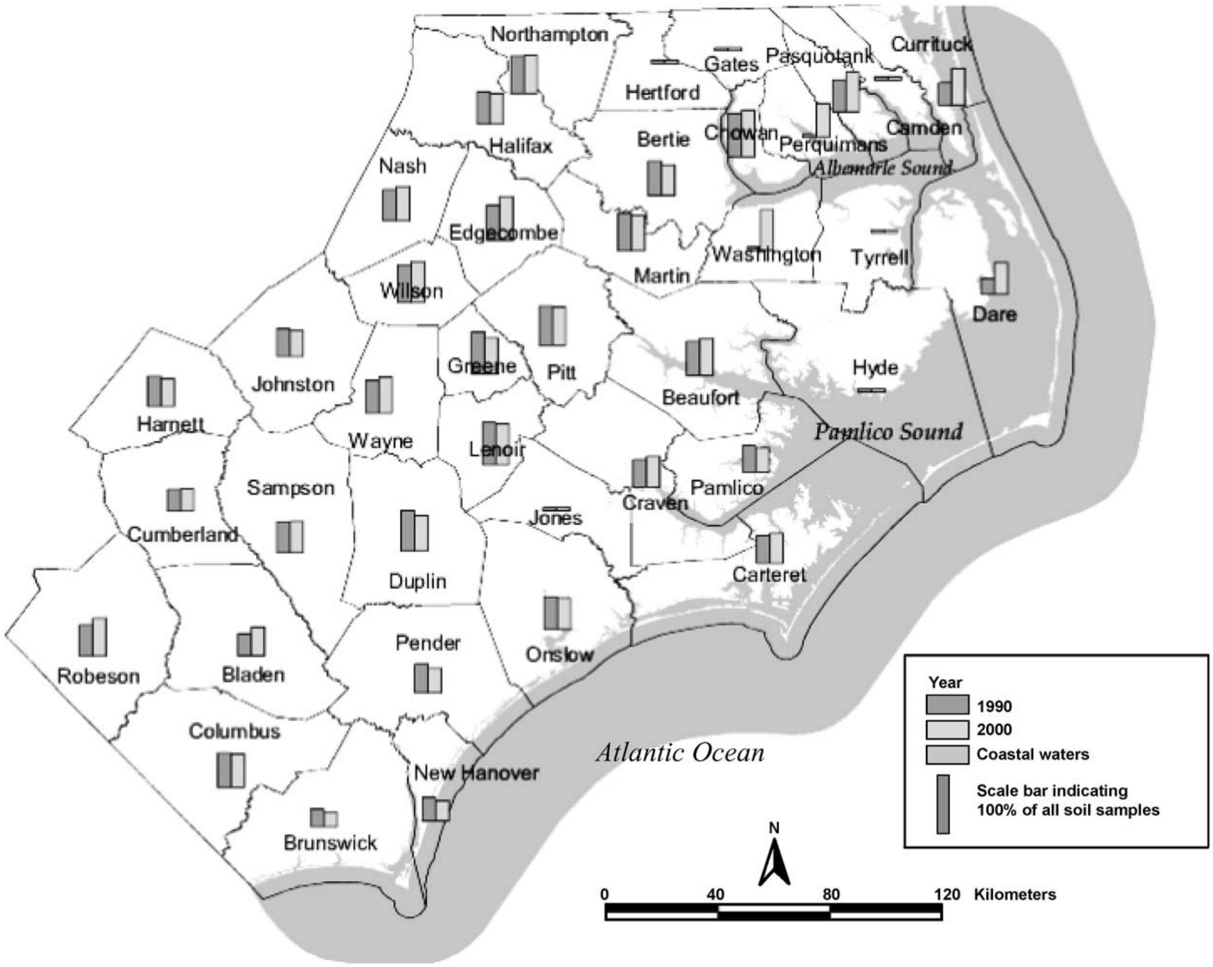

Figure 6. Percentage of soil reports from 'home grounds' and 'turf' with excessive soil P-I levels for each county in eastern North Carolina for FY90-FY91 and FY00-FY01.

for integrator-owned operations, and 172 (413 kg P ha^{-1}) for contracting operations. Liquid swine waste is generally land-applied to various cover crops, particularly coastal Bermudagrass, which has a high nitrogen absorption capacity (N.C. Coop. Ext. Serv. 1997). Data from 1,549 individual samples from coastal Bermudagrass fields associated with swine production operations yielded an overall mean soil P-I value of 188 (451 kg P ha^{-1}), 208 (500 kg P ha^{-1}) for integrator-owned operations, and 170 (408 kg P ha^{-1}) for contracting operations. Bermudagrass is included in 'hay' and 'pasture' categories for data on crop acres harvested and soil P-I values, respectively.

Excessive soil P-I values and non-agricultural land uses

The highest frequencies of excessive soil P-I associated with residential and recreational land use occurred in the central coastal plain and some northeastern counties, with no major shifts during the 1990s (Figure 6). Counties adjoining estuarine and oceanic waters had generally lower frequencies of excessive soil P-I levels, although some of these counties reported no data for each period. Mean frequencies of excessive soil P-I values associated with home grounds and turf were slightly higher than for the summary soil data (Table 2) and variation among counties was high (Table 5).

Table 5. Mean and range of values for frequency of excessive soil P-I levels associated with home grounds and turf in eastern North Carolina for two-year periods, FY90-FY91, and FY00-FY01.

Period	Mean %	Low value		High value	
	P-I > 100	%	County	%	County
FY90-FY91	48.3	21.7	Dare	68.1	Chowan
FY00-FY01	52.8	20.1	Brunswick	69.7	Edgecombe

Discussion

Excessive soil P-I levels occurred in 43% of almost a million soil samples reported from the periods assessed, spanning two decades, in eastern North Carolina. Excessive soil P-I levels occurred in large portions of soil sample results for many land use types across much of the region. These widely distributed and recently increasing levels of excessive soil phosphorus represent a significant potential threat to water quality in the rivers and estuaries of coastal North Carolina.

Agricultural activities (row crop production and intensive livestock production) were clearly associated with a significant portion of the excessive soil P-I levels in eastern North Carolina. The highest frequencies of excessive soil P-I levels were found in the heavily agricultural counties of central eastern North Carolina (Figures 1 and 2). Temporal changes in the frequency of excessive soil P-I levels paralleled changes in crop area harvested, fertilizer shipments, and growth of animal production.

Residential and recreational land uses (‘home grounds’ and ‘turf’) also contributed to the distribution of excessive soil P-I levels, with frequencies of excessive soil P-I levels that were similar to those reported for the summary data (Tables 2 and 3). Although it is difficult to compare these land uses to agricultural land uses, owing to lack of comparable areal data and likely differences in soil testing frequencies, several points suggest that residential and recreational land uses accounted for a generally smaller, if sometimes locally significant, portion of the excessive soil P-I levels in eastern North Carolina than agricultural land uses. As stated above, agricultural land uses dominated in eastern North Carolina, except in some of the counties along the ocean. The large and growing contribution of phosphorus-rich wastes from North Carolina’s massive animal production industries, particularly during the 1990s, must be considered an agricultural cause of excessive soil P-I levels in addition to row crop fertilization practices. The frequencies of excessive soil P-I associated with ‘home grounds’ and ‘turf’ in the coastal counties were generally lower than inland; the highest frequencies were found in the same central eastern North Carolina counties where the highest overall and row crop-associated frequencies of excessive soil P-I levels were found (Figures 2, 3 and 6). It should be noted that soil samples from ‘home grounds’ included samples from vegetable gardens and that soil samples from ‘turf’ likely included samples from turf farms, both forms of agricultural land use, and not strictly residential or recreational land uses. Finally, soil P-I data for New Hanover County, the most heavily urbanized (population: 146,000 in 1997; New Hanover County Planning Dept. 1997) and least agricultural (< 500 ha harvested in 1997, N.C. D.A. 1998) county in eastern North Carolina, had declining frequencies of excessive soil P-I levels throughout the period considered here: 52.7% in FY80-FY81, 35.0% in FY90-FY91, and 30.8% in FY00-FY01. Although residential application was the main use of fertilizer in New Hanover County (Cahoon 2002), excessive soil P-I levels in that urban, coastal county had a very different trend than the inland counties, suggesting that residential fertilizer applications were less likely to create excessive soil P-I levels than agricultural uses.

The increasing frequency of excessive soil P-I levels in eastern North Carolina between the period FY90-FY91 and FY00-FY01 was associated with several trends. Fertilizer shipments rose dramatically in the last two reporting years (FY96 and FY97), out of proportion with crop area harvested (Figure 4). Fertilizer shipments to eastern North Carolina during these two years accounted for 67% of total fertilizer shipments to the whole state (N.C. D.A. 1997, 1998). Total fertilizer shipped for the entire state rose again in FY98 (N.C. D.A. 1999), then declined to levels comparable to the late 1980s by FY00 (N.C. D.A. 2001). Declines in fertilizer shipments and crop area harvested in the 1980s may have allowed the declines in excessive soil P-I levels observed during the interval FY80-FY81 to FY90-FY91, so it is reasonable to assume that increases in these measures in the late 1990s would drive increases in soil P-I levels as well.

Although the actual nutrient contents of fertilizers were not reported by the N.C. Department of Agriculture, an approximate estimate of the phosphorus contents of fertilizers can be made. The fertilizer totals reported above included other materials, such as lime and land plaster, which left about 60% of the total as nutrient-containing fertilizer materials. If phosphorus as P_2O_5 was about 6% of nutrient-containing fertilizers, then phosphorus ($=0.436 \times P_2O_5$) would constitute approximately 1.56% of total fertilizer shipped, or approximately 28,500 metric tons of phosphorus shipped to eastern North Carolina in FY97. Similarly, the excess phosphorus present in soils in eastern North Carolina may be conservatively estimated as the difference between a P-I level of 50 (120 kg ha^{-1}) and 100 (240 kg ha^{-1}) for the 0.64 million hectares with excessive soil P-I levels in 2000, yielding 76,800 metric tons of phosphorus. Clearly, accumulation of this minimal estimate of excess phosphorus must have taken years of fertilization.

It is difficult to attribute the large increase in fertilizer shipments to eastern North Carolina in FY96 and FY 97 to any one crop or land use, partly because different crops may have been grown on the same fields at different times. However, the rapid increase in cotton production, area harvested for cotton, and excessive soil P-I levels associated with cotton production between 1990 and 2000 (Table 4) strongly suggested that heavy fertilization of increasingly widespread cotton crops drove up soil P-I levels widely or that cotton was rotated into already overloaded fields.

The contribution by land application of animal manures to increasing soil P-I levels must also be considered. Eastern North Carolina is a regional center of intensive livestock production, with a swine inventory ($>$8.7 million in 2001) alone exceeding the entire state's human population (~7.6 million in 2000), plus significant populations of broiler chickens, turkeys, and cattle. Much of the growth in these animal industries occurred during the decades of the 1980s and 1990s (Figure 5; Cahoon et al. 1999), so the contribution of animal wastes to soil phosphorus levels also increased proportionately. Mallin and Cahoon (2003) calculated that animal waste produced in the coastal plain of North Carolina (38 eastern counties) represented an annual contribution of 29,000 metric tons of phosphorus as of 2001. Cahoon et al. (2001) showed that in portions of eastern North Carolina where animal production was particularly intense, animal manures were the single most important source of nutrients, exceeding commercial fertilizers and human waste. Furthermore, most of the nutrients in animal manures were imported from out of state, thus representing 'new' nutrients (Cahoon et al. 1999), also likely true for much of the inorganic fertilizer. Soil P-I levels from swine production operations averaged well above 100, and even higher for coastal Bermudagrass fields, which are commonly used to receive land-applied liquid swine waste. Swine CAFOs owned by corporate integrators and by other private contractors exhibited similar patterns of excessive soil P-I levels, indicating that standard industry practices led to these conditions. Increases in crop area of 'hay' (which includes coastal Bermudagrass), excessive soil P-I levels from 'pasture', and crop area of 'pasture' with excessive soil P-I levels (Table 4) during the 1990s were almost certainly driven by increasing swine and poultry production (Figure 5) and land application of wastes, not to use of pasture for beef cattle production, which did not change significantly during that period. Examination of individual soil reports from swine production operations also showed that swine waste was applied to a variety of other crops, including cotton. Therefore, animal waste production, particularly by swine, has contributed significantly to increasing soil P-I levels in the region. This effect was most noticeable in central eastern North Carolina, where animal production was concentrated and where soil P-I levels rose most significantly in the 1990s (Figure 2). Moreover, the 'organic fertilizers' produced by animals did not significantly displace commercial fertilizer use, which increased substantially in the late 1990s (Figure 4).

The frequency of excessive soil P-I levels was highest and increased most significantly in the 1990s in central eastern North Carolina. The well documented relationship between soil phosphorus levels and the potential for phosphorus export (Sims et al. 1998; Turner and Haygarth 1999; Novak et al. 2000; McDowell et al. 2001a, b, c) therefore suggests that the rivers and streams of eastern North Carolina are at greater risk of eutrophication problems than previously. Stow et al. (2001) have shown relationships between agricultural and point sources and nutrient loads in the Neuse River in eastern North Carolina, although relationships vary within the basin. Mallin et al. (2001) have shown that phosphorus inputs to blackwater streams, a common feature of eastern

North Carolina, can drive significant increases in heterotrophic production and Biochemical Oxygen Demand (BOD). Aerial and ground observations show that many of these streams adjacent to agricultural areas have extensive coverage of a wide variety of aquatic macrophytes (Cahoon, personal observation). Mallin et al. (1999) have demonstrated springtime phosphorus stimulation of phytoplankton production in the Cape Fear River Estuary, which drains major animal production and row-crop agricultural areas. Phosphorus-driven eutrophication of North Carolina's coastal rivers during the 1980s led to a ban on residential use of phosphate-rich detergents in 1989, with significant benefits (N.C. D.E.M. 1991). Buildup of excessive soil P-I levels may reverse the progress made by that measure. However, the greatest accumulations of excessive soil P have occurred relatively recently upstream of the region's estuarine waters most vulnerable to eutrophication. The relatively slow transport of phosphorus through erosion, surface runoff, wind-blown dust, and groundwater flow will likely take years to exert their full impact.

North Carolina has recognized the potential threat to water quality posed by the buildup of soil P-I levels in recent years, and is developing a management approach to the problem (a 'Phosphorus Loss Assessment Tool' or PLAT) in response to federal directives (U.S. Natural Resource Conservation Service's Nutrient Management Standard 590, adopted in 1999). The PLAT considers soil P-I levels, soil type, slope, distance to water, land cover, rainfall, soil loss rates and other factors to estimate relative risk of phosphorus export and identify the most effective remedial measures, similar to the P indexing system described by Sharpley et al. (1994). However, the PLAT has not (as of this writing) been formally adopted, may need further revision, and will only be voluntarily implemented when it is finalized and adopted. It remains to be seen if this approach will mitigate the threat to water quality posed by eastern North Carolina's widespread and increasing frequencies of excessive soil P-I levels.

Conclusions

1. Excessive levels of soil phosphorus are widespread across eastern North Carolina. Much of the excess soil phosphorus is associated with row crop agriculture, but this may be partly an artifact of sampling effort.
2. Both excessive use of commercial inorganic fertilizers and widespread land application of animal manures contributed to increases in excessive soil phosphorus levels in the 1990s. Fertilizer shipments increased even as row crop acres declined and animal waste production increased in the 1990s.
3. Increasing levels of soil phosphorus and the widespread distribution of soils with excessive soil phosphorus pose a potentially significant threat to water quality in this coastal region.

ABSTRACT

The application of the circular economy concept should utilize the cycles of nature to preserve materials, energy and nutrients for economic use. A full-scale pig farm plant was developed and validated, showing how it is possible to integrate a circular economy concept into a wastewater treatment system capable of recovering energy, nutrients and enabling water reuse. A low-cost swine wastewater treatment system consisting of several treatment modules such as solid-liquid separation, anaerobic digestion, biological nitrogen removal by nitrification/denitrification and physicochemical phosphorus removal and recovery was able to generate 1880.6 ± 1858.5 kWh d^{-1} of energy, remove 98.6% of nitrogen and 89.7% of phosphorus present in the swine manure. In addition, it was possible to produce enough fertilizer to fertilize 350 ha per year, considering phosphorus and potassium. In addition, the effluent after the chemical phosphorus removal can be safely used in farm cleaning processes or disposed of in water bodies. Thus, the proposed process has proven to be an environmentally superior swine waste management technology, with a positive impact on water quality and ensuring environmental sustainability in intensive swine production.

1. Introduction

Pork meat has been reported as the most widely consumed meat worldwide, with an increase of 20% from 2008 to 2018, producing more than 4 millions of tons in 2018 (FAOSTAT, 2018; Sporchia et al., 2021). To supply these increasing demands for animal protein, the Confined Animal Feeding Operations (CAFOs) model have been applied, also resulting in the generation of high volume of waste in small geographical areas. Generally, wastewater from swine production systems is stored and stabilized in anaerobic lagoons before application as biofertilizer on cropland. In cases of geographical areas with excess swine wastewater application to the soil, due to high organic matter, nitrogen and phosphorus surplus, environmental impacts must be considered, causing water, soil and air pollution besides unpleasant odors, water eutrophication and nutrient accumulation in soil (Ferreira et al., 2018; Kunz et al., 2009a, 2009b; López-Pacheco et al., 2021).

Due to the high pollutant potential of swine manure, the implementation of better management systems on farms must be considered and often swine wastewater treatment is an alternative when the soil support capacity is exceeded. As an important component of a treatment process, anaerobic digestion (AD) can be applied as a cost-effective solution for animal manure treatment, removing the biodegradable organic matter present in the effluent (López-Pacheco et al., 2021; Tan et al., 2021). Furthermore, the major benefit of AD is the biogas generation that can be used as a renewable fuel (*e.g.,* thermal or electrical applications). However, such treatment is not able to solve the problems with nutrients (nitrogen and phosphorus), pathogens and heavy metals present in the digestate. Therefore, treatment technologies are necessary to achieve the effluent environmental standards (González-García et al., 2021; Vanotti et al., 2018; Zubair et al., 2020).

Beyond the main biological processes applied to nitrogen removal, the process based on nitrification/denitrification could be used when a

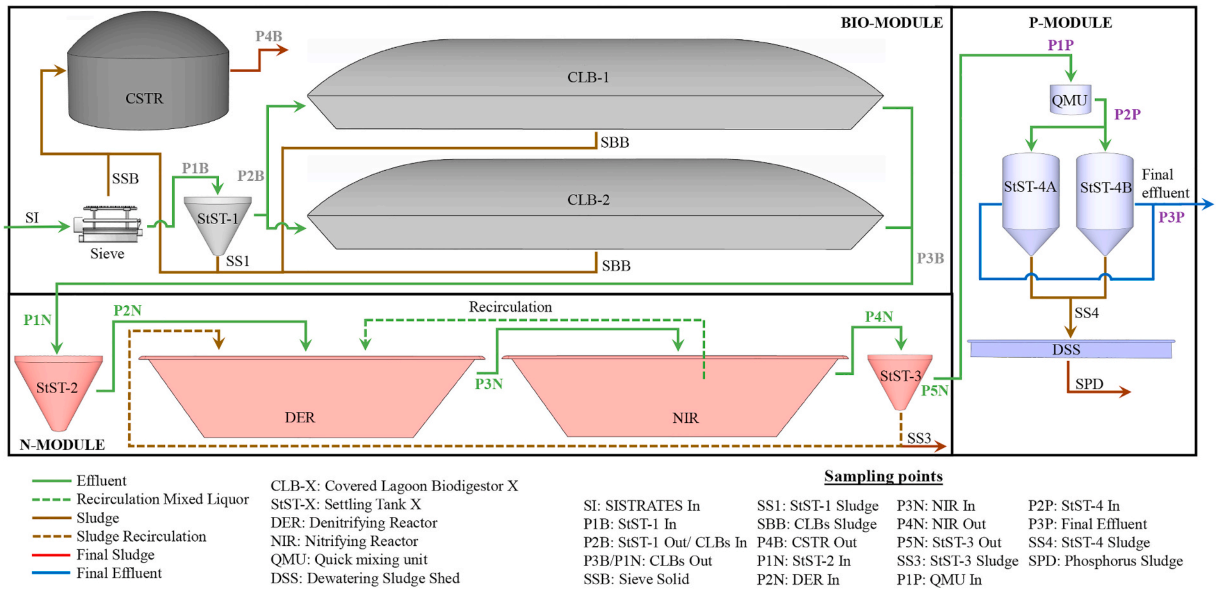

Fig. 1. The configuration of SISTRATES® system. *Bio-module*: composed of the receiving unit, sieving, settling tank-1, CLB (liquid fraction anaerobic digestion) and CSTR biodigester (treatment of sludges fraction). *N-module*: settling tank-2, followed by a denitrification and nitrification tank, and settling tank-3. *P-module*: composed of a quick mixing unit and two settling tanks (4a and 4 b) and sludge drying unit.

pre-treatment for carbon abatement as AD is applied (Bonassa et al., 2021). Through this process the ammoniacal nitrogen is oxidized to nitrate by nitrification and subsequently reduced the nitrite and gaseous nitrogen by denitrification, using an organic substrate as electrons acceptor (He et al., 2018; Liu et al., 2018). It has been proved that denitrification/nitrification process could be applied to treat wastewater with high loads of organic carbon and ammoniacal nitrogen with high removal efficiency (Hollas et al., 2019). The configuration of the process is an important point and the Modified Ludzack-Ettinger System (MLE) meets the necessities of swine manure, that has high concentrations of carbon, enabling its application to wastewater with high solids concentrations, and demonstrating yours robustness to withstand variations in operational feeding rates, but is not efficient in terms of phosphorus removal and recovery (Bortoli et al., 2019; Hollas et al., 2019).

For phosphorus removal and recovery, several treatment methodologies can be applied, as physical separation, biological treatment, adsorption and chemical precipitation (Fernandes et al., 2012; Li et al., 2019; Magrí et al., 2020; Peng et al., 2018; Sperlich et al., 2010; Suzin et al., 2018; Wang et al., 2018). The physic-chemical process for P removal that consists in precipitation using calcium hydroxide ($Ca(OH)_2$) is a great alternative for swine effluent, once hydrated lime is cheaper than the other reagents. It consists in the addition of a $Ca(OH)_2$ suspension up to pH 9,0, followed by settling after precipitation process to achieve a removal percentage of $P_{soluble}$ and P_{total} at least of 96% (Fernandes et al., 2012; Suzin et al., 2018). To ensure satisfactory performance of this process, a pre-treatment for removal of ammonia, organic carbon, and alkalinity is recommended (*e.g.,* AD and nitrogen removal processes), because these parameters have a significant influence on P removal efficiency and purity of the P recovered. High carbon concentrations will cause the co-precipitation of organic matter generating a impure sludge, that can infeasible the process (Peng et al., 2018; Suzin et al., 2018; Szogi and Vanotti, 2009). The inactivation of pathogens is another favorable point in this treatment technology, which makes it applicable following the precepts of circular economy for water reuse (Viancelli et al., 2015).

Considering wastewater management and treatment processes, a big challenge is to connect different processes keeping efficiency and reducing costs. In this way, inside the manure management system, the resources and wastes from the treatment plant can be converted into value-added products based on the cascading principle. For example, the swine manure treatment system could consist of: (i) solid-liquid separation (SLS) by sieving and settling (Amaral et al., 2016); followed by (ii) AD at different reactor configurations (Lins et al., 2020); (iii) digestate treatment for ammonia removal (Bortoli et al., 2019; Hollas et al., 2019); and (iv) phosphorus recovery (Fernandes et al., 2012; Suzin et al., 2018; Viancelli et al., 2015). Following the above principle of cascading idea, the integrated management system would provide: generation of biofertilizer (steps i. ii and iii); bioenergy and biogas (ii); second generation phosphorus (iv); and water for reuse (iii and iv).

In this sense, the SISTRATES® (Kunz et al., 2021) (a Portuguese acronym that means Swine Wastewater Treatment System) is an on-farm technology composed by: (i) SLS; (ii) AD in continuous stirred tank reactor (CSTR) and covered lagoon biodigesters (CLBs); nitrogen removal by nitrification and denitrification; and phosphorus recovery by chemical precipitation, designed to efficiently integrate these technological routes and maximize the environmental benefits of the treatment system. Thus, the aim of this study was to evaluate a full-scale swine manure treatment system where it was possible to perform the removal efficiencies, mass and energy balances, characterization, and evaluation of each step. The correlations between each unitary process were also studied to process control and to establish the technical coefficients. All component systems were evaluated during cold and warm periods.

2. Materials and methods

2.1. Site location

The SISTRATES® was implemented on a farm located in Videira, Santa Catarina - Brazil (27°02′38.8″S 51°05′35.7″W), in a farrow-to-wean piglet producing unit with 6655 ± 201 sows, with average daily flow rate of $192 \pm 45\ m^3\ d^{-1}$ of swine manure. Water consumption and swine manure generation were monitored during two years for conversion calculations.

2.2. Wastewater treatment system description

The treatment system - SISTRATES® aims to treat the swine wastewater in a complete way and therefore it is divided in tree modules. Bio-Module, to reduce total solids (TS) and total organic carbon (TOC) and recovery of biogas, N-Module, to reduce nitrogen and at last the P-

Module to reduce phosphorous and release a high-quality treated effluent. The system configuration, as well as the sampling points (which will be described in the next items), are presented in Fig. 1.

This research was conducted during the period of January 2019 until December 2020. or statistical analysis the periods were subdivided in **Period I** (January, February, March, April, May 2019), **Period II** (June, July, August, September 2019), **Period III** (October, November, December 2019 and January, February, March, April, May 2020), **Period IV** (June, July, August, September 2020) and **Period V** (October, November, December 2020).

2.2.1. Bio-Module: anaerobic digestion setup and operation

This module consists in a SLS process followed by AD biological treatment. The Bio Module was fed in a semi-continuous regime at a daily flow rate of 191.10 ± 44.98 m^3 d^{-1}. The SLS process is composed of a brush-roller screen (2 mm mesh), followed by settling tank 1 (StST-1,40 m^3). The liquid fraction flow rate is split and sent to two CLBs (2500 m^3 each one) without heating or mixing systems. The solid/sludge fractions (0.005 Qin_{screen} + 0.07 Qin_{StST-1} + 0.02 Qin_{CLBs}) were sent to a CSTR (700 m^3) operated under mechanical mixing and mesophilic conditions.

The biogas generated in the process (CLBs and CSTR) was measured using thermal mass flowmeters (Contech, model FT2, Brazil). The biogas composition was also simultaneously checked for methane (CH_4), carbon dioxide (CO_2), oxygen gas (O_2) and hydrogen sulfide (H_2S) (Awite, model Awiflex, Germany). Biogas H_2S concentration was reduced by microaeration (Awite, model Awidesulf 300/500) previously to a combined Heat and Power (CHP) unit.

For the AD treatment system, composite liquid samples were collected, from eight points: (SI) SISTRATES® in; (P1B) input of StST-1; (P2B) input from CLBs (supernatant from StST-1); (P3B/P1N) digestate from CLBs; (SS1) settled sludge (sludge of StST-1); (SBB) sludge from CLBs; (SSB) solid retained in sieve; (P4B) digestate from CSTR.

Samples were collected monthly and submitted to analysis of, alkalinity, pH, VFA/TA ratio, TOC, total nitrogen (TN), total ammoniacal nitrogen (TAN), TS, Volatile Solids (VS) and Fixed Solids (FS) and total phosphorus (TP). Biodigesters temperature and biogas production were continuously measured.

2.2.2. N-module: nitrogen removal setup and operation

For the nitrogen removal process, a MLE system was implemented (Bortoli et al., 2019). The effluent from CLBs flows to settling tank 2 (StST-2,40 m^3), previous to the nitrification/denitrification process, aiming to reduce TOC and solids concentration specially during wintertime. The liquid fraction flows in series mode through an anoxic tank for denitrification (983 m^3) an aerated reactor for nitrification (1272 m^3). Another settling tank, the settling tank 3 (StST-3,30 m^3), was installed after the nitrification tank, to separate and discharge biological sludge (Hollas et al., 2019). To start-up the nitrification process, the reactor was previously filled with water and inoculated wit 30 m^3 of nitrifying sludge acclimated to achieve high activity prior to starting the complete system ($0.01351 g_N\ g^{-1}{}_{VSS}\ h^{-1}$) (Antes et al., 2020).

The aeration inn nitrified tank was supplied with an air grid system (B&F DIAS, model B&F Air Grid, Brazil) using tubular membrane diffusers. The dissolved oxygen (DO) was kept around 2.5 ± 0.5 $mgO_2\ L^{-1}$ and monitored online (Hach, model SC200, USA). The N-module feeding flow rate (Q_{in}) consisted of a fraction of the discharge effluent from the CLBs (which did or did not pass through the StST-2 (as it will be discussed afterwards), at an average flow rate of 147.32 ± 19.50 m^3 d^{-1}. Nitrification reactor and StST-3 sludge (from nitrification) were constantly recirculated to denitrification reactor at a flow rate of 5.5 $Qin_{N\text{-}module}$ and 1.0Q_{in} $in_{N\text{-}module}$, respectively according to described by Bortoli et al., 2019. The exceeded sludge is discarded and sent to fertigation.

The MLE process was weekly monitored through analysis of samples collected from the following points: (P3B/P1N) in digestate from CLBs, (P2N) denitrifying reactor in, (P3N) denitrifying reactor out, (P4N) nitrifying reactor out, (P5N/P1P) StST-3 out and (SS3) sludge from StST-3. The samples were submitted to determination of alkalinity, TOC, TAN, nitrate ($NO_3{}^-$-N), nitrite ($NO_2{}^-$-N), Total Suspended Solids (TSS), Volatile Suspended Solids (VSS), Fixed Suspended Solids (FSS) and TP. The daily monitoring consists in determination of temperature, pH and DO that were measured in each reactor.

2.2.3. P module: phosphorus removal setup and operation

The effluent from N-Module flows to P-Module (138.3 ± 20.19 m^3 d^{-1}). Firstly, it fed a quick mixing unit (QMU, 0.186 m^2), were the effluent receives a suspension of $Ca(OH)_2$ 10% (m v^{-1}), until pH 9. The pH set point is determined using a pH controller (Digimed, model TH-48, Brazil) (Suzin et al., 2018).

After QMU the mixture flows by gravity to two parallel settling tanks (StST-4,35 m^3 each), with a hydraulic retention time (HRT) of 12.5 ± 2.9 h. The StST-4 liquid fraction is discharged to a water body and the P sludge, rich in calcium phosphate, is diverted for dewatering in polypropylene bags or directly sent to agricultural use.

The P-module effluent was also monitored weekly during a six-month period, from three points: (P5N/P1P) QMU in; (SD4) sludge out of StST-4 (4a and 4 b); (P3P) final effluent.

Samples were collected weekly and submitted to determination of alkalinity, TOC, TAN, $NO_2{}^-$-N, $NO_3{}^-$-N and TP (liquid fraction), to verify if the final effluent meets the quality requirement by Brazilian regulation (CONAMA 430, 2011) and TS, VS, FS, TP, TOC, potassium (K) and calcium (Ca) (solid fraction). Microbiological analyses (*Escherichia coli*, *Salmonella* spp. and *Porcine circovirus* type 2 - PCV2) were performed in the final effluent (P3P) in warm and cold periods corresponding to the months of August/2020 and January/2021, respectively.

2.3. Analytical methods

2.3.1. Physical-chemical parameters

TOC, total carbon (TC), TN, TAN (TAN = $NH_4{}^+$-N + NH_3–N, expressed as NH_3–N), $NO_3{}^-$-N, $NO_2{}^-$-N, alkalinity (expressed as $mgCaCO_3\ L^{-1}$), VFA/TA ratio, VSS, FSS and TSS, VS, SF and TS and TP, were determined according to Standard Methods for the Examination of Water and Wastewater (Rice et al., 2017). Analyses were performed in triplicate following standardized protocols based on good laboratory practices and quality assurance policy.

TOC and TN were determined with a TOC analyzer (Shimadzu, TOC-LCPH/CPN, Japan). TC was measured by CNHS elemental analyzer (Thermo Fisher Scientific, model Flash, 2000; USA); both following the manufacturer recommendations, NH_3–N (modified Berthelot's reaction colorimetric method), $NO_2{}^-$-N (colorimetric method at pH 2.0–2.5 using sulfanilamide with N-(1-naphthyl)ethylenediamine) and $NO_3{}^-$-N (same method of $NO_2{}^-$-N, but by its reduction in a cadmium column) were measured in a flow injection analysis system (Fialab Instruments, model 2500, USA). Alkalinity and VFA/TA ratio determination were performed in an automatic titrator (Metrohm, model 848 Titrino plus, Switzerland). TP was quantified by spectrophotometric molybdovanadate method using a spectrophotometer (Varian, Cary® 50 UV–Vis, USA). The samples were dried at 105 °C for the determination of TS and TSS, and calcined at 550 °C for VS VSS, FS and FSS determination. Samples were also analyzed for determination of Ca and K. The K was quantified by flame photometry Micronal, model B-462 Brazil), and Ca was quantified by flame Atomic Absorption Spectrometry (Varian, Spectr AA 220, USA), according to Standard Methods for the Examination of Water and Wastewater (Rice et al., 2017).

2.3.2. Microbiological parameters

E. coli was quantified using a Chromocult Coliform Agar (Merck, Germany) following manufacturer's instructions, and results expressed in the form of Colony Forming Units (CFU). *Salmonella* was quantified in deoxycholate-lysine-xylose agar (Merck, Germany), as described by

Michael et al. (2003), and also expressed in CFU. PCV2 determination was performed using VetMAX™ Porcine PCV2 Quant Kit (Applied Biosystems®, Foster City, USA), according to the manufacturer's protocol.

2.4. Technical coefficients

Based on the monitoring of the treatment system over a period of two years it was possible to determine several technical coefficients related to the treatment processes employed. The technical coefficients used for the system were calculated according to the Equations shown in Table 1S, in the supplementary material.

2.5. Statistical analysis and machine learning

Data management and analysis of variance (ANOVA) for data validation were performed with software STATISTICA 8.0. Analysis and predictions of the wastewater treatment system, based on the known past events, was done with the WEKA® Software. The algorithm used for the decision tree to perform the data mining task was J48, operated in the WEKA® computer program, based on the C4.5 tree training algorithm (Quinlan, 1993).

3. Results and discussion

3.1. Swine manure characterization

The daily manure flow rate that fed the SISTRATES® during the two years of monitoring was 192 ± 45 $m^3{}_{manure}\ d^{-1}$ and presented TS and VS concentrations of 15.63 ± 9.71 g L^{-1} and 10.70 ± 7.13 g L^{-1}, respectively with TC concentration of 6489 ± 4514 mg L^{-1}. The nutrient concentrations in the influent wastewater were for TN 1817 ± 708 $mg_N\ L^{-1}$, TAN 1221 ± 457 $mg_N\ L^{-1}$, TP 453 ± 368 mg L^{-1} and K 757 ± 338 mg L^{-1}.

The high variability of these parameters is justified due to the influence of seasonality. According to Cárdenas et al. (2021) the main factor that impacts the swine manure characteristics is the water consumption in productive system, which tends to be higher in the summer, affecting the concentration of manure. The averages of environmental parameters such as temperature and precipitation are presented in Table 2S, in addition to the volume of water consumed in the farms and swine manure generation, according to the warm and cold periods, where in general the highest water consumption was for the warm periods.

3.2. - SISTRATES® performance

The complexity of the swine wastewater points out that the appropriate way to manage these effluents is a decisive key for the success of the treatment. For this reason, SISTRATES® is divided in incremental modules that aim to reduce and stabilize distinct parameters and fractions of swine wastewater. This assumption will base the discussion afterwards.

3.2.1. Bio-Module

The first SISTRATES® module is the Bio-Module consisting in a SLS unit, followed by AD biodigesters (CLB and CSTR). The SLS unit liquid fraction fed the CLB, and the solids and sludge fraction were sent to a sidestream CSTR. This module enable the separation of solids fraction and reduction of organic matter beyond the biogas generation in the biodigesters, that is sent to a CHP unit for energy production.

3.2.1.1. SLS. The SLS process aims to prepare the swine wastewater fractions that will be directed to each type of reactor while this step begins in the brush-roller screen (2 mm mesh), which has the purpose of separating the coarse solids followed by a StST-1 (HRT 1.8 ± 0.7 h).

Table 1
CLB removal efficiency considering the seasonality effect in Bio-Module of SISTRATES® (n = 14).

Parameter	Seasonality				
	Period I	Period II	Period III	Period IV	Period V
VS removal (%)	76.5[a] ± 4.0	58.4[b] ± 1.7	81.0[a] ± 0.6	63.9[ab] ± 5.8	72.8[a] ± 2.6
FS out (%)	61.0 ± 4.0	71.3 ± 1.1	53.3 ± 5.5	72.2 ± 6.9	66.7 ± 7.3
TC removal (%)	74.6[a] ± 7.0	55.3[b] ± 7.0	70.9[a] ± 7.8	61.0[ab] ± 7.4	72.8[a] ± 2.5
TOC removal (%)	79.3[a] ± 4.8	55.9[b] ± 11.7	81.9[a] ± 5.4	67.2[ab] ± 6.9	79.3[a] ± 3.0
TN removal (%)	15.3[a] ± 8.9	3.9[a] ± 3.2	5.22[a] ± 3	12.3[a] ± 6	5.3[a] ± 2.8
P removal (%)	68.1[a] ± 3.3	58.4[a] ± 14.6	47[a] ± 18	62[a] ± 2	65.8[a] ± 6.3
K removal (%)	11.2[a] ± 6.4	8.2[a] ± 3.6	8.5[a] ± 1.4	7.3[a] ± 3.8	5.9[a] ± 5

Where: VS_{in}: 9.3 ± 1.2 g L^{-1}; FS_{in}: 3.9 ± 0.4 g L^{-1}; TC_{in}: 4963 ± 1157 mg kg^{-1}; TOC_{in}: 3818 ± 1296 mg L^{-1}; TP_{in}: 338.0 ± 97.8 mg L^{-1}; K_{in}: 665.4 ± 91.8 mg L^{-1}; NT_{in}: 1641 ± 453 mg kg^{-1}.
Evaluated seasonality: **Period I** (warm) - correspond to the months of January, February, March, April and May 2019; **Period II** (Cold) - correspond to the months of June, July, August and September 2019; **Period III** (warm) - correspond to the months of October, November, December 2019 and January, February, March, April and May 2020; **Period IV** (Cold) - correspond to the months of June, July, August and September 2020; and **Period V** (warm) - correspond to the months of October, November and December 2020.
*Means followed by the same lowercase letters on the lines of the same parameter do not differ significantly by the Tukey test ($p < 0.05$).

This step presented a TS removal of 7.4 ± 6.9% in the brush-roller screen, and 32.90 ± 18.9% in StST-1 (Tables 3S and 4S), which will ensure the efficiency of the next operational units to be performed in the treatment system. According to Amaral et al. (2016) the sieving step has an average efficiency in the reduction of VS that varies around 6–20.5%, depending on the type and age of effluent.

The concentrations of TC and TP showed removal efficiencies of 7.2 ± 6.7% and 3.8 ± 3.6%, respectively, in sieving, and 34.1 ± 22.3% for TC and 42.9 ± 33.45% for TP after StST-1. Nutrients such as TN and K, on the other hand, did not have such significant interference in the SLS process, due to the solubility of these elements, with average efficiencies of 1.6 ± 1.5% for TN, and 0.6 ± 0.5% for K, in the sieving; and of 12.7 ± 3.9% for TN and 15.1 ± 5.7% for K in the StST-1.

The success of this separation step is extremely important to obtain better results in AD, besides prolonging the life of the CLBs reactors because it avoids silting, since after SLS the solid and liquid fraction are conducted to distinct AD reactors, as described below.

3.2.1.2. CLB. The use of CLB to treat swine manure has intensified in Brazil in view of easy operation and low cost. CLBs receive the StST-1 supernatant, with an average concentration of VS at 11.0 ± 2.5 $g_{VS}\ L^{-1}$, and an organic loading rate (OLR) of 0.35 ± 0.16 $kg_{VS}\ m^{-3}d^{-1}$ (Tápparo et al., 2021). The values are according to this type of reactor, working better for liquid manure with less than 3% (w v^{-1}) of TS and low OLR (approximately 0.5 $kg_{VS}\ m^{-3}d^{-1}$) (Wu, 2013).

The average biogas productivity was 0.18 ± 0.05 $Nm^3{}_{biogas}\ m^{3}{}^{-1}{}_{reactor}\ d^{-1}$ and biogas yield was 0.56 ± 0.27 $Nm^3{}_{biogas}\ kg_{VSadd}{}^{-1}$ (Tápparo et al., 2021). The biogas productivity and yield variation in this reactor design is predictable, due to seasonal temperature fluctuation. A biogas productivity decreases of 30% was observed during winter and consequently the TOC and VS removal was reduced (Table 1). CLBs are left operate at ambient temperature, due to impracticality in temperature control, consequently biogas productivity and carbon removal decrease at low temperature was expected (Yu and Schanbacher, 2010). The decrease of biogas productivity was similar as observed by Schmidt et al. (2019) that indicated a 30% reduction in biogas production when

Table 2
Concentration of nutrients, total carbon and solid removal efficiency of CSTR in Bio-Module of SISTRATES® (n = 10).

Parameter	Average ± S.D.
TC removal (%)	55.9 ± 9.7
TS removal (%)	53.8 ± 9.2
VS removal (%)	64.4 ± 5.6
TP_{out} (mg L^{-1})	1295.4 ± 378.6
K_{out} (mg L^{-1})	807.2 ± 138.6
TN_{out} (mg L^{-1})	3183.4 ± 642.2

Where: TC_{in}: 21.9 ± 5.3; TS_{in}: 55.4 ± 18.7; VS_{in}: 50.7 ± 7.2; TP_{in}: 1935.9 ± 733.6; K_{in}: 709.0 ± 58.1; TN_{in}: 1653.0 ± 188.4.

the temperature decreased 7 °C in a CLB operated at lab scale. The CLB was operated in a way to have a residual TOC (1040 ± 482 mg L^{-1}), due to the denitrification step, where carbon is used to convert nitrate and nitrite to gaseous nitrogen.

The SLS unit proved to be an excellent strategy to increase the useful life of CLB, considering that only 3.94 ± 0.45 g_{FS} L^{-1} entered the reactor, with an output of 70 ± 9%, so we can assume that approximately only 30% was settled at the reactor bottom. Furthermore, this system has a daily discard of CLB sludge. Usually, there is no physical pre-treatment before CLB, then periodic cleaning is necessary due to FS accumulation (Yu and Schanbacher, 2010). The solid accumulation can decrease the useful volume of the reactor, HRT and consequently the biogas recovery and digestate quality (Cantrell et al., 2008).

In addition to process preservation due to the lifetime of the reactor, SLS enables an increase in gas production as reported by Amaral et al. (2016) who also used SLS as a strategy to increase biogas yield, observing an approximately 2-fold increase. As reported by Hollas et al. (2021), that studied the effect of SLS on biogas production and implemented the same separation techniques described here, an increase of 4.5 kWh of electricity for each m^3 could be obtained, proving the importance of the implemented configuration, corroborating in practical terms the useful life of the system as well as technically benefiting the increase in biogas production.

3.2.1.3. CSTR. As previously described, the CSTR feeding consists in a mixture of three solid fractions of SLS step, solid retained in a brush-roller screen, sludge from StST-1 and sludge from CLBs. The flow rate was 20 ± 5 m^3 with a VS concentration of 60.6 ± 10.8 mg L^{-1} and OLR of 1.69 ± 0.34 kg_{VSadd} m^3 $reactor^{-1}$ d^{-1} (Tápparo et al., 2021).

The CSTR, differently from CLBs, has a heating system that maintains the temperature control thus room temperature has no influence directly on the process performance, remaining between 35 ± 2 °C (because this the global results were presented). The biogas productivity was 0.65 ± 0.23 $Nm^3{}_{biogas}$ m^3 $^{-1}{}_{reactor}$ d^{-1} and biogas yield was 0.38 ± 0.14 $Nm^3{}_{biogas}$ $kg_{VSadd}{}^{-1}$ (Tápparo et al., 2021). With the combination of temperature control and the CSTR design, an increase pf biogas productivity over 10-fold was expected in comparison to CLB (Cantrell et al., 2008). Furthermore, due to high the process stability observed during all operation period, the OLR could be increased, using other substrates available on the farm, increasing biogas production and energy conversion.

The variability of nutrients on digestate was a consequence of manure variation, the inherent fluctuations of the production process (Amaral et al., 2016; Kunz et al., 2009b). The TP out in CSTR is until 5 times higher than CLB digestate, probably through P aggregation on the solid fraction (Chini et al., 2021; Deng et al., 2014). The concentration of the NPK elements and removals of TC and VS are presented in Table 2. Moreover, the nutrients are concentrated in the CSTR digestate, compared to swine manure, which increases the digestate value as fertilizer, reducing the costs with transportation and digestate spread (Deng et al., 2014).

The configuration adopted for the digestion of swine waste according to the solid matrix of the wastewater proved to be an efficient strategy for the management of swine waste maximizing energy recovery and technically ensuring the operation of the treatment plant. Environmentally, AD is favorable for reducing the impacts associated with the production of pigs, since it replaces the treatment lagoons, allowing the reduction of greenhouse gas emissions combined with energy recovery, which can be considered one of the biggest future challenges, especially for developing countries. Thus, the AD of animal waste can be one of the most viable strategies both in economic and environmental terms to promote changes in the global energy matrix (Vanegas Cantarero, 2020).

3.2.2. N-module

The digestate from the Bio-module has high concentration of TAN, due to swine manure organic nitrogen mineralization. Thus, digestate treatment strategies are necessary when the direct use as fertilizer is not possible. The N-Module is responsible for nitrogen removal from CLBs reactors using nitrification and denitrification based on the MLE process (Bortoli et al., 2019; Hollas et al., 2019).

The system took 56 days to achieve high TAN removal efficiency, which means that the final effluent achieved concentrations below 20 mg_N L^{-1} (Fig. 2). The concentration of TAN_{in} of the N-module had fluctuations over the period studied, with an average concentration of 1317 ± 222 mg_N L^{-1}. However, even with such variation, TAN at the

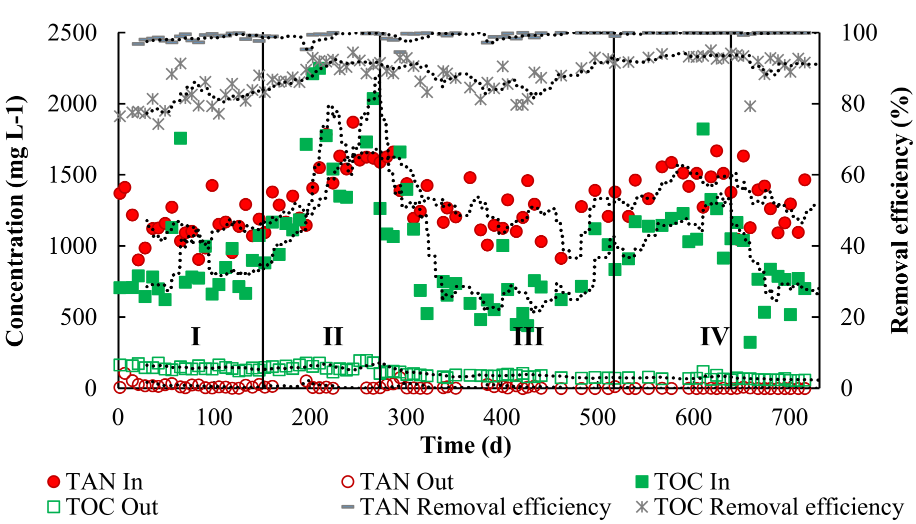

Fig. 2. Total Ammoniacal Nitrogen (TAN) and Total Organic Carbon (TOC) in and out with the respective removal efficiencies in N-Module. Evaluated seasonality: **Period I** (warm) - correspond to the months of January, February, March, April and May 2019; **Period II** (Cold) - correspond to the months of June, July, August and September 2019; **Period III** (warm) - correspond to the months of October, November, December 2019 and January, February, March, April and May 2020; **Period IV** (Cold) - correspond to the months of June, July, August and September 2020; and **Period V** (warm) - correspond to the months of October, November and December 2020. The dashed line corresponds to the moving average for a period of 30 days.

final effluent and the process efficiency was maintained at levels that supply the standards into water bodies discharge based on Brazilian national regulation (CONAMA 430, 2011).

The average TAN removal efficiency obtained was 98.6 ± 2.1%, similar to the obtained by Vanotti et al. (2018), that verified 96.6% of TAN removal efficiency, with a treatment system composed by a SLS unit followed by nitrification/denitrification. For TOC, the variations were relatively high in the evaluated period making necessary to activate the StST-2 many times in wintertime (June, July and August) to reduce the concentration. The concentration of TOC in the affluent was 1039 ± 482 mg L^{-1}, with a removal efficiency of 88.0 ± 5.7%. The variations of TAN and TOC observed in the system input were due to the CLBs biomass temperature decrease during the cold periods reaching 20.2 ± 2.1 °C with an average of 25.6 ± 2.4 °C in the warm periods.

The TOC loading rates in the N-Module varied from 0.10 ± 0.04 kg m^{-3} d^{-1} to 0.23 ± 0.08 kg m^{-3} d^{-1} between seasonal periods, while TAN loading rates varied from 0.13 ± 0.01 kg m^{-3} d^{-1} to 0.18 ± 0.02 kg m^{-3} d^{-1} (Table 5S). The C/N ratio showed significant differences in the second period, corroborating with the discussion at topic 3.2.1 (Bio-Module), as well as that the variation in the applied TOC (Table 3).

As described in Tables 3 and 6S, it is possible to observe that all the parameters (except alkalinity consumption and TN removal) showed significant statistical differences between periods 1 and 2. This behavior may be linked to the fact that the first two monitoring periods are part of the initial period of N-Module, where the reactors showed instability behavior due to the variations in loads in the module, and adaptation of the microbial community. This can be observed if compared to periods 3, 4 and 5, that did not show significant difference, even in different seasons, which shows that the nitrification and denitrification processes were highly active and suffered less from the pressures exerted by

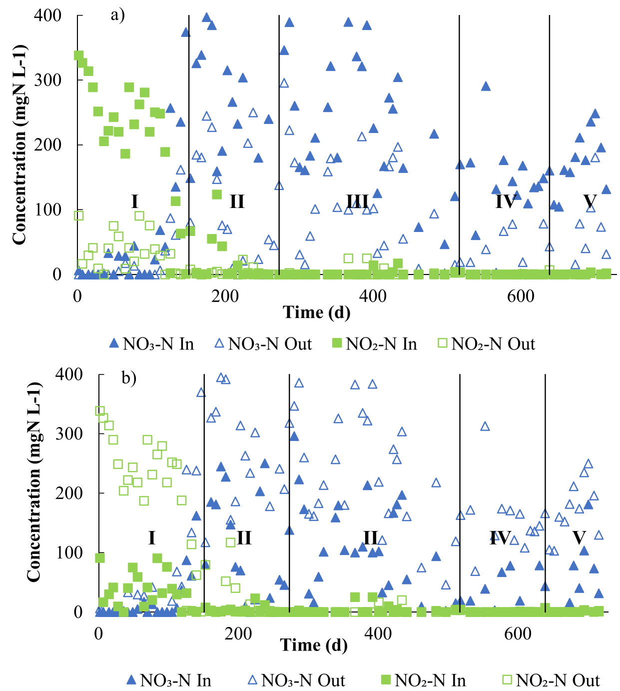

Fig. 3. Nitrite and Nitrate species concentration in N-Module denitrifying (a) and nitrifying (b) reactors. Evaluated seasonality: **Period I** (Warm) - correspond to the months of January, February, March, April and May 2019; **Period II** (Cold) - correspond to the months of June, July, August and September 2019; **Period III** (Warm) - correspond to the months of October, November, December 2019 and January, February, March, April and May 2020; **Period IV** (Cold) - correspond to the months of June, July, August and September 2020; and **Period V** (Warm) - correspond to the months of October, November and December 2020.

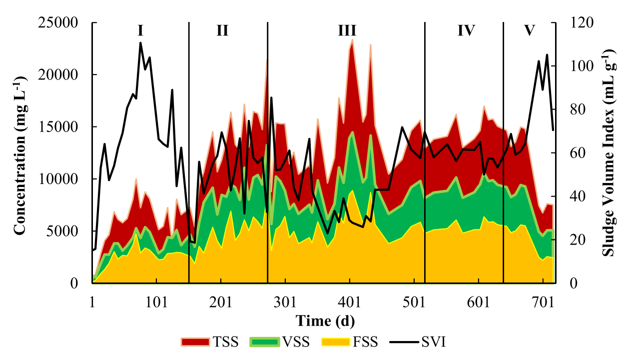

Fig. 4. Suspended solids profile inside the nitrifying reactor during the experimental period. (TSS - total suspended solids; VSS - volatile suspended solids; FSS - fixed suspended solids; SVI – sludge volume index). Evaluated seasonality: **Period I** (Warm) - correspond to the months of January, February, March, April and May 2019; **Period II** (Cold) - correspond to the months of June, July, August and September 2019; **Period III** (Warm) - correspond to the months of October, November, December 2019 and January, February, March, April and May 2020; **Period IV** (Cold) - correspond to the months of June, July, August and September 2020; and **Period V** (Warm) - correspond to the months of October, November and December 2020.

seasonal variations. Zhang et al. (2020) showed that the adaptation of the microbial community is a key element for the stability of the process, even after a load shock, raising it from 0.553 kg m^{-3} d^{-1}, to 0.790 kg m^{-3} d^{-1}. In this work the nitrogen removal system, based on nitrification, anammox and denitrification, maintained high N removal efficiency (96%), which the authors attributed to the long system operation time (246 days) and adaptation of the reactor community.

According to nitrogen species concentration in the nitrifying and denitrifying reactors (Fig. 3, and Tables 7S and 8S), it is possible to verify that in the first 120 days the denitrifying reactor (Fig. 3a) presented a high concentration of NO_2^--N in the influent (253.97 ± 104.03 mg_{NO2^--N} L^{-1}) and effluent (38.86 ± 29.01 mg_{NO2^--N} L^{-1}). This supports the high nitrite values at the nitrifying reactor effluent (253.97 ± 104.03 mg_{NO2^--N} L^{-1}) (Fig. 3b), due to the establishment and stabilization of the nitrogen removal process. After that, the NO_2^--N output and input decreased and it was observed an increase of NO_3^--N concentration, for both N-reactors. For nitrifying reactor effluent, the concentration of NO_3^--N of 219.4 ± 99.6 mg_{NO3^--N} L^{-1} could be attributed to the establishment of complete nitrification.

The content of suspended solids inside the nitrifying reactor also varied considerably (Fig. 4). During the evaluated period, the average concentration of VSS in the nitrifying reactor was 6943 ± 3000 mg_{VSS} L^{-1}, with a volatile and total suspended solids ratio (VSS/TSS) of 0.63 ± 0.06. Von Sperling (2007) shows that the ideal volatile suspended solids concentration in prolonged aeration systems is between 2000 and 4000 mg_{VSS} L^{-1}. However, Hollas et al. (2019) studied the behavior of a modified MLE system for nitrogen removal from swine manure under high suspended solid concentration (7800 mg_{VSS} L^{-1},12,500 mg_{VSS} L^{-1} and 18,500 mg_{VSS} L^{-1}) reaching good efficiency of TAN removal (99.6%, 99.1% and 96.5%, respectively) pointing out that it is possible to work at higher TSS in modified MLE systems than previously reported in literature.

During the two years of monitoring, sludge discharge from N-Module was 9.0 ± 5.0 m^3_{sludge} d^{-1}, which corresponds to an average of 2–15% of the reactor flow rate (Table 9S). The high solids concentration in the nitrifying system increases the energy consumption, since it requires higher aeration to provide the ideal mass transfer and oxygen consumption by the aerobic heterotrophic microorganisms that will act on solids degradation, raising oxygen requirement. On the other hand, the higher sludge residence time in the system reduces costs with the management of excess sludge, a challenge found in several treatment systems (Kim et al., 2020).

During the evaluated period the N-Module showed an energetic expenditure of 11,832 ± 2930 kWh $month^{-1}$. Admitting the TAN removal of 5746 ± 1213 kg_{TAN} $month^{-1}$, the energetic expenditure was 2.04 ± 0.26 kW kg^{-1}_{TAN}, resulting in 2.65 ± 0.57 kWh $m^{-3}_{treated\ effluent}$. For calculation purposes, based on the year 2020 and the price paid by the SISTRATES® project user, the kWh was US$0.1. Thus, the cost of energy for TAN removal was US$ 0.2 ± 0.026 kg^{-1}_{TAN} or US$ 0.28 ± 0.070 $m^{-3}_{treated\ effluent}$ in N-Module. It is important to highlight that the energy consumption of this module represents 23 ± 8% of the energy generated by the Bio-Module, and the N-Module does not have O_2 control, which could generate savings in energy expenditure.

Although the current trend is directed towards the recovery of resources, transforming linear chains into circular, with the insertion of waste as valuable substrates ensuring future activities, the removal of nitrogen, as presented in this study, is still configured as a fundamental tool for reducing environmental damage associated with the pig activity (Zhao et al., 2020). The environmental impacts caused by the improper release of N in the environment are known and include the eutrophication of freshwater and marine dead zones, as well as damage to human health. Therefore, the proposed configuration presented here was able to efficiently mitigate the nitrogen present in the swine waste, ensuring the viability of the activity and associated with other technologies that add to the benefits generated (Zubair et al., 2020). Although the N-Module presents a P removal (35.3 ± 39.2%), the concentration of this element on the effluent of this step still remains as potential pollutant if released without discrimination to the environment, and the addition of one more module to the system is necessary to remove this pollutant.

3.2.3. P-module

The scarcity of phosphorus resource added to the potential environmental damage that P can cause, makes its recovery an essential practice to ensure the sustainability of future activities (Jupp et al., 2021; Peng et al., 2018). Thus, the last SISTRATES® module aims the removal and recovery of P from swine digestate, by chemical precipitation with $Ca(OH)_2$.

Table 4
P-module removal efficiency considering in and out (liquid fraction) of this module compared to the whole system.

Parameter	Input SISTRATES® Concentration	Final effluent Concentration	SISTRATES® Global removal (%)
	Average ± S.D.	Average ± S.D.	Average ± S.D.
Alkalinity (mg_{CaCO3} L^{-1})	3744 ± 871	340.0 ± 117.0	99.6 ± 3.5
TAN (mg L^{-1})	1221 ± 457	2.4 ± 4.2	99.8 ± 0.3
TP (mg L^{-1})	453 ± 368	3.9 ± 2.6	99.2 ± 0.6
K (mg L^{-1})	757 ± 338	649.8 ± 178.0	20.7 ± 13.8
Ca (mg L^{-1})	–	64.2 ± 26.2	–

The start-up of P-Module was in May 2019, with the addition of an amount of 10% (m v^{-1}) $Ca(OH)_2$ to the effluent that fed the P reactor, until it reach pH of 9.0. This resulted in a consumption of 4.74 ± 2.13 $L_{suspension}$ $m^{-3}_{effluent}$ of reactant suspension. The Ca:P ratio was 1.98 ± 0.89, slightly above the theoretical molar ratio for the precipitation reaction which is 1.5 (Fernandes et al., 2012). The higher Ca:P ratio in the SISTRATES® full scale plant could be attributed to the operational drawbacks, as lack of pH sensor calibration, effluent alkalinity or organic carbon in the effluent from N-module due to seasonality effect (Karunanithi et al., 2015; Vanotti et al., 2003).

The effectiveness of using nitrification before P precipitation was observed by Szogi and Vanotti (2009) on 10 diverse North Carolina swine production farms. Chemical P precipitation was able to remove >90% of initial TP. Our results showed that the liquid fraction, that was the final effluent of the system presented TP concentration of 7.89 ± 11.85 mg L^{-1}) resulted in removal efficiency 89.6 ± 9.7% (Table 4). Similar results were found by Suzin et al. (2018) that obtained 90% of phosphorus removal at pH 9.0 promotes and (Fernandes et al., 2012) which observed that pH above 8.5 could remove >96% of the soluble phosphorus. This treatment allows the use of phosphorus sludge, rich in calcium phosphate, as a renewable and valuable fertilizer, and enables the effluent reuse or discharge into a water body.

The recovered P obtained in this module could be applied in the soil, as a fertilizer, or as a phosphorous source for animal feed. The solids concentration (dry matter) in the sludge was, on average, 1.8 ± 0.9% (w v^{-1}). Regarding the purity of the sludge, the results obtained for some elements were 1.7 ± 1.1% (w w^{-1}) for N, 5.8 ± 2.1% (w w^{-1}) for P, 2.1 ± 1.1% (w w^{-1}) for K and 21.4 ± 6.0% (w w^{-1}) for Ca.

It has been already proved that chemical precipitation is a good technique to P recovery from swine digestate and concomitantly inactivate *E. coli*, *Salmonella enterica* serovar *typhimurium* and PCV2. Vanotti et al. (2005) studied the inactivation of *Salmonella* and microbial indicators of fecal contamination (total coliforms, fecal coliforms, and enterococci) in a multi-step system composed of biological and chemical treatment of swine manure, reporting after P removal (precipitation with $Ca(OH)_2$) no colonies to count at the upper threshold limit value of <2 CFU mL^{-1}. Similar results were found in the present study, once the biomarkers *Salmonella*, *E. coli* and PCV2 were not observed in the final effluent. The sanitization of final effluent may be important for biosecurity reasons, impacting on environmental, animal, and human health, the three pillars of "One Health" concept.

The results are in line with the World Health Organization (WHO) and Environmental Protection Agency (EPA) recommendations (EPA, 2012). The WHO Guidelines (2006) recommend various levels of wastewater treatment according the irrigation category. For example, to water reuse in drip irrigation of high-growing crops must contain less than 10^3 in 100 mL of *E. coli* with 4 log reductions during the treatment. Thus, the water from the P-Module can be safely used for washing the swine houses or discharge in water bodies.

So far, there is few literatures available on water reuse for washing swine installations. According to Australian Pork (2016) the water consumption for cleaning the swine houses is on average 26% of the total water consumption. Considering the farrow-to-wean piglet producing unit described in the item 2.1, the estimated water consumption for washing and cleaning was 66.6 $m^3\ d^{-1}$. The SISTRATES® system recovers 124.5 ± 27.5 $m^3\ d^{-1}$ in liquid form. This effluent could be reused for cleaning the swine houses as one of its applications. Considering the water consumption per sow (38.5 L $sow^{-1}\ d^{-1}$), with the final effluent generated in P-Module, the results would bring water saving of 48.6% from farm water consumption.

The water scarcity affects more than 40% of the world population and this index tends to increase with the global temperature increase (Cantelle et al., 2018). According to the WWAP (2014) 70% of the total water consumption is from agriculture, including irrigation, livestock and aquaculture. Brazil plans to remain one of the main suppliers for the food and agricultural markets, a fact that highlights the importance of wastewater treatment and water reuse (Cantelle et al., 2018).

3.3. Technical coefficients, mass and energy balances

To be able to estimate the masses that were removed and recovered with SISTRATES®, to know if the recovered energy supplies the demand for energy consumed by the system, mass and energy balances for the three modules were calculated. The flow rates considered for mass balance calculations are presented in Table 10S.

Evaluating the Bio-Module mass balance, the CLBs are fed with 1151.5 ± 553.9 $kg_{VS}\ d^{-1}$, being 55.4 ± 28.9% of this daily load converted into biogas. The mass balance showed that 29.1 kg d^{-1} of FS is retained in these reactors, which represent 0.0003% of the CLBs useful volume. The CSTR reactor on the other hand was fed with 689.6 ± 316.9 $kg_{VS}\ d^{-1}$, and the conversion of VS into biogas in this reactor reaches up to 58.6 ± 32.8% while the FS accumulation is 72.6 $kg_{FS}\ d^{-1}$, which represents 0.0052% of the CSTR useful volume.

Khanh Nguyen et al. (2021) highlighted the importance of the manure pretreatment for AD, pointing out that the substrate becomes more bioavailable, optimizing the methanogenic potential of the feedstock, increasing the degree of degradation, and consequently decreasing the amount of sludge to be discharged, prolonging the useful life of these reactors.

The mass from the P-Module sludge (second generation phosphorus) results in 33.79 ± 19.40 kg d^{-1} of TP and 11.81 ± 6.19 kg d^{-1} of K, and the residual P in the liquid effluent fraction was 0.45 ± 0.34 kg P d^{-1}. In function of P_2O_5 recovery (considering the global average, according to Drangert et al., 2018) obtained with the system during this study, it would be possible to fertilize 350 ha per year, in need to supplement N. The completely nutrients balance of the system is shown in Fig. 2S.

According to FAO (2018) a ton of phosphate rock, that is used for fertilization, costs US$ 110.30, The nutrient mass balance of SISTRATES® showed that per year the recovery of P_2O_5 in average is 28 ton. This would result in savings of approximately US$ 3100 per year. However, a noble use of this material could be suggested, like the study developed by Shim et al. (2019) that evaluated the use of phosphorus recovered from swine manure applied in animal feed. The study analyzed the in vivo toxicity and in vitro solubility and concluded that it is possible use the phosphorus recovered as a P source in animal feed, representing a future application possibility for the nutrient recovered by SISTRATES®.

For energy generation considering the year of 2020 reached average values of 1881 ± 1859 kW d^{-1}, which resulted in conversion data of an average of 2.32 ± 2.4 kW $m^{-3}_{Nbiogás}$. According to the energy balance (Fig. 3S), SISTRATES® has an energy requirement of 15,925 ± 2201 kWh $month^{-1}$, which is 30 ± 11% of the total energy generated by the system.

The increasing demand for electricity worldwide confirms the importance of an effluent treatment system where energy can be recovered from agro-industrial wastes. The renewable energy from biomass represents 9.2% of Brazil in energy matrix, within the framework of renewable energy (46%) of the Brazilian energy matrix (EPE, 2018). According to CIAS (2021), the number of swine sows housed in 2019 was 2,017,645 in Brazil. With the data from this work, each sow provides daily 0.28 kWh d^{-1}, consequently the capacity of electricity generation of the Brazilian pig sector would be 565 MWh d^{-1}, emphasizing the importance of proper management of animal waste for the viability of livestock activities.

The environmental damages associated with animal waste are widely known and its efficient management is a challenge (Zubair et al., 2020). Thus, SISTRATES® can be considered an efficient model applicable to

Table 5
Technical coefficients raised in the SISTRATES® project per housed sow and per m^{-3}_{manure}.

Equation	considering sow	Average ± S.D.

the management of swine waste. In this sense, Table 5 summarizes the technical coefficients calculated to extrapolate the unit where SISTRATES® is currently able. Thus, the treatment system can be used in different production cycles, farm sizes and configurations since there is the possibility of modular implementation.

3.4. Machine learning

Decision trees are supervised learning algorithms that divide a large data set into smaller sets with certain decision rules. In WEKA®, this is accomplished by the J48 algorithm, which is an open-source Java implementation of the C4.5 algorithm (Rossi et al., 2020). In this sense, artificial intelligence approaches are important for analysis and decision making in treatment systems (Asami et al., 2021; Oprea, 2018).

Based on the large data set collected throughout the SISTRATES® monitoring, the use of data mining is important for machine training, making it possible to determine possible existing correlations not perceptible in the interpretation of the data individually, or with simple correlations. Considering this, decision trees were built, to predict behaviors in the treatment plant, considering data that can be monitored in the field to predict other parameters. The first decision tree is related to the prediction of energy expenditure in N-module. Considering the average energy spent in the process, the size of the tree was 11 and the number of leaves (tips) was 6, which have the attributes (variables) (Fig. 5). It was possible to correctly classify 100% of the instances (731), indicating a high predictive power (100% correct), with a low mean absolute error (0.0024).

The month was one of the influencing factors on energy consumption, as already discussed. It presented two nodes, being the first, marked by the end of summer and beginning of winter (January/May = summer and June/October = winter) and the second between the end of winter and beginning of summer (June/October = winter and November/December = summer). The warm months tend to present a lower energy consumption than the average, mainly because of the settleable solids present in the system as already discussed. The other nodes were directly related to solids, returning important information about the concentration of settleable solids in the nitrifying reactor, which should be below 495 mL L^{-1} to not have an unnecessary energy expenditure.

Another decision tree elaborated, predicts the need to use StST-2 to reduce the solids loading of the CLBs output. The size of this tree was 25 and the number of leaves (tips) was 13, larger than the previous one, *i.e.,* the decision making considers more factors (Fig. 6). It was possible to correctly classify 98.5% of the instances (715), also indicating high predictive power, with low mean absolute error (0.0259).

Following the trend discussed above, of the influence on energy expenditure as a function of system settleable solids, this was also a determining point for the decision making presented in the tree in Fig. 5, as well as the seasonal issue, with the increment of information on settleable solids in input of denitrifying reactor. In addition, more specific information from the nitrifying/denitrifying reactors is required, since the environmental conditions determine the performance of the N-module. Caglar Gencosman and Eker Sanli (2021) studied machine learning techniques, including the generation of decision trees, to predict the removal efficiency of polycyclic aromatic hydrocarbons from wastewater treatment sludge about the initial levels of these. The authors found that the decision trees showed an average performance of 78.0%, with high specificity and accuracy, not only for the variable of interest but being able to predict other parameters. Asami et al. (2021) also studied the use of decision trees for data prediction of biological processes in a wastewater treatment plant and found high coefficients of determination (0.83–0.90) in the trees created for the parameters BOD_5, COD and TSS, concluding that this approach is a good tool to describe and analyze the behavior of the data.

Another important prediction is to determine which sludge discharge flow rate, in StST-3 must be applied to the N-module without compromising the process based on simple analyses that can be quickly performed in the treatment plant by the operator. With this, by means of the linear regression between the sludge height of StST-3 and the concentration of settleable solids in the decanter supernatant. It was possible to verify with a correlation coefficient of 0.5052, that the sludge height cannot be higher than 1.31 m, otherwise, the concentration of settleable solids in the supernatant fraction increases indicating that the system has sludge accumulation.

Also, by means of linear regression, between the C/N ratio and the ammonia concentration at the output of the N-module, it was verified that the C/N ratio must be higher than 0.72, so that the system efficiency is higher than the average and the concentration at the output is lower than 20 mg L^{-1}, with a correlation coefficient of 0.4188. Although the regressions do not present such high fits, they describe well the behavior of the system and help in future decision making.

The surveyed data provides a valuable decision support resource, and from the increment of deeper knowledge of existing relationships, not always exploited for the operation of SISTRATES®. Data mining combined with machine learning has proven to be an important tool for simplifying the interpretation of easily measured variables in the field.

4. Conclusions

From the results presented here, it is evident the potential that swine waste presents as a precursor to changes in the production chain, in terms of taking advantage of the benefits that can be derived from its adequate management. Thus, SISTRATES® proved to be an efficient model applicable to the management of swine waste, due to the simultaneous nutrients and energy recovery reducing the main environmental contaminants. In addition to enabling the reuse of water in production facilities, a great benefit considering the world's water shortages. There are still challenges in the management of this waste, so future work should focus on improving the proposed system, such as the maximization of energy use, nutrient recovery, and water reuse, towards circularity in the pig chain.
